The practice leans to the Broussaian: all irritants and tonics are avoided; bleeding is very generally employed: small quantities of blood, as four, six, or eight ounces, being abstracted at a time: consequently the frequent repetition is necessary, which has the effect, in many cases, of debilitating the patient, without effectually arresting acute inflammation. Hence one cause of the fatality attending acute inflammation of the lungs, known by the name of *Mal di Petto*, which so frequently occurs from the variable temperature of Florence. Leeches are often used, but not so generally resorted to as in France. Counter-irritation, by means of the application of tartarised antimony, is frequently employed. Purgatives are seldom used, from a dread of their inducing gastro-enterite; sedatives are not unfrequently employed. Prussic acid, or the aqua lauro cerasi, is sometimes given in bronchial complaints. Internittents are not of frequent occurrence; they are treated by venesection when required, and by the exhibition of the preparations of bark. In continued fever, small general bleedings are employed; more frequently, however, the application of

leeches to the pit of the stomach, lemonade and cooling drinks are resorted to.

Rheumatism is treated by bleeding, warm bath, and diaphoretics: the colchicum is not used; its effects in this class of diseases do not appear to be known.

In gastric and intestinal irritation, the application of leeches, and the administration of demulcent mixtures, are chiefly depended on. No operation is performed without a previous consultation, at which the superintendent of hospitals is present. All persons, professional or not, are allowed to be present at operations, which are frequently performed by the more advanced pupils, under the guidance of the professor of surgery. Operations are in general pretty successful; patients are bled subsequent to their performance in most cases. The lateral operation is performed for stone in the bladder; the *bistouri caché* is generally used for incising the neck of the bladder. Hydrocele is treated by the operation of excision, the method by injection is adopted only in recent cases. The operation of couching is preferred in cataract. Cases of strangulated hernia are operated on immediately: no other remedial means are employed, nor are many attempts made to effect reduction by the taxis. Strictures of the urethra are treated by confining the patient to bed, and passing an elastic gum catheter into the bladder, the size being gradually increased: when a catheter cannot be introduced into the bladder, a catgut bougie is passed into the urethra as far as possible, and retained against the stricture for some time: on withdrawing this, a catheter can generally be passed. Fractures of the lower extremity are treated by placing the limb in the extended position: in fracture of the thigh, the limb is confined by two long splints, connected together by a piece of cloth, passed under the limb, and extending its whole length; the splints are tied together by pieces of tape. By this mode sufficient extension is not kept up, and shortening of the limb, more or less, is the consequence. Ophthalmia, whether acute, chronic, or strumous, is treated by general or local depletion, warm emollient applications and fomentations; the patients being kept in a darkened room: stimulating collyria are scarcely ever had recourse to, and blisters are not frequently used in the treatment of diseases of the eyes. Under this treatment patients are long in recovering, and, from the debilitated state in which the organ is left, suffer frequent relapses after exposure to the sharp winds so prevalent in Florence. Inflammations of joints are treated by rest, local abstraction of blood, and emollient cataplasms; counter-irritation is seldom employed. It is generally a long while before recovery takes place. Mercury, both used externally and given internally, is chiefly trusted to for the cure of syphilitic

complaints; its use, however, is not carried so far as to induce copious salivation.

Union by the first intention is generally attempted after operations, or recent wounds. Abscesses are opened by a very minute aperture being made, and the matter forcibly pressed out. In two cases which I saw, this gave rise to severe inflammation of the part, accompanied with a high degree of febrile irritation.

(To be continued.)

Hospital Reports.

NORTH LONDON HOSPITAL.

Creosote in Gastrodynia.

CATHERINE O'KEEFE, aged 47, a married woman, who has had four children, was admitted August 25, under the care of Dr. Elliotson. She has not menstruated since Christmas. About nine years ago, she began to have attacks of spasmodic pain in the stomach, which occurred in paroxysms of two or three hours' duration, and at intervals of a day or two. These attacks always occurred a few hours after dinner. She has been salivated several times, and also bled and blistered, but these means have never afforded her any relief. On two occasions she was perfectly free from pain for six months. Nine months ago she began to feel pain, and a sensation of weight between her shoulders, and she also had sour eructations and a burning pain along the œsophagus. At present she is quite free from pain when the stomach is empty; but as soon as she has taken food the pain returns. When the pain seizes her, she can lie only on her back, and is at all times easier in that position. The abdomen is very tender to the touch. The pain is always relieved by hot ingesta. Pulse 60, small; tongue covered with white fur; bowels regular; urine clear; appetite variable; head-ache. *Creosoti m. ij. 6 ta. quaque horâ.* Middle diet.

27th.—Some pain in the left shoulder, shooting down the inside of the arm to the elbow; slight pain on pressing upwards under the diaphragm. Pain in the stomach continues.

29th.—Pain in the shoulder and arm has disappeared; but continues in the stomach. Bowels regular; pulse, 80. *Auge creosot. ad m. iv.*

Sept. 1st.—Much pain across the forehead; pain in the epigastrium continues. *Auge creosot. ad m. vi.*

3rd.—Pain in the stomach very severe occasionally; at first she becomes very hot, a perspiration then breaks out, and this is succeeded by cold shiverings, which after lasting for a short time, give way to the natural temperature. *Auge creosot. ad m. vii.*

5th.—Pain returns every now and then, but does not last very long. *Auge creosot. ad m. vii.*

8th.—Pain more severe; can scarcely sleep

at night; no appetite; pulse 78. *Sum. creosati m. x. 4tis horis.*

12th.—Pain very severe at times. Sleeps ill; bowels regular; she has taken additional doses of creosoti when the pain is severe, but without good effect. *Auge creosotum ad m. xii, 4tis horisum et sæpius si opus site.*

15th.—*Auge creosotum ad m.*

17th.—Pain much less: she says her urine is much increased in quantity since taking the creosote.

22nd.—Pain diminished; tongue white, slightly furred; pulse 75; appetite improved. *Auge creosotum ad m. xvi.*

25th.—Has scarcely any pain, and little tenderness at the epigastrium on pressure; tongue nearly clean; appetite good; thirst not greater than in health; pulse 70, full.

30th.—Feels very little pain in the stomach; the tenderness at the epigastrium is present only after paroxysms of pain; bowels open; appetite good.

Oct. 3rd.—Has only a slight pain occasionally in her stomach; her general health is good. *Auge creosotum ad m. xvii.*

6th.—Is now free from pain, except occasionally. *Auge creosotum ad m. xiii.*

Discharged cured.

LECTURE XIX.

*Necroscopy of Gastro-enteritis, continued—
Question of General Symptoms.*

WE now proceed to the necroscopy of gastro-enteritis of longer standing, in which the patients do not die suddenly from the nervous phenomena, as in the preceding cases, and indeed, the inflammation may go from ten to a hundred days inclusive: but in stupor, when the disease is intense, they do not resist more than thirty or forty days at most. You then find the stomach no longer of a vivid red and contracted, but flaccid, and with black vascular ramifications resembling ecchymoses; in the greater arch, an utter absence or extreme thinning of the two internal tunics, and near to this a softening of the mucous membrane, extending gradually from the points where it is entire and appears hypertrophied and red, to those where it has disappeared, leaving only a serous lamina, which sometimes tears on the smallest touch. This great arch is pale and colourless. If you attentively examine the stomach, you behold the redness and sanguineous globules remaining in the organ diminish in proportion as you retreat from the undestroyed spots. The same may be observed with regard to the blood-vessels: you behold bloody streaks proceeding from the orifice of the stomach, and chiefly from the cardia: but as you approach the disorganized spot, you see no more of them. The same is remarked towards the pylorus, with this difference, that the brown and blackish colour is more frequent. Taking these discolorations of the stomach as examples, some anatomo-pathologists have concluded that the softening and wearing of the gastro-intestinal mucous membrane are not the effects of inflammation. But before adopting this conclusion, we must look to what actually takes place,

and to several circumstances of which they take no note. In the first place, it must not be forgotten that individuals who die on the onset of the disease exhibit redness of the great arch of the stomach, and those only who die at a later period are without it. In the next place, it must be remembered that those who sink from a pure and simple enteritis have not the membrane of this arch destroyed. Now, what happens when death does not occur in the acute stage of gastro-enteritis? One of two things—either the inflammation exhausts life by the incessant agitation of the nervous centres before leaving its principal situation, or, after having broken down the structure and destroyed the vitality of the mucous membrane, it leaves it for some other locality. Would you consider this phenomenon as physiologists, and not confine yourselves to the barren descriptions of pure anatomo-pathologists, you should observe the phlegmasiæ when in action, and not the traces of them alone; you should incessantly return to our great principle, that inflammation traverses the entire frame, and that when it no longer has wherewithal to feed on in one place, it leaves that place livid and dead, and passes to some other. But, turning to this said discoloration of the great arch, you will ask me, how it happens that neither redness nor blood is any more seen there? Because the patients drank copiously, and the fluids they took, remaining in the great sac, wash the portion of membrane that has lost its vitality, carry off the remains of the blood globules, and aid in the softening process—that is all. And so true is this, that in examining the inflammation in the neighbourhood of parts where the liquid has not been retained, you will still see vessels, and a coloration approaching more or less to the red of the acute stage. I may remark, in passing, that at the time when this destruction of the mucous membrane takes place, the cerebral functions become deteriorated. When an experienced physician observes that the adynamic symptoms have not yielded, that the ataxic phenomena are changed in form, and that there is idiocy, with deep-marked alteration of the physiognomy, hippocratic countenance, carphology, total want of intellectual and affective

faculties, that the irritation has ceased to predominate in the stomach, and that there is no more thirst, nor vomiting, nor red tongue, he conceives the mucous membrane to be irrevocably injured, and that the stomach is only an inert vessel that allows matters to glide through it, carrying with them the remains of the blood globules. Death being then inevitable, and at length passed, you open the stomach, and you find only a thin serous-like tissue in the great sac, which readily tears.

Some intermediate cases may be mentioned: for instance, those shades of phlegmasia which have not yet worked out the complete destruction of the internal membrane, and when it is covered by a kind of mucous web. But in this case it retains unequivocal marks of the alteration which inflammation has caused in it. For the rest, this paleness of the great arch of the stomach is not so decidedly remarkable in the duodenum, doubtlessly because fluids do not remain so long in that organ; yet there is a certain degree of discoloration, and you may then meet with softening, loss of substance, and slate-coloured patches, without a trace of blood, when the patient has sunk at an advanced stage.

The same observation applies to the portions of the intestines wherein inflammation prevailed in the first instance, and which are decolorized. They are so, because, the inflammation, having destroyed them, has passed into other parts: indeed, it rarely confines itself to partial attacks of the mucous membrane: after working the destruction of two or three feet of the small intestine, it fades there, and passes to the mesentery and large intestine, there, too, sometimes leaving a black colour, and even gangrene.

But you have other facts which explain these decolorations consequent on inflammation. Sometimes, in the latter period of the disease, a peripneumonia, peritonitis, or a violent congestion comes on, and induces the mortal agony. The blood has obeyed the inflammatory stimulus, and abandoned the red part of the mucous membrane, which then turns pale: you see nothing more of it then, and if you assert that the ulcerations and softening you meet with have been effected without inflammation, be assured you are in error. Further reasons are, that the patient has lost an excess of blood, either artificially or by a spontaneous hemorrhagic movement; in which case you find no blood, or else the little that remains has collected in the most suffering parts, and is discoloured. You should establish relations between the different autopsies, compare them with the symptoms and the different epochs of the disease: thus it is that difficulties are to be explained, and objections answered. Bear in mind, moreover, that this decolorization is far from being so common and so complete in any portion of

the intestines as in the great arch of the stomach, and that there are almost invariably traces of inflammation in their ulcerated follicles and the mucous membrane around them. Persons have insisted on the small number of cases in which they say it is decolorized, and no traces of phlegmasia are found. I know not with what sort of eyes they have looked, but I know that mine have never seen anything of the kind during the thirty years that I have been engaged in inspecting bodies, unless they wish to qualify as a non-inflammatory state the different deep slate-coloured tints, or the kind of paleness that succeeds inflammation, and have misunderstood the attraction of the blood towards the organ that had been the last affected. Such are badly observed cases, of which they cunningly make use to combat the method of observation followed by us, if you would not that I should say the doctrine we profess; for, what care I whether you call it doctrine or method! I do not pride myself upon being a *doctrinaire*; on the contrary, I reject the title, thinking, as I do, that our opponents are the actual *doctrinaires*.

To sum up; the mucous membrane is always phlogosed when the follicles are, or if it be not actually so, it is because the blood has left it, shortly before death, for other parts, or there have been excessive abstractions of blood, or this latter fluid is aqueous, as is the case in some lymphatic infants, in whom the traces of inflammation are not so red as in the adult. This I know, for I have also inspected a great number of children, and am convinced that they easily lose these red globules, that inflammation in them rather fixes on their parenchyma than their membranes, and that many adults, especially women, resemble them.

Such, then, are the principal alterations exhibited by the gastro-intestinal mucous membrane after inflammations. First, there is redness with hypertrophy, then the blackish-brown colour: increase of consistence and cohesion in the first degree; friability and softening in the second: gelatinous consistence and destruction in a still more advanced degree: necrosis in some cases. This detritus, observable in long-continued phlegmasiæ, is more or less red and impregnated with blood, according to the quantity of that fluid remaining in the digestive canal, and the manner in which the patient has been treated. We should also mention intussusceptions, which may be regarded as a consequence of disordered peristaltic and antiperistaltic movements, produced by a phlegmasia that convulses the muscular membrane: in intussusception the strangled end of the intestine is ordinarily pale, and the strangled end red—a fact that tells for those who treat inflammation by compression.

Remark that the different conditions that we have passed in review may be seen in the same individual, for inflammation is never

uniform in the whole extent of the digestive canal, except in dreadfully intense gastro-enteritis, such as yellow fever, or in epidemics produced by exceedingly powerful causes. You may sometimes open a hundred bodies, and in one only find the digestive canal equally red in all the points that had been previously occupied by inflammation. The later the patient dies, the less red colour do you find, and the more brown colour and softening. For the rest, there are varieties that it is impossible to explain: you may several successive times see the black colour without follicles and ulcerations; at other times you shall see the like lesion, altered follicles and ulcerations. The same may be said of worms. Something yet requires to be known concerning the action of the modifiers that engender the different forms of disorganization and morbid productions. Certain it is, that in some years follicular patches of the intestines are more frequent; in others more lumbrici are found: in others, again, some of all kinds are observed. During eighteen years that I have practised at Val-de-Grâce, I have remarked all these variations. Last year the multiform gastro-enteritis was more frequent and serious there, because the garrison was composed in great part of youthful conscripts, who only made complaint at a late date, and were not treated from the onset: there was not sufficient watchfulness on the part of the officers, in seizing the moment of the outbreak of the inflammation, and in causing the patients to be conveyed to the hospital. I suggested an order of the day, to which the colonels of regiments attended, and in a short time the diseases became less serious and more tractable: the black colour was less deep in those who sank, and the pathological disorders less numerous. The regiments departed and were replaced by others: the new commanders, who were not *au fait*, neglected to take the necessary precautions, and the same mischief ensued, to be again repressed by the enforcement of the same order of the day.

There are so many causes that are capable of varying the progress and results of diseases, that great care should be had not to be peremptory in the estimation of the pathological alterations, and not to create specific entities for the differences they exhibit. Sometimes, in places where there have been ulcerations, the digestive canal is in part perforated, especially in the phlegmasia of isolated patches and follicles. In some cases the peritoneum even gives way, and the intestinal gases pass into it: if this occurs during life, a peritonitis, proving mortal in from six to eighteen hours, may ensue. The inflammation may also reach the peritoneum without perforation of the intestine, and even without ulceration; in which case the entire thickness of the canal is invaded by the inflammation; certain

points are gangrened, and have sphacelated pieces hanging from them: other points exhibit indurations: others have contracted adhesions, or are covered with a false membrane. It is commonly in the ileo-cæcal region that these disorders are met with.

I must also give an account of the accessory cadaveric traces, the alterations of the bladder, the pharynx, larynx, nervous centres, and lungs. Phlegmasiæ of the bladder do not exist in all individuals: they rarely appear in the commencement of the disease; but when inflammation predominates in convolutions of the ileum that are in the neighbourhood of the pelvis and bladder, it is often communicated to that organ by the mere contact, so that I am convinced in some cases there is a kind of contagion, and not merely a propagation or sympathetic repetition. In other circumstances, when copious evacuations take place by vomiting and purging, little or no urine is secreted. The internal surface of the urinary apparatus then becomes heated and inflamed, as in yellow fever, for we have shades of gastro-enteritis that equal that one in intensity, and the suppression of urine very frequently dates from the very first day. This symptom is remarked in cholera, and, indeed, as a general rule, occurs on all occasions of excessive losses by vomiting, purging, sweats, hæmorrhages—in short, any sudden withdrawal of the serosity by the excretions, or any considerable loss of blood. In the instance of hæmorrhage the urinary passages do not inflame; but if there be at the same time heat of the digestive canal, they are threatened with inflammation. When you perceive in the hypogastrium swelling, heat, meteorismus, have a fear of the communication of inflammation to the bladder, and sometimes also to the kidneys. Even the genital organs occasionally contract it if it has not been properly combated.

So also of the pharynx and larynx, not in a consecutive manner, but primitively, while phlegmasia is raging in the upper portion of the digestive tube.

The lungs do not necessarily become inflamed by gastro-enteritis, although it is often accompanied with a certain degree of bronchitis: the part they take in inflammation is rarely such as to jeopardize their texture in warm weather; still, as gastritis frequently exists in cold weather, and is then almost always complicated with catarrhs and pectoral congestions, you may find various indurations of the pulmonary parenchyma more or less distant from the acute inflammatory aspect, but of which you would be wrong to make specialties. When a man has been a prey for forty or sixty days to successive phlegmasiæ, you may conceive that less redness and density is exhibited towards the close, and more paleness and watery humours than at the first day.

In the brain there are sanguineous congestions, or serous injections, more or less

decided in character, but always secondary, unless the encephalitis has become predominant, in which case, the disorders are more pronounced and more complicated. From facts which every one may substantiate, I think that in acute gastro-enteritis death only comes by the nervous system, and that it is possible to live with all the alterations it produces in the digestive canal, except softening of the stomach to a great extent. Anatomic-pathologists, as well as myself, have been struck with these alterations, but they have drawn a different conclusion; they believe that they can of themselves induce death—but it is not so; so long as there remains a sufficient surface for digestion, the patient may continue to survive, with frightful disorganizations of the abdominal viscera, unless, as I have already said, he be exhausted by marasmus and consumption; this, however, only happens in the chronic state. In the acute stage, it is the superexcitation of the brain, the disordered innervation that kills him. Thus, previous to the fatal termination, you perceive the nervous and ataxic symptoms by which this disorder is manifested appear; these symptoms, as well as the alterations that produce them, putting on a different aspect according to the manner in which the brain is affected, the strength of the patient, the treatment, and the period of the disease. If he dies at the onset, you find excessive congestion of the brain and spinal cord. This degree of the mischief we have frequent opportunities of seeing in military hospitals, where patients are brought in with frightful gastro-enteritis. We may sometimes destroy the patient, or ward off his end for twenty or thirty days, when the disorders of the gastro-intestinal membrane are not too far advanced; but most frequently he sinks in less time. We then find in the nervous centres, and particularly the brain, a violent sanguineous congestion without inflammation, without albuminous exudation, without softening, without any sign of suppuration; in short, only an immense accumulation of sanguineous globules with increased density. Death happening at a more advanced period of acute gastro-enteritis, you are not so sure to meet with congestion. Has the patient sunk in the ataxic phenomena, without stupor, with delirium, convulsions, increase of muscular power, more or less disorder of the locomotive apparatus, small pulse, excitement of the genital organs, fury, &c., the congestion of the cerebral parenchyma may be wanting, but you always find gastro-enteritis, frequently with ulcerations of the ileum, and injection of the periphery of the brain, or of the pia mater, and sometimes a commencement of arachnoid inflammation.

Has the patient sunk at a later period, with comatose phenomena, some distinctions are to be made; A, if he has retained his intellectual faculties, if he has not appeared

to suffer in the head, but simply in a state of stupor, from which he may be momentarily roused by speaking; if he has exhibited that reddish brown colour of the face, with sordes, and bloody oozing from the gums, and subsultus tendinum, you will find congestion; B, if he has been in a state of profound coma, senseless, with grinding of the teeth, clenching of the jaws, distortion of the features, cries of pain, permanent contraction of the arms, without possibility of getting them out of that state, you will find phlegmasia at the base of the brain and in the ventricles, and chiefly in the arachnoid of the base, if there has been much convulsive movement of the face. What I now state I shall repeat with greater details in speaking of primary encephalitis; nor is it from want of order that I do not now enter more into them, but for the purpose of being more methodical and complete. Irritations are ever the same, whatever may be the provoking causes; inflamed surfaces, whether primary or secondary, present constant and indelible characteristics; thus, consecutive inflammation of the brain will exhibit the same symptoms as the primary, except that it will be less intense.

In the states now under consideration, the muscular system is frequently softened, and the heart so friable, as easily to be perforated by the finger, and within it more or less fluid or coagulated blood is contained. But it is not enough to take note of this; you must endeavour to reconcile it with the symptoms and circumstances. When the disease has been rapidly mortal, the heart is not softened, unless an anterior phlegmasia of it and the great vessels has existed; but it ordinarily is softened when the disease has been lengthened out, the fever long and violently agitating, and the patient has died in a state of marasmus; it is also softened or only inflamed when the nervous symptoms have been intense from the onset, and the circulation, after being vehemently excited, has fallen into a collapsed state; so that the softening of the organ in question and its inflammation are proportioned to the degree of irritation of its parietes. Nevertheless, if the nervous phenomena have killed the patient before he has been exhausted, the heart will be as strong and firm as in an executed victim. And the same applies to the voluntary muscles.

You have also differences with reference to the treatment, the season, the regimen, not only in the state of the muscular and circulating apparatus, but also in the digestive canal. Patients treated with stimulants, and who have not been bled, will have their tissues firmer, more filled with blood, and more readily putrescible after death; those who have been purged will exhibit more bile and mucosities, accumulated principally in the naturally narrower parts of the digestive tube; those who have died in wintery and humid weather, after

taking improper food, will present still greater accumulation of matters, particularly if they be of lymphatic temperament; and such often have worms and numerous follicular patches. The latter are more remarked if there have been preliminary abdominal pains, diarrhoea from bad food, whereas they are wanting without these preludes, and if the stomach and duodenum have been violently stimulated. Of all these circumstances it would be easy to make so many entities and particular diseases: you have only to bring together on the one hand, those cases in which there is no diarrhoea, and on the other, those in which it does exist—the latter being the instances in which ataxic and adynamic phenomena have predominated, the latter the contrary instances, &c. &c: taking observations thus collected, each of you might in a few years present us with a particular disease, as well founded as dothientery. To resume, however; you will find the quantity of fluids accumulated in the digestive canal more copious as the patient has been more stimulated, as the distance from exhaustion shall have been more remote, as his constitution shall have been more lymphatic, and as he has more readily responded to stimulation of the secretory organs.

As regards the phlegmasiæ of the circulating system, you find them first of all in the heart. Whenever you find therein an unusual redness not removeable by washing, you may affirm that there is carditis present. In the arteries it may be more or less deep and adherent, confined to the lining membrane, and penetrating the entire thickness of the middle membrane. When the disease has existed a short time, this redness is only superficial, but suffices to attest the inflammation. Doubtlessly there are better proofs of its existence when these are intimately mixed with the various arterial and venous tunics, deep colorations or kinds of ecchymoses; but there is no occasion for the thing to go so far; superficial redness, in bands or zones on the internal surface of the vessels, are sufficient indices of the phlegmasia, especially if symptoms of excitement in the sanguineous system existed during life. On this proposition I insist, because people are daily venting opposite assertions.

These last details may be regarded as the full account of acute gastro-enteritis as regards its necroscopy. The principal point is, that every pathological alteration may be connected with it, not as a necessary accompaniment, but as a possible consequence of the inflammation primarily fixed in the mucous surface of the digestive canal, and as capable of invading other parts and producing the effects I have stated.

Pass we to another question already hinted at—are we to stay by fevers? Those who answer in the affirmative, lay stress on a distinction they make in febrile diseases

between the local and general symptoms. There certainly are local symptoms in gastro-enteritis indicative of inflammation of an organ; this is now allowed after being for a long time denied, and it is now agreed that phlegmasia of the digestive canal is the fundamental and local phenomenon *par excellence*, on which certain local symptoms depend. But what are the general symptoms, and in what light are they to be regarded? Would you apply the name to fever, restricting its meaning to the acceleration of the blood's course? but that is only the effect of the irritation, transmitted to the heart, or of the superexcitation of that organ. Would you apply it to the lassitude of the limbs and the various painful sensations experienced in the locomotive apparatus? but these phenomena are only pains from stimulation propagated by the brain and spinal cord to the nerves of that apparatus, and the first starting point of which is in one or more inflamed organs: in proof of which you may stay or increase them by calming or stimulating those organs. Moreover, you should remember that that which essentially constitutes the limbs and locomotive apparatus is not in a morbid condition: the cellular tissue is neither in a state of phlegmon nor infiltration—neither are the muscles and fibrous parts—nor are the circulating fluids more changed in these than in other parts. You have only a very vehement stimulus proceeding from the stomach or elsewhere, and passing along the nerves to the nervous centres, whence it is reflected; you cannot call that a general symptom. Would you call prostration such? but the heart which beats stronger, the pulse that is accelerated, the stomach that absorbs or vomits, are not in a state of prostration. Nothing but the muscles are prostrated, because a morbid innervation cripples their action. These symptoms relate to a modification of the nervous irritability. Would you have the moisture or dryness of the skin stand as general symptoms? but these states are only lesions of the skin, and then again the skin sometimes secretes and sometimes does not. Would you have the alteration of the urine? but that depends on the kidneys, varies as does the sweat, and both products are in inverse ratio of each other. Would it please you to consider the inflammatory state as general? but the dead body only gives traces of it in the points that have been occupied by phlegmasia. There exists no identical modification of the system that can be placed in precisely the same line as inflammation; the whole body is not inflamed when the gastro-intestinal mucous membrane is inflamed; the whole does not secrete too much when it does; the whole body does not become injected and decolorized when it does. Would you have the alterations of the humours constitute general phenomena? certainly these fluids will be changed when there is inflam

mation; hematosiis is no longer so perfectly performed; watery and medicinal fluids are introduced into the blood, there is absorption of putrid matters, &c. But it cannot be said that this is a general phenomenon characteristic of the febrile essentiality; for this alteration of the fluids is a fact common to all phlegmasiæ, and is of no leading importance, since it disappears with them. In fact, as soon as the irritation has ceased, the humours return to their primary condition. There is no general modification but death, which is a general loss of the powers of all the organs, and yet it does not leave them all in the same condition. Thus, then, the words *general symptoms* afford no signification when we would investigate their meaning. Were they made use of to designate consecutive irritations of different organs and of different shades, occurring with various degrees of congestion and innervation, and originating under the influence of a primary and fundamental inflammation, I could conceive of them; but having the meaning they generally possess, I cannot admit such expressions, and I hold that they should be expunged from the language of science as false and fit only to cause confusion, and that in their place should be substituted the words *consecutive phenomena or symptoms*.

Dispensary, Gerrard Street, Soho:*

Session 1834-35.

LECTURE LII.

Vices of Conformation—Intra-uterine and Extra-uterine Diseases of the Respiratory Apparatus, continued.—Vices of Conformation, and Diseases of the Thoracic Portion of the Respiratory Apparatus.

GENTLEMEN—Under this head are included vices of conformation and diseases of the thorax, lungs, bronchiæ, and pleura.

These organs are liable, in common with all others, to malformations and diseases during intra-uterine life, and from the moment of birth to the end of existence.

The lungs and bronchiæ may be partially or totally absent in acephalous fœtuses. Otto found the trachea impervious in a case of this kind (Meckel). The lungs may be imperfectly developed, or placed external to the thorax, when the anterior wall of this cavity is undeveloped. Haller cites cases of this description, which were narrated by Burner, Bianchi, Fracassini, &c. He also

observes, that absence of the anterior wall of the abdomen is of more frequent occurrence. (*Opera Minora de Monstris*). A large portion of the abdominal viscera, as the stomach, part of the intestinal tube, liver, and spleen, have been found in the chest, and in such cases the lungs were very imperfectly developed. In other cases the lungs formed one mass, which was undivided by lobes. The right lung may replace the left, and *vice versa*; and the heart may be situated in the right side of the chest.

Every part of the lungs has been found in a state of malformation at some time or other. MM. Chaussier and Billard have observed congestion of the right lung at the Foundling Hospital of Paris; and the latter ascribes it to the custom of nurses, in placing infants on the right side in bed. He is also of opinion that the condition is to be referred to the flow of blood, as in the dead body, to the most dependent part. He found the bronchiæ pale, though this congestion existed in the right lung.

Infants are often born with rickets, and have the chest very much contracted, a condition also observed in congenital pleuritis. Examples of the latter are now often observed in young infants, since the attention of physicians was directed by Laennec to the true pathology of pleurisy. I have seen it in an infant under the age of two years.

Pleurisy and pneumonia may exist during intra-uterine life, of which MM. Mauriceau, and Billard have recorded examples. The latter adopts the judicious conclusion of Professor Capuron, that feeble infants do not always fill the air vesicles during respiration; and after death, the lungs sink in water. This fact is amply attested by writers on medical jurisprudence.

Pulmonary congestion, and apoplexy, are often observed in infants after birth. In some there is simple infiltration of blood; in others there is hepatization, which is most common on the posterior borders of the lungs, and more common in the right than in the left lung. The sound organ preserves its ordinary state and solidity; it is only infiltrated with a great quantity of blood, which is easily removed by ablution in water, and it sometimes happens that the bronchiæ are intensely red, and covered with a sanguineous exudation. Pulmonary hepatization is generally accompanied by a sanguineous congestion of the heart and great vessels, which it is necessary to remember, when we wish to distinguish the former condition.

Congestion and hepatization are caused by the superabundant quantity of blood in the heart and lungs during parturition.

The symptoms of pulmonary congestion are often obscure, but the following are usually present: the respiration impeded or difficult, the thorax is badly developed, the countenance is florid or violaceous, the cry

is weak and short, and percussion renders a dull sound, if one hand be applied to the front of the chest, and percussion gently made with the index or middle finger on the back, a method practised by M. Baron, with great success, in cases of the youngest infants. This method is considered much more accurate in early life, than even immediate auscultation, more especially in hepatization. In my own practice, I use the latter also, and it find a most valuable means of diagnosis. The treatment is similar to that for pneumonia, which will be immediately described.

Pulmonary apoplexy is more common in very young infants than in adults or aged persons, on account of the extreme frequency of congestion during this period of life. It consists in an effusion of blood, which is circumscribed in the tissue of the lung. This disease was first described by Laennec, and afterwards by Gendrin, Bouillaud, Denis, and Billard, the last of whom has related several examples in new-born infants. This disease succeeds pulmonary congestion, and its chief symptoms are great difficulty of respiration, stifled cries, and apparent threatening of suffocation; while percussion indicates the absence of the air from the affected part of the lung. There is sometimes an expulsion of sanguinolent mucosity.

The indications of *treatment* are ablation or weaning, however young the infant may be, because the dilatation of the chest, caused by suction, increases the danger of the congestion. It is also important to apply a leech or two to each axilla, as the venous plexus in this region communicates with the vessels of the thorax, and facilitates the sudden evacuation of blood, so essentially necessary in this disease. The use of the warm bath, blisters, and other counter-irritants, with the means proper for pneumonia, ought to be employed.

Pneumonia of infants at the breast arises from a peculiar cause, and one different from that which excites the disease in adults. The disease in infants is not induced by exposure to the atmosphere, but is evidently the result of congestion in the lungs. The blood acts as a foreign body, tends to alter the tissue with which it is in contact, and forms hepatization. In proof of this, M. Billard urges the frequency of the disease in the right lung, as infants are generally placed on the right side when put to bed; and thus pneumonia arises from a physical or mechanical cause, which is not the case in adults. Thus inflammation is circumscribed in infants, and the pleura is seldom implicated as in adults. The disease passes through all its stages, as hepatization, supuration, and ramollissement, as in adults. It is not, however, to be supposed that exposure to cold is not a frequent cause of infantile pneumonia, at a period of life when there is a great predisposition to the disease. It is also necessary to state that febrile

symptoms are not always present, though the real nature of the disease is determined beyond all doubt by percussion and auscultation. M. Billard relates cases in infants of a few days old, which presented all the phenomena already enumerated. According to his great observation, pleuritis is rarely present.

Pleuro-pneumonia is scarcely ever observed in very young infants, but attacks those more advanced in age, and is caused by exposure to atmospheric vicissitudes, and other external causes. It has been observed in an infant aged five months. The symptoms are those of pneumonia, accompanied by painful and more interrupted respiration.

Treatment.—The infant ought to be removed from the breast, and its strength supported by spoon diet in all the preceding diseases. Leeches are to be applied to the axillæ, or chest, and the number must be varied according to the age and strength of the infant. Dry cupping on the chest is a valuable auxiliary, and then a blister, which ought to be removed after three hours, or a thin mustard cataplasm, which will produce sufficient irritation in the course of a few minutes. Friction with warm oil of turpentine for a minute or two is also a very effectual rubefacient. The legs and feet may be placed in warm water with which some salt is mixed, and the bowels ought to be regulated, both of which means are efficient derivatives. Expectorants are of no use, as the bronchiæ are free from inflammation, which is confined and circumscribed in a certain part of the lung; and, moreover, an infant does not expectorate. Nevertheless, it is usual to administer ipecacuan and antimonial wine, the white oxide of antimony, antimonial and James's powder. M. Dugès has praised oxymel of squill in syrup. It is an erroneous and empirical practice to prescribe syrups whenever an infant coughs, as this is prescribing for a symptom of numerous chest diseases, but not for the real morbid condition.

Large doses of antimony are dangerous in pulmonary diseases of infants, on account of the prevalence of gastric or gastro-intestinal irritation among subjects of this age. M. Trousseau, of Paris, has lately praised the oxide of antimony in large doses in pneumonia of infants; but subsequent experience has proved the inefficacy of this remedy.

The warm bath is a favourite remedy, though M. Billard considers it injurious, on the grounds that the heat and pressure of the fluid augments the afflux of blood towards the chest, and increases the difficulty of respiration. It is certain, however, that a warm bath causes determination of blood to the skin and extremities, and equalizes the circulation, and is often followed by the greatest relief. I have often administered a minim or two of hydrocyanic acid prepared by Clarke's process, in an ounce of syrup,

in doses of a teaspoonful every hour, or second hour, with good effects. Mr. Hughes, of Holborn, witnessed the beneficial effects of this remedy in two violent cases of pneumonia, after all other means had failed; and I have used it in a vast number of cases at the hospitals and dispensaries.

It frequently happens that during convalescence great debility remains, tubercles are often developed, and the foundations of phthisis, asthma, habitual cough, or disease of the heart, are laid, which will become urgent in after life. When infants are recovering from pneumonia and other pulmonary affections, great attention ought to be paid to their general health; they ought to be kept warm by means of flannel clothing, the digestive functions duly attended to, and a nourishing diet prescribed. Proper employment of these means will, in general, re-establish health; but it is always necessary to impress on the minds of parents the great liability there is to a return of the disease, especially in cold and damp weather.

Bronchitis is a common disease of new-born infants, and is accompanied by a mucous and sonorous râle in some cases, though these characters may be absent. The disease may prove fatal, without the existence of any of its usual symptoms, as cough or any kind of râle, four examples of which are described by M. Billard. The disease often succeeds pneumonia, and may extend through the whole bronchial mucous membrane, and give rise to all the symptoms of suffocating catarrh. It may also become chronic and continue for a long time, and excite a copious secretion in the mucous membrane of the bronchiæ, and sometimes in that portion which lines the trachea. It is generally complicated with inflammation in the tissue of the lung, or it accompanies tubercular development at the root of the bronchiæ. This form of the disease of generally occurs about the age of ten or twelve months, and is attended with continual cough, difficult or laborious respiration, mucous râle, fever, and pallor of the countenance. To these symptoms are often added inflammation of the digestive tube, the mucous membrane of which becomes ulcerated or softened; the alvine motions are depraved, and all the symptoms of infantile remittent fever developed. The disease continues during the whole period of lactation or dentition, in some cases. At other times acute bronchial catarrh of new-born infants will frequently terminate in a few days, without the employment of any medicine. Its ordinary termination is by resolution, though serous infiltration, or œdema of the bronchiæ, or a sanguineous exhalation, may be the result, as proved by dissection.

The treatment should consist in the employment of the same remedies as in pneumonia; and when the disease becomes chronic, it has been proposed to employ those medicines which act on the mucous

membranes; such as the extract of copaiba but this last remedy is seldom prescribed in this country except in cases of adults.

Pleuritis is a more common disease of new-born infants than is generally supposed, and may exist independently of pneumonia or bronchitis. The symptoms are incessant restlessness and crying, insomnolence, cough, impeded respiration, florid or livid countenance, physiognomy indicating severe pain, and when there is effusion, dullness on percussion, dilatation of the chest, although the cries are clear.

Percussion and auscultation afford uncertain evidence of the existence of this disease, and it is difficult to distinguish it from pneumonia. I cannot assent to the conclusions of MM. Denis and Guersent in considering that auscultation and percussion are unless in cases of infants, as I have often found both exceedingly valuable in forming a diagnosis. It is fortunate, however, that the treatment is the same in both diseases, although the sequelæ are very different.

Pleurisy may become chronic, as in adults, and be followed by the same alterations of tissue, as adhesion or effusion. Some years ago these morbid changes were seldom suspected; but the discovery of auscultation, aided by percussion, has rendered their detection extremely easy. I have frequently observed effusion or hydrothorax in very young children, and in three instances the chest was contracted. Dr. Davies has described similar cases, and so have all the recent writers on diseases of the chest. The treatment for dropsies is required in this form of the disease, and the hydriodate of potass is a very valuable remedy in proper doses, for example, from two to five grains of the hydriodate, and an ounce of distilled water, of which a teaspoonful, or a drachm by measure, may be given twice or thrice a day, sweetened with syrup or sugar. The cathartic and diuretic powders prescribed for other forms of dropsy on a former occasion, are also valuable remedies in appropriate doses. Moderate counter-irritation on the chest, or the application of the ointment of hydriodate of potass or ioduret of lead, is a good auxiliary.

Œdema of the lungs consists in a serous infiltration, more or less abundant, into the pulmonary tissue; is rarely idiopathic and is generally consecutive on pneumonia or chronic pleurisy. The disease accompanies anasarca or infiltration of the cellular membrane, and also induration of the cellular tissue. It often exists without any symptom except laborious respiration, and for this reason it is said to occur in some cases in the agony of death, or to be a cadaveric phenomenon. At other times it is accompanied by cough, great difficulty of respiration, and danger of suffocation, and on dissection pneumonia, bronchitis or pleuritis is detected as well as the serous infiltration.

The indications of treatment are the same

as in hydrothorax, and the other diseases just mentioned.

Pertussis—Hooping Cough.—This commences as a common catarrh, and after ten or fifteen days assumes its peculiar characters; the cough becomes convulsive, and recurs by fits at variable intervals. The inspiration is long and sonorous, succeeded by several short and quick respirations, during which the air is expelled with unusual velocity, causing a peculiar sound which obtained the name of hoop; several of these fits rapidly succeed each other, the face becomes florid, there is a sense of suffocation, until a quantity of mucus is coughed up, which is expectorated or swallowed, and in the last case may be vomited, then the fit ceases, with all the appearances of perfect health. The patient now returns to his amusements, and often craves for food; but when the attack has been severe, it may be succeeded by fatigue, hurried respiration, and great languor.

On analyzing the paroxysms, we find much cerebral and pulmonary congestion; the former is so great, that there is often bleeding from the nose, and I have seen it from the eyes and ears. The return of blood from the head is impeded, and also the circulation of blood through the lungs; and for this reason hooping-cough is often succeeded by hydrocephalus or pneumonia. According as the disease advances it becomes more severe, but after an indefinite period of weeks or months it abates and finally disappears, or death is induced by disease in the head or chest.

It has been frequently observed that children exposed to the same atmosphere present symptoms of catarrh, but the disease disappears in some, and is succeeded by hooping-cough in others.

In some cases the disease is complicated with cerebral and pulmonary congestion, or pleurisy, and generally proves fatal. The fit comes on suddenly without any apparent cause, and the child grasps whatever it can lay hold of during its continuance. The disease is seldom accompanied by fever, until the brain or lung becomes congested or inflamed; but this form of complication is of comparatively rare occurrence. When hooping-cough occurs to infants affected with tubercles, it often accelerates their development and terminates by laryngeal or pulmonary phthisis.

The prognosis is unfavourable in proportion as the complications are dangerous, and the infants very young. M. Guersent has well observed, that infants at the breast are often affected with cerebral congestion, which usually destroys them. We can also estimate the danger to be apprehended from pneumonia, pleuritis, softening of tubercles, pneumo-thorax, and other complications which may occur with hooping cough.

Some contend that the disease is inflammatory, on account of the catarrhal symp-

oms at the commencement, and others on account of the appearances of inflammation found in the chest; but a preponderating majority maintain that it is spasmodic, as they treat it successfully in most cases with remedies proper for such condition, and without any antiphlogistic means. They hold also, and I entertain the opinion, that the inflammatory appearances found in the brain and in the lungs, are the effects or consequences, and not the causes of the disease.

Treatment.—The indications of treatment are to abate the catarrhal symptoms at the commencement of the disorder, and to moderate or remove the nervous complication which gives rise to the convulsive respiration.

The first indication is to be effected by bleeding, or leeching when the inflammatory symptoms demand it—the plan adopted by Willis, Sydenham, Astruc, Home, &c. This mode of treatment is very seldom necessary. Emetics are ordered, to free the stomach from the mucosity of the lungs, which is coughed into the pharynx, and then swallowed, and are said to be indicated by the spontaneous vomiting, which is a symptom very frequently absent. Antimonial and ipecacuan wine, with oxymel or syrup of squills, are the emetics usually employed. Mild aperients, as calomel, castor oil, manna, senna, and such like, are usually administered.

The second indication is fulfilled by the use of narcotics and anti-spasmodics, as opium, hyosciamus, conium, aconitum, belladonna, and hydrocyanic acid. These remedies ought to be used both internally and externally, so as to influence all the respiratory nerves. It is on this principle I employ them at the hospital and dispensary, and many students have observed more immediate benefit derived from the external than the internal use of these remedies. Thus I usually prescribe from two to four ounces of compound camphor liniment, with from two to three drachms of tincture of opium, a table spoonful of which is to be rubbed over both cheeks, the nape of the neck, dorsal spine, and sides and front of the chest, night and morning; and I generally find that in simple pertussis the hooping ceases in three or four days.

Some caution is required in using this liniment in delicate infants, as it may produce sleep, and would aggravate cerebral congestion if that existed, but in such cases a drachm of the tincture of opium will be sufficient. The splendid discovery of Sir Charles Bell, by which it was first clearly shewn that some of the nerves of the face were respiratory, afforded a satisfactory explanation of the method of Professor Hamilton of Edinburgh, in resuscitating still-born infants by rubbing the face with ammonia or ardent spirit; the rationale of which he was unable to give before the

important discovery of Sir Charles Bell. Stimulating liniments may be employed in the same manner as sedative, but I prefer the latter as less painful, and as equally, if not more efficacious. The empirical remedy called Roche's Royal Embrocation, is a stimulating liniment. Many mothers have requested me to prescribe the liniment alone, and omit the syrup if I pleased, which was composed of compound tincture of camphor, and hydrocyanic acid, with mucilage of acacia and simple syrup; and I have sometimes complied with the request, when the case was slight, for the purpose of enabling the clinical students to appreciate the value of the remedy.

A grain of the extract of conium, and of the extract of hyosciamus, may be mixed with an ounce of syrup, and a drachm administered every sixth hour, carefully watching their effects, and suspending their employment when necessary. The dose of aconitum or belladonna ought to be the eighth, sixth, or fourth of a grain, the quantity being most cautiously increased at the same intervals.

Some advise extract of conium, camphor, and opium, in powders; and I have known a pure apothecary, not a general practitioner, modestly exact two guineas for a dozen of these powders.

M. Guersent, of Paris, administers with great success a quarter of a grain of belladonna, hemlock, and oxide of zinc, three or four times a day, gradually and cautiously increasing the dose; and he administered a grain of the zinc every hour, to an infant of six weeks old.

Drs. Graves and Beatty very strongly advise a combination of tincture of cantharides, and compound tincture of camphor, so as to produce slight strangury, as very effectual in whooping-cough*.

Some strongly recommend blisters, antimonial ointment, and mustard cataplasms to the chest; but these are not, in my opinion, necessary, unless there is congestion or inflammation present.

Dr. Autenreith lauds antimonial ointment urged to pustulation in infants; but this requires much caution, as infants have been destroyed by the irritation of the remedy.

When cerebral or pulmonary congestion or inflammation is present, the proper plans of treatment advised under these heads are to be employed.

Carbonates of potass and soda are considered correctives of the condition of the stomach; but these are powerful medicines when the battle is won.

In some cases, change of air alone effects a cure.

Foreign Medicine.

EPISIORAPHY—ARTIFICIAL CONTRACTION OF THE VULVA.

BY DR. FRICKE, OF HAMBURGH.

We have already published, several months ago, an article on this operation; but just now, when the attention of surgeons appears directed towards means of effectually curing prolapsus of the uterus, the following details will be read with the greater interest, for the methods lately adopted in Paris have unfortunately not attained all that they promised. The patient operated on by M. Berard, junior, shown by him to the Academy of Medicine, and the history of whose case we published, saw before long her malady entirely reproduced. By a singular coincidence, which will give greater interest to the following analysis, the very day in which that account appeared, a paper on the subject, by Dr. Fricke, was announced at the Academy.

Episioraphy, or artificial contraction of the vulva, is an operation which has for its object to remedy prolapsus of the womb, in cases in which that organ cannot be retained in its place by any mechanical means. Dr. Fricke, director of the surgical department in the great hospital of Hamburg, published the first case of the kind in the second volume of its Annals. Since that period, he has repeated the same operation four times, and in three of them with success. D'Autrepont has likewise recommended it.

The operation is easy, short, and but slightly painful; but the subsequent treatment requires great care. The utmost neatness should be observed in the dressing of the wound, in order to avoid the contact, always pernicious, of a profuse muco-purulent secretion, and to obtain union by the first intention. Complete union as far as the perineum, has been obtained only once by Dr. Fricke. In the other cases there has always remained an opening greater or less; nevertheless, the design of the operation has been far from being defeated. The author considers, indeed, that this want of complete union may be regarded as a favourable circumstance, since the escape of pus and mucus is rendered more easy by this

* Dublin Journal of Med. Science, 1832.

inferior opening remaining. The sutures should be removed on the third day. If the edges of the wound have not united by that time, they will not do so at a later period; and the edges must then be pared afresh. The employment of lapis infernalis is of very great utility in cases where the adhesion is only partial. The following case is an example of success in circumstances the most unfavourable.

K. E. Sornsen, of Hamburg, forty-four years of age, the mother of four children, has laboured under *prolapsus uteri* since her last confinement, which took place quickly and easily, four years ago. A large cylindrical tumour, becoming smaller towards its inferior extremity, and of a pale red colour, was suspended between the thighs, in front of the external organs of generation. At its lower extremity was perceived the mouth of the womb, giving exit to a muco-sanguinolent fluid. Through this orifice a sound may be made to penetrate about a quarter of an inch into the uterus. The upper extremity of the tumour adhered to the internal surface of the labia, in such a way as to prevent the passage of the finger: the tumour was not painful: it measured nine inches and a half in its greatest circumference, and four in its least.

A prolapse of the womb could not be mistaken. Walking was difficult; the neighbouring parts, excoriated by the friction, were very painful; the stools were rare, taking place only every two or three days, and most commonly, only from injections. The passage of urine, although difficult, nevertheless took place spontaneously. The tumour could be easily reduced when the patient lay down; but whenever she rose up, it returned immediately. When it was replaced in the pelvis, the external organs appeared of such magnitude as to permit the closed hand to be easily introduced into the vagina. The mucous membrane of the latter was very much enlarged and relaxed. The condition in life of the patient, who was a work-woman, and the state of the parts, did not permit the idea of applying any mechanical means. Recourse was had, therefore, to the operation, although the extreme relaxation and dilatation of the parts was a condition very unfavourable to success.

The patient being placed on the operation-table, with the buttocks raised, and the knees brought near the abdomen, as in lithotomy, the operator, with a pointed bistoury, removed a portion of the skin covering each of the labia, to the extent of half an inch in length, and about two lines in breadth. In this manner the incisions formed a sort of V, the closed extremity of which was directed towards the perineal angle. During the operation, an assistant prevented the vagina from protruding. The surfaces of the labia thus bared, were then brought together, and retained by three sutures, after having previously introduced a soft sponge into the vagina, cut in the form of a cone. The thighs were afterwards brought close together, and maintained in that position by bands. The orifice of the vagina thus closed, had not more than an inch of longitudinal diameter.

After the operation, which was prompt, and not very painful, the patient was placed carefully on the right side. From that time until the cure was complete, the urine was constantly drawn off by means of an elastic sound.

First Day after the Operation.—Slight fever; little pain; moderate suppuration of the wound. Careful injections were made of tepid water.

Second Day.—A little swelling around the wound, and suppuration more abundant. The sutures were taken away without separating the thighs of the patient. The superior and anterior part of the wound was found to be united by the first intention. The inferior and posterior part opened afresh the moment the threads were taken away. A little sanguinolent pus escaped. Injections were made with a small syringe, of a solution of acetate of lead in infusion of camomile.

Third and Fourth Days.—The inferior edges of the wound, which separated on the second day, have begun to suppurate, and are become a little flabby; they were washed with a little compound tincture of benzoin. The sponge, filled with pus, was carefully extracted by the superior opening of the vagina.

Sixth Day.—That portion of the wound which was united by the first intention, is still solid and secure. Extending from one

labium to the other, it forms as it were a bridge, which divides the opening of the vagina into two; the one superior, which is the larger; the other inferior and smaller. This bridge was touched with a solution of the nitrate of silver. Little tents of charpie were introduced into the vagina by the inferior orifice. A natural stool was passed.

Eighth Day.—The patient, whose condition became very uncomfortable, was removed to another bed, placed on an inclined plane; the thighs always kept together.

Twelfth Day.—The borders of the wound were touched with *lapis infernalis*. The bridge formed by the union of a portion of the labia, was surrounded carefully with pledgets of charpie.

Sixteenth Day.—The part of the wound united by the first intention, is still firm and secure; the other part, of which the edges remained separate, have begun to cicatrize.

Twentieth Day.—The cicatrization is almost complete; there only remains at the lowest point, a little opening where suppuration continues.

Twenty-sixth Day.—The wound has cicatrized throughout its whole extent. The little bridge passing from one labium to the other, is five lines broad, five lines long in front, and six behind. The bands were removed from the thighs, which the patient was allowed to separate; she was also permitted to take a more comfortable position; nevertheless, she did not get up till the end of the fourth week. The vaginal opening is, as we have already said, divided into two; the anterior orifice, next the pubis, being an inch in length, and the posterior one, towards the perineum, being fifteen lines. The uterus and vagina are perfectly retained in their position; and the woman can, without any inconvenience, return to her occupation.

—o—

CROUP WITHOUT COUGH.

BY DR. MICHAELIS.

In the month of February, 1831, at ten o'clock in the morning, Dr. Michaelis was called to a child four or five years of age, and of a robust constitution. The patient, of a lively disposition, and very well in health up to the previous day, was lying on

the back, indifferent to all around, scarcely uttering a word, and with an expression of pain on his countenance. He answered questions with difficulty, by means of motions of the head. After an attentive examination, nothing could be discovered beyond an embarrassment in the respiration; no pain in the head or abdomen. Under the supposition of intense inflammation of the lung*, leeches were ordered to the chest, together with sal ammoniac and tartarized antimony, in divided doses. At five o'clock in the evening, the difficulty of breathing was so great, that immediate death was apprehended. He lay motionless on the back, with the head a little turned round, and the arms extended abroad on the bed, forming a large angle with the rest of the body. The child has not yet coughed once.

In this state of the symptoms, Dr. Michaelis, after much consideration, recognized the case as an example of croup without cough, a pathological phenomenon excessively rare. After having urged the patient in vain to cough, he made him respire the vapours of hot vinegar. Scarcely had he made a few respirations, when he began coughing. This cough had so distinctly a croupy character, that a woman who was present, exclaimed with astonishment, "Can it then be the croup?" An emetic was administered to the little patient, which brought up a quantity of glairy matter, and of membranous substances, the nature of which could not be mistaken. The respiration became more easy, and the child brought his arms to his body. Leeches to the neck, with calomel and golden sulphuret of antimony, which produced several stools. A good night. Several fits of coughing, with easy expectoration. Respiration good, and without any particular sound. General perspiration. Urine natural, with single light film. The child no longer answered the questions of the physician, although he replied to his mother. Powders continued, then the antimonial sulphuret alone; and lastly senega. Complete recovery, without relapse, on the fifth day.

Dr. Michaelis, who knew nothing more of croup without cough, than what has been

* Where was Dr. Michaelis's stethoscope in this case?

said by the celebrated Heim, remarked that the case related above is unique, in the circumstance that the cough, regarded by all authors as a pathognomonic sign, was brought on in an artificial manner. In the cases cited by Heim, the existence of croup was only made known by the post-mortem examination, provided the cough had been wanting throughout the whole course of the disease.

Heim, in a work which he published at Berlin, in 1810, on the Nature and Treatment of Croup, says on this subject, at the 8th page:—"An experienced physician might mistake this disease. A little while ago, died of this affection, at Berlin, a child of two years old, who had a cough at the commencement of the affection, and who, in consequence, never had a clear voice. It was not till two days before his death, that I recognized the disease, and then principally from the circumstance that the child kept his head continually bent forwards. All assistance came too late." Again, at page 15—"Catarrh sometimes exists without a cough, properly so called. The latter is often only very moderate in croup; for if it becomes severe, the patient cannot produce the well-known characteristic sound." "If the voice be wanting, we may easily be deceived. I candidly confess having been deceived more than once."—page 19.

These quotations leave no doubt of the existence of croup without cough; and, since the work of Heim is well known, it is astonishing that no other author has mentioned the affection. In order to do honour to the work of that celebrated physician, Dr. Michaelis proposes for the future to call the disease, *Angina membranacea occulta Heimi*.

—o—

CHLORIDE OF SODA IN INTERMITTENTS.

—

Two physicians, Messrs. Munaret and Lalesque, had each presented to the *Academie des Sciences*, for the Monthyon prize, a paper on the efficacy of chloride of soda in intermittent fevers. Both claimed the priority of discovery. Dr. Roche, in a letter which he has addressed to the Academy, asserts that the honour belongs neither to the one nor to the other, but that he is himself the

author of the discovery. He had expounded, in the *Journal Universel et Hebdomadaire*, and in the third edition of the *Traite de Medecine et de Chirurgie*, which he published in conjunction with M. Sanson, a new theory on the subject of intermittent fevers, from which he deduced the utility of the chlorides in those diseases; and this was at the beginning of September, 1833. Now, M. Lalesque, who had the priority of date to M. Munaret, did not make and publish his first experiment, until a month after M. Roche had recommended the attempt.

ITALIAN MEDICAL INSTITUTIONS AND HOSPITALS.

(Concluded from page 384.)

ROME.

The practice in the treatment of disease inclines to the Broussaian; the abstraction of blood in small quantities is resorted to in the majority of cases, and as a preventive against malaria fever. Blisters are used to combat the consequences of inflammation. The exhibition of large doses of antimony in acute inflammation is less frequent than formerly. In bronchial affections, prussic acid and sedatives are frequently employed. Vaccination is not much encouraged, nor is the stethoscope used. When constitutional disorder accompanies surgical disease, the physician is frequently called upon to prescribe, the surgeon confining himself to operations and the application of external remedies.

NAPLES.

The lectures of the Colleges of Medicine and Surgery on the several branches of medicine and surgery are delivered at the *Spedale degl' Incurabili*; clinical lectures on medical and surgical cases, and on diseases of the eyes, are also given. Dr. Quadri is professor of this last branch of surgery: he employs depletion and warm applications only at the commencement of acute ophthalmia; in the varieties of chronic inflammation, he has recourse to counter-irritation and stimulating collyria.

The practice is chiefly "Hippocraticque," the administration of remedies being determined by observation of the symptoms in each particular case. Bleeding is not so general as at Florence or Rome; antimony and James's powder are in very general use in acute disease: this remedy, however, is not given in the same large doses as formerly. In syphilitic cases, mercurial frictions are made in the sole of the foot, and continued for about twenty minutes each time, by an assistant, whose hand is covered by a leathern glove. Vital operations are only performed in spring and autumn, except in cases of

emergency. Over the operating theatre a hand is painted, with an eye in the palm.

The dressings made use of to wounds are mostly simple, stimulating applications being rarely used; union by the first intention is attempted, where practicable.

—o—

GERMAN MEDICAL INSTITUTIONS.

The hospitals of Germany, like those of France and Italy, are under the superintendence of their respective governments; but are inferior in point of size and interior organization. They are mostly supported by funds derived from taxes on parishes and districts, and by contributions from servants and others of inferior classes, who thus, when ill, acquire a title to admission. Some of the patients also pay a certain sum weekly for their support. A fixed salary is allotted to the medical men, who are not elected by public competition, but are mostly appointed by government. Hired nurses attend upon the sick, there being no religious sisterhood to undertake this duty. The bodies of those who die in hospitals are generally examined, though morbid anatomy is not very zealously cultivated. Professional visits are made daily, at a later hour than in French and Italian hospitals.

Germany contains upwards of twenty universities—a larger number than any other country. The situation of most of them in small quiet towns is well calculated to favour studious habits.

The relations between professors and students are much more intimate than in France and Italy, and the love of science is stronger than in those countries. This devotion to science, and seclusion from general society, occasionally gives rise, however, to a degree of pedantry and confined views, even in men of extensive acquirements, and no where are there so many poor *savans* as in Germany.

In most universities the instructing body forms a part of the state. The chief has the title of Rector Magnificus, a dignity frequently retained by the prince himself. As the rector cannot always personally superintend the affairs, most universities have a pro-rector chosen annually from among the professors. After the pro-rector come the deans of the faculties, also chosen from the professors, and lastly the professors, who are divided into three kinds, private professors, extraordinary professors, and ordinary professors.

The usual manner of becoming attached to an university is to begin by filling the office of private professor, who is not a public functionary, but who has the right of giving lectures, and if he distinguish himself, is appointed an extraordinary professor when a vacancy occurs: he is then a servant of the state and receives emolument. The highest degree is that of ordinary professor, who has a higher salary and peculiar privileges. It results from this arrangement that the number of

professors is very great; the different branches of science being frequently taught by two or three at the same time. It is customary in most universities for students to pay for attendance on the courses of lectures. Those of the Austrian states form, however, an exception. Professors are indeed obliged to give a public course every six months; this, however, treats only of secondary objects: the most important courses are never gratuitous.

The students, notwithstanding the roughness of manners which prevails in some universities, are for the most part attentive, persevering, regular in attendance, and decorous in their behaviour, in the lecture-room. Of late years drinking, quarrelling, and taking part in political disturbances, occur much less frequently among them.

The practice of medicine is not in general based upon any particular theory, but it is regulated by the observation of symptoms in individual cases, and approaches nearer to the English than to the French method. The abstraction of blood, both by venesection and leeches, is less frequently had recourse to than in France and England, but active internal medicines are pretty generally employed: baths and enemata are also much used, while tisanes, infusions of simple herbs and demulcent potions are not usually given, except as vehicles for the exhibition of more energetic medicaments.

Auscultation and percussion do not find many adopters in Germany, and lithotripsy has, I believe, only been performed at Berlin. Medicines are not in general given in surgical diseases with a view to their constitutional operation, and, with the exception perhaps of Berlin, the management of surgical cases is very inferior to that of England and France. As, however, the practice varies considerably in different parts, it will be best illustrated by reference to individual hospitals.

The following is a list of the German Medical Schools and Institutions.

Stuttgart; Tübingen; Nuremberg; Prague; Dresden; Leipzig (the Professors are, of anatomy, Weber; physiology, Kühn; pathology and therapeutics, Cerutti; clinical medicine, Clarus; clinical surgery, Kuhl; Berlin (professors, Kluge, Rust, Wafe, Graefe); Halle (the University of the two Meckels); Göttingen (anatomy by Langenbeck, physiology by Blumenbach); Bonn.

With regard to the curriculum of study required the following may stand as instances.

At Prague, five years is the required period of study preparatory to the examination for a medical diploma. The three first are devoted to attendance on the different lectures, the two last principally to the clinics, pupils having patients placed under their care, of whose progress they are required from time to time to render an account. Pupils are examined every six months during their studies; the final examinations for the diploma are two: the first is on anatomy, physiology,

natural history, medical and surgical pathology and therapeutics, before the dean, and the professors of these sciences: the second is on chemistry, materia medica, medical jurisprudence, practice of medicine and surgery, and clinical examinations at the bedside. A thesis must also be written and defended. Surgical candidates have likewise to perform two operations on the dead body, describing the steps of the operation, the advantages of various methods, &c. The expenses of examination amount to about twenty pounds.

At Berlin the number of students in the four faculties is sixteen hundred and fifty-one. Of these, four hundred and thirty-one are not Prussians. Three hundred and fifty-eight attend the medical classes in the following order;—first year, anatomy, physiology, botany, chemistry; second year, materia medica, therapeutics, general and special pathology; third and fourth year, the medical, surgical, obstetric, and ophthalmic cliniques. Each course of lectures costs the student from two to three louis: the fees of examination amount to about twenty-five louis, and the whole expense of professional education to about one hundred and fifty. Candidates have to undergo four examinations; the first is for promotion, the second, termed the *tentamen*, is made by the dean, and takes place before the period of study is terminated; the third, or *rigorosum*, is made before the professors of the faculty, when each professor examines on his particular branch of education. Three or four students are examined at a time, and the examination generally lasts upwards of three hours. Candidates have also to write and defend a thesis in Latin.

After passing these ordeals, the candidate acquires the title of doctor, which, however, does not authorize him to practise before undergoing the last examination. The title of doctor may be obtained at any of the Prussian universities; but all candidates are obliged to repair to Berlin for the public examination, which is divided into several parts, and lasts several days. In the anatomical examination, the candidate takes from a vase the name of one of the bones, of which he is required to give a description without hesitation. In like manner, the name of a viscus is drawn by lot, and described: a part of the body, to be dissected and demonstrated, is also indicated in the same manner. An anatomical description of the contents of the cranium, thorax, or abdomen, with the relative position of the viscera, is likewise required. In the surgical examination, the candidate has to make a dissertation on a subject chosen by the professor: he has also to perform operations publicly on the dead body, and describe the different steps of the operation; also to give a demonstration on the skeleton, of the method of treating fractures and luxations: he has the treatment of two patients in the hospital for a fortnight, and

takes daily notes of the cases, which are read at the examination. Candidates for the medical diploma, have in like manner, the care of two hospital patients.

—o—

TORSION OF ARTERIES. BY DR. BAMBERGER.

M. Bamberger has instituted comparative researches into the different modes of executing the torsion of arteries, in order to estimate the hæmostatis power of each, and the greater or less facility which each plan offers in its execution. According to him these methods may be reduced to the four following.

1. Simply lay hold of the end of the divided artery with a pair of forceps; separate it from the surrounding parts; draw it out a little, and twist it.

2. Begin the operation as in the first method; but before twisting the artery with the forceps, which hold it in a direction parallel to the axis of the vessel, fix the latter by means of another pair of forceps, held perpendicularly to the first pair, and applied about half an inch from the end which has been drawn out, that is to say, just about the level of the surrounding parts. The forceps last applied prevent the torsion from extending into the flesh. The extremities of the instrument are to be rounded and smooth, without teeth, in order that they may not lacerate the portion of the artery to which they are applied.

3. Seize the vessel, as before, with forceps held parallel to its axis; then apply, across the artery, the forceps which are to fix it, at the point where the extremities of the first pair terminate; and by sliding the second pair towards the origin of the artery, the internal and middle tunics are made to pucker up within the external coat. This done, take away the second instrument, and complete the torsion with the first.

4. This differs from the method last described only in the circumstance that, in the last stage of the operation, we continue to fix the artery with the second pair of forceps, while the twisting is performed with the first, just as was done in the second plan.

Each of these methods, again, may be modified in two different ways, according as the twisting is limited to a few spiral turns, or is continued till it produces, on the end of the vessel, a little conchoidal cone.

M. Bamberger has repeated these four plans a great number of times, and in different circumstances, in order to compare them with each other. He has operated upon horses, cows, goats, sheep, dogs, and rabbits. In general he has succeeded by them all; and in the very few cases where he has failed, the consecutive hæmorrhage always depended on causes independent of the operation. He has also performed it several times on the dead human subject; he

has examined the form which the extremity of the twisted artery assumes; and has made comparative injections, for the purpose of ascertaining which kind of occlusion resists best the force of the liquid column. They all appear to him equally secure, the injection not having succeeded in forcing an issue in either of them. He has made necroscopic examinations of animals submitted to these experiments, at different dates from their performance. Sometimes he has found the internal tunics irregularly torn and puckered; at other times, twisted in a spiral form, and presenting a little hardened cone; frequently they were cut smoothly across, and were covered only by the external tunic, which formed at their gaping extremity a little conical hood.

In the third and fourth methods the end of the vessel always bulged a little, before terminating in a cone, and the internal coats which constituted this bulging, always formed a very solid cone. In the second and fourth methods the external tunic is injured at the point where it has sustained the pressure of the second pair of forceps; and this, in some cases, may expose it to rupture.

Coagulated blood, and the exudation of lymph, are found equally in all the modes of proceeding. In the first, the clot is prolonged furthest toward the heart; generally as far as the spot where the first collateral branch is given off. If the internal coats are ruptured longitudinally, in consequence of the simple twisting, the blood distends the external coat, at the place where the rupture exists, and thus gives rise to a kind of consecutive false aneurism. When the internal tunics are forced back towards the heart, as in the third and fourth methods, the exudation and adhesion of lymph between the compressed tissues appears to take place more promptly.

All the preceding modes are good. The first is unquestionably the most simple and easy. The third offers the greatest security, but it is more complicated, and more difficult of execution. The second and fourth labour under the disadvantage of injuring the external tunic; but they prevent the twisting from extending into the flesh.

M. Bamberger insists much on the choice of the forceps; but this does not appear to us to merit such great attention. If we take away a portion of the twisted artery, a foreign body is not left in the wound, which may thus be closed more perfectly—an essential advantage in the operation of torsion; and in consequence of which it deserves a preference over the ligature. We shall not enter into all the author's details respecting the experiments he has instituted, nor into his description of the instruments which he adopts, and of those he rejects. Neither shall we meddle with his critical remarks on the crotchet, on the forceps of M. Amussat, Schröder, Rust, &c. As the au-

thor promises us shortly another work, on torsion practised on the living human subject, we shall have occasion to revert to all these matters.

—o—

CONCEPTION—CAN IT TAKE PLACE WITHOUT COITION?

—

Under this title Doctor Casper, of Berlin, has published a paper, taken from the manuscripts of Professor Heim, comprising seven cases which have for their object to establish an affirmative answer to the foregoing question. It is a question, undoubtedly, of great importance, with respect not only to physiology, but also to legal medicine. Examples are incontestible of pregnancy while the hymen remains entire. The celebrated Heim, a man of great name and high authority in Germany, has even collected instances where conception took place, although the spermatic fluid was lodged only at the entrance, or before the orifice of the vagina. We may conceive this possible, if we admit that the fecundation of the ovum takes place from the emanation of the *aura seminalis*. But Heim goes still farther, and allows the possibility of fecundation by the simple aspersion of the semen on the lower part of the abdomen. In support of this opinion he cites four cases, which he met with in his own practice, and three others from the papers of M. Ribke, professor of midwifery; which cases, according to him, leave no doubt of the possibility of the fact which he advances. We will confess that the perusal of these cases has not left on our mind the same conviction which appears to animate the author. But, could this be otherwise? This conviction of the celebrated Heim, was it not in consequence of the reliance which he placed on the persons who were the subjects of his observations? It is a purely *moral* conviction which he has acquired, and which cannot be possessed by him who has not the same faith in the veracity of the persons whose cases Heim relates.

These facts are of no importance by themselves. They only obtain weight from the name of the two celebrated men who have published them, and who still enjoy, among our German neighbours, unbounded credit and confidence. The last consideration alone has induced us to dwell on this delicate and long unresolved question, to which we call the attention of French accoucheurs and medical jurists.—*Journ. Hebd.*

—o—

TRAUMATIC TETANUS CURED.

—

There are so few instances of recovery from this dreadful disease, that it is consolatory to be able to relate a fortunate termination. This case is related in the 5th volume of the Calcutta Transactions, by Mr. Grant. The

patient was a *Parsee*, who had received a slight contused wound in the face, and a fortnight afterwards exhibited unequivocal symptoms of trismus. Some mercurial ointment and camphor had been rubbed on the side of the face before entrance into the hospital. The pulse was quick, but there was no other constitutional disturbance. One hundred drops of laudanum were given him at bed time—the warm bath—belladonna plaster. Next day he seemed a little better, and a quill could be got into the mouth, to inject nourishment. Fifty drops of laudanum were given the second night; the bath to be repeated. A turpentine injection was ordered, to obviate the constipating effects of the laudanum. Next day he could open the jaw half an inch. Medicines as before. On the fourth day, he retrograded much. He was ordered three grains of extract of belladonna. Fifth day, the pupils dilated. The medicines to be repeated, and to have an enema twice, each containing fifteen grains of tartrate of antimony. Sixth day: the injections had produced a general feeling of coldness and weakness, but no vomiting. The second enema was followed by two motions. He could not swallow pills. Sixty drops of laudanum to be given. To have the warm bath usque ad deliquium. These remedies, with some variations, were continued several days. On the 12th day opethotonos occurred, and rendered the case more hopeless. Was ordered two grains of extract of stramonium every two hours. This seemed to afford relief, and the medicine was continued in smaller doses. On the 18th day, the stramonium was omitted, and ten grains of opium were given. The bowels were kept open by enemas. He continued to mend, though slowly, from this date.

Another case, somewhat similar, is related in the same volume, by Dr. Gilmore, where tetanus followed a severe sword-cut in the thigh. This patient was freely bled after the spasms had commenced; and the treatment consisted chiefly of calomel, camphor, soda, and purgatives. One of these purgatives produced vomiting and purging, during which large indurated masses of feculent matter were discharged. From this time the symptoms became more favourable, and recovery took place.—*Dr. Johnson's Medico-Chirurgical Review.*

—o—

TWO CASES OF ANÆMIA.

In the fourth number of the Baltimore Medical and Surgical Journal and Review, there are some observations upon the pathology and treatment of anæmia, pointing out some of its most striking peculiarities. That its existence depends upon a previous morbid condition of the solids, there can be but little doubt, and that it should be

generally regarded rather as a symptom of pre-existing disease, than constituting a disease itself, we think is equally true. Yet, when the anæmic stage is once fully developed, that it excites symptoms which are peculiar to itself, and which call for a method of treatment somewhat special, we are fully satisfied from repeated observation. The general commotion of the vascular system; the violent throbbing of the vessels about the neck; the excessive palpitations of the heart; the hurried and embarrassed respiration; the frequent and *shattered pulse*, and in some instances, the intense heat of the skin, all of which are symptoms frequently observed to attend it, would seem, at first view, to call for blood-letting, and the general employment of antiphlogistics. We have more than once seen them attacked by such remedies: we have seen repeated bleeding resorted to—antimonials, cathartics, and mercurials, diligently employed; yet with the constant effect of exasperating all the symptoms. Under the same circumstances, we have seen an opposite course pursued, consisting of a combination of antiphlogistics, corroborants and alteratives, and although apparently incompatible with the general train of symptoms, they have all been speedily subdued under the use of these remedies, and health rapidly restored. But as these facts have been fully explained in the paper above referred to, we merely propose to offer here, two cases in illustration, which have fallen under our care since those remarks were published.

CASE 1. *Anæmia succeeding Intermittent Fever.*—George Purse, seaman, aged 19, was admitted into the Baltimore Infirmary, August 5th, 1834. Has been sick two months, on the voyage from New Orleans to Baltimore. Has had a chill every day at 12 o'clock, which was constantly followed by fever. His abdomen is now very much swollen, and presents evidences of visceral enlargement with effusion of water. His tongue is very pale and slightly furred; his gums almost white, and his skin bloodless, pale, transparent, and of a waxen aspect. His pulse is full, frequent, and presents a peculiar thrill; his respiration short and hurried, and his fever almost constant; there being generally a chill every day at 12 o'clock.—Bowels rather costive; cups to the abdomen; Massa, Pil. Hyd. Extract Alk. Jalap. Pulv. Rhei. ã ã gr. iij., ft. Pil. et cap. ter in die.

Aug. 6. Little or no change in his condition—cups repeated, and medicine continued.

Aug. 9. Blister to the abdomen, and medicines as before.

Aug. 10. No chill, but the fever and other symptoms not much mitigated. Blistered surface to be sprinkled with sulphate quinine, gr. x. three times a day, and skin sponged with cold water as long as it continues hot.

Aug. 13. No effect observed from the quinine.

Aug. 14. Fever somewhat less—Prussiat Ferri, gr. x. three times a day.—The alterative aperient pill at night.

Aug. 19. He had improved very much under the use of the prussiate of iron, but in consequence of imprudence in diet, the excitement has been renewed. Ol. Ricini $\frac{3}{4}$ ss.—Tinct. Digit. gutt. x. three times a day.—The iron only to be given at night.

Aug. 24. Much improved—Digitalis discontinued, and the iron to be administered three times a day—dose increased to gr. xv. Iodin. $\frac{3}{4}$ ss. Hydriod. Pot. $\frac{3}{4}$ i. Unguent. Hyd. Fort. $\frac{3}{4}$ i. m. to be rubbed upon the abdomen daily.

Sept. 10. His improvement since the last date has been rapid and steady. The bloom of health has returned to his cheeks, and he feels himself relieved of all his distressing symptoms. He still continued to take the iron in the form of the muriated tincture, as a substitute for the prussiate. *Reported by Mr. S. G. Baker.*

CASE II. Charles Winn, seaman, aged 18, was admitted into the Baltimore Infirmary, July 30th, 1834. He was born in a malarious district of North Carolina, and from his earliest youth has been annually subject to intermittent fever, until two years previous to his admission, during which time he has led a seafaring life,

The whole body at the present time is exsanguined, more or less mottled, and of a pale waxen hue. His cheeks and ankles are oedematous; the abdomen tumid; adnata of the eye of a pearly lustre; lips, gums and tongue blanched, and the latter pointed; muscles flaccid; body emaciated; digestive powers partially impaired; respiration much disturbed, the least exercise occasioning hurried and oppressed breathing, and if continued producing speedy exhaustion. The heart palpitates violently even when lying at rest, and there is tumultuous throbbing of the carotids and other large vessels about the neck. The pulse is also frequent, and presents a peculiar *shattered* thrill. The liver and spleen are perhaps enlarged, but the effusion of water into the abdomen renders it difficult to decide by exploration. Massa. Pil. Hydrarg. gr. iij. Pulv. Soc. Aloes, gr. i. Pulv. Ipecac. gr. ss. every night. Carb. Ferri, gr. x. three times a day. Generous diet with porter.

Aug. 10. The improvement of his general health has been steadily progressive. Tongue and lips slightly reddened—abdomen less tumid. The oedema of the cheeks and ankles has lessened—digestive function invigorated, and the evacuations more healthy.

Aug. 25. Still improving. Tinct. ferri muriatis substituted for the carbonate of iron. Alterative pills to be continued.

Sept. 11. All the prominent symptoms of the disease have yielded, in a great measure, to the treatment. Tongue and lips more coloured; the tumefaction of the abdomen has

entirely subsided, as has the oedema of the cheeks and ankles. The palpitations of the heart, and the excessive throbbing of the vessels are no longer perceptible. His pulse is regular and full, and he is able to bear considerable exercise without fatigue. *Reported by Mr J. C. W. Wederstrandt.—The North American Archives of Medical and Surgical Science, Edited by Dr. Geddings. October, 1834.*

—o—

Reports of Surgical Cases, with Remarks.

By N. R. Smith, Professor of Surgery in the University of Maryland.

Morbid State of the Spermatic Cord simulating Hernia.

IN June last I was requested to visit, in consultation with Drs. Warner and O'Donovan, Mr. —, a young man aged about twenty, living in Pennsylvania Avenue. I was informed by the attending gentlemen that for three days previous, he had been labouring under severe symptoms of enteritis, that had in no degree yielded to the active means which they had employed. Complete iliac passion had indeed taken place, the alvine evacuations having entirely ceased, and stercoraceous vomiting occurring at frequent intervals. The pulse was small and frequent; the extremities cold; the countenance hippocratic; the belly tumid, tense, and tender to the touch. The medical gentlemen in attendance informed me that within the last six hours they had discovered a swelling in the left inguinal region, apparently affecting the spermatic cord. All the symptoms of strangulated hernia being present, it of course immediately occurred to them that a concealed hernia had, previously existed, and that it had now become in a degree manifest by the increased tumefaction of the parts concerned. They regarded the case, however, as one of obscure and doubtful character, and such indeed I found it.

The scrotum was much enlarged, but this was manifestly an oedematous swelling. Extending from the internal ring along the course of the cord was an elongated swelling, of a firm, unyielding feel, and evidently issuing from the ring. It was sufficiently obvious that no intestine could be involved in the tumour, as the characteristic elasticity was entirely wanting. It was not so easy to determine, however, the part which the omentum bore in the case. We could not, it is true, distinguish the cord from the tumour, and we were perfectly aware that, after all, the enlargement might prove to be nothing more than one of the cords itself; but, supposing a semi-congenital sac to exist, it was manifest that a portion of omentum might have been thrust within the investing membranes of the cord, and become strangulated at the ring, or neck of the small sac. Certainly the existence of such a tumour, together with all the

symptoms of strangulated hernia, justified such a conclusion.

The patient was now so exceedingly low as to render an operation, under any circumstances, extremely doubtful in regard to its result. But as death appeared inevitable without our interference, we determined on the *remedium anceps*. We resolved to cut upon the cord, and at least to reveal the true character of the local disease.

In the presence of the attending gentlemen I executed the incision, and quickly exposed the cord. It immediately became apparent that the tumour resulted from an enlargement of the cord, caused by the infiltration of serum into the tissues which enveloped its vessels. It was manifest that the fluid had issued from the cavity of the abdomen, and percolated along the cord, even to the scrotum, giving rise to the oedema of that part. The envelopes of the cord not readily yielding to the distension, the tumour of this part became hard and cylindrical. As there evidently existed in this case a high degree of peritoneal inflammation, I inferred that effusion had taken place into the cells of the fascia propria exterior to the peritoneum. This fascia, it is hardly necessary to say, is continued along the cord, and becomes one of the proper coverings of that fasciculus of vessels and nerves, and therefore might easily convey the effused fluid from the cavity of the abdomen.

As soon as the condition of the cord was ascertained, I closed the wound, the patient having suffered but in a very slight degree from the incision. The case terminated fatally on the following night.

A post-mortem examination of the case was made by my friend, Dr. Warner, and the ordinary evidences of high enteric and peritoneal inflammation discovered.

I am at this moment in attendance on another case of peritoneal inflammation, occurring in a servant boy of my friend, Dr. Cockey. The disease was ushered in by pain in the right lumbar and iliac regions, accompanied with soft, puffy swelling above and within the spine of the ilium. This swelling, early in the attack, was elongated in the course of the cord; and the cord was the seat of considerable morbid sensibility. On one occasion the patient complained of agonizing pain in the testicle of the same side. The condition of the cord, and the presence of the swelling, immediately caused attention to be directed to the possibility of the existence of obscure ventral hernia; but a careful examination, and the history of the early progress of the case, showed clearly enough that nothing of the kind could exist.—*The North American Archives of Medical and Surgical Science*. Nov. 1834.

On the Diseases of the Natives resident on the Banks of the River Niger. By K. A. K. OLD-FIELD, F.R.G.S. Late Surgeon to the Niger Expedition, and Assistant-Surgeon to the Preston Dispensary.

THE diseases met with among the natives resident on the banks of the Niger, are numerous and severe; and from the circumstances of their not possessing any efficacious remedies, but relying principally on the virtues of charms, and drinking fetish water, great numbers annually die.

Commencing with the natives near the River Nunn, one of the numerous outlets of the majestic Niger, and the natives of the countries between there and Eboe, a distance of two hundred miles, we find the most prevalent diseases to be diarrhoea, dysentery, dracunculus, syphilis, continued and remittent fevers, rheumatism, lepra, elephantiasis, and kraw kraw (an inveterate form of tabies), the country is low and swampy, the banks covered with a profusion of shrubs and vines, the latter from seven to ten feet in height; the pernicious mangroves (*khiz of hera mangle*)* extend as high as the influence of the tide, between sixty and seventy miles; up to this distance not a bank or a piece of elevated ground is to be seen; the country is nothing but a perfect swamp, unfavourable to the existence of human life, even in a savage state; the soil then becomes alluvial; banks are met with from seven to ten feet high, which are lined with plantain tree (*Musa Paradisiaca*), the bannana tree (*Musa Sapientum*), the wild cotton tree (*Bomax Ceiba*), cocoa nut tree (*Cocos Nucifera*), sugar-cane (*Saccharum Officinavum*), palm tree (*Carica Papaya*), and a variety of indigenous grasses.

During the rainy season the banks of the river and surrounding country are frequently overflowed, the retreating waters leaving behind animal and vegetable substances in a state of decomposition, which become, under the influence of a tropical sun, but too prolific of disease and death.

The natives on the banks of the river, like the generality of men not far advanced in civilization, are of opinion that to live is to live for enjoyment alone; their nights are spent in dancing and drinking; most part of their day in sleep; they drink large quantities of spirit undiluted, which is brought to the coast of Africa in vessels trading for palm oil; the Spaniards introduce a large quantity of a very bad quality in exchange for slaves.

The natives, as far as Eboe, are notoriously filthy in their habits, which accounts for the numerous cases of scabies, and other cutaneous diseases constantly met with; their food consists of dried fish, goats and their entrails, dogs, monkeys, plantains, bannanas,

* They are never found out of salt water. —Humboldt.

capava (*jatropha janipha*), and palm oil; from the general aspect of the country, their irregularity in living, their excesses, their paucity of medicines, or the means of cure, it is not surprising to find that few of them attain old age; it was remarkable to observe so few aged men in the Eboe country, considering the vast population.

Their huts are constructed of bamboo (*Arundo Bambos*), and plastered over with mud and red clay; they sleep on mats upon the floor of the hut; no attention is paid to ventilation; the huts being without chimneys, the smoke escapes through the doorway, which, in a great measure, secures them from the annoying attacks of moschetoes.

The few following cases which came under my observation, will shew the native plan of treatment, which is combined with superstition:—

Deda, a pilot, a native of Braptown, a very intelligent black, and pilot to the river Nunn, about thirty years of age, had been labouring under phthisis for nearly three years; he was wasting away rapidly, and was in the habit of eating large quantities of capsicum baccatum (bird pepper), and using a shower-bath each morning in the following manner: one of his wives mounted on the stump of a tree five feet in height, and poured water out of a calabash upon him, repeating certain words as charms; this man died during my residence in the interior.

Lumbago is treated in the following singular manner: the patient lays himself flat upon his belly, when one of his companions jumps upon the lumbar region five or six times; this practice is repeated frequently during the day. I witnessed this novel treatment upon a black servant of mine, a native of Brass, who informed me it invariably produced a cure.

Dracunculus (or guinea worm) is much more common among the natives of the coast and the lower country, than in the interior; I have frequently met with it in the Kroumen, a useful class of men, who inhabit the Cape Palmas country; they are employed on board of English ships to procure wood and water, and perform the most laborious duties; and are rendered particularly liable to this disease. I had two cases on board the iron steamer, Alburkah; one worm which I have at present in my possession is upwards of thirty-two inches in length.

The symptoms commence with a violent itching in the part affected, heat, swelling, and inflammation; a vesicle forms, and in a few days the head of the worm protrudes; their mode of treatment is to draw the worm gently out, and secure the end round a piece of stick or lead, and gently withdraw a portion each day; this is perhaps the best mode of treatment, with the application of poultices.

At Eboe we find the country a little more elevated but still thickly wooded; the Eboes are a fine race of people, much more so than

their neighbours, occupying the towns lower down the river near the sea-side; they are tall and robust, capable of enduring great fatigue, frequently paddling large canoes for forty-eight hours without taking food. Their diet is superior to that of the natives lower down, consisting of bullocks of a small breed, fine goats, fowls, and an abundance of yams (*Dioscora Bulbifera*). In colour the Eboes are much lighter than their neighbours, many of them being of a light copper colour, their physiognomy is not very prepossessing, being that of the negro, with retreating forehead, flat nose, thick lips, &c. &c. At this place I met with two cases of elephantiasis in middle aged men; it is considered contagious by the natives; they possess no means of curing or alleviating this dreadful disease*.

The natives suffer from attacks of dysentery and intermittent fevers; the former is very prevalent; they have a great horror of this disease, as very few recover when once attacked. Anthrophagi are said to exist in the Eboe country, but I never met with authentic proofs, although from the general bad character of the Eboes we have no reason to doubt it. Syphilis is also very common among the natives, more especially those inhabiting the sea coast and lower country, from their intercourse with European seamen. At Brass town, I saw several cases in the worst forms, nodes, and loss of the soft palate of the mouth.

Leaving Eboe and proceeding to Iddah, 150 miles from the former, we find the country higher and less wooded; it assumes altogether a healthier aspect, the high grounds being cultivated with tobacco, rice, and yams. The domestic animals increase in size. Fowls, sheep, and bullocks are plentiful. The natives are well shaped, cleanly in their persons and habits, and industrious.

At Iddah, in addition to cases of febres and dysentery, I met with several cases of cataract, and two cases of lepra nigricans: the native plan of treatment in the latter disease, consists merely in washing the affected parts with river water. The unfortunate patient is taken to the river side, and the ulcerated surfaces are washed. Judging from their

* When I accompanied the late Mr. Richard Lander in an open boat, nearly four hundred miles up the Niger, I had occasion to go to the king at Eboe (Obie) at three o'clock in the morning; poor Lander was then labouring under a dreadful attack of dysentery, which nearly carried him off; this being known to Obie, he addressed me through an interpreter to the following effect: "you be ezofu (doctor) for my friend, he sick for belly, no good," shaking his head; "man sick for belly, he die; go for ship, no stay; suppose my friend die while you are here, it will be my fault, for detaining you, I kill him! go, go;" such is their dread of being belly-sick as they term it.

distressing cries, the application must be extremely painful: one of the cases above alluded to was a young female slave about eleven years of age; she was brought down to the river side for the purpose of being washed, morning and evening, for several months; her cries at these times were truly distressing: lepra is considered by the natives to be contagious, and so great is their horror of persons afflicted with this dreadful disease, that they are not allowed to mix in society, and too frequently are thrown into the river as a sacrifice to the river god. Such is their deplorable state of ignorance, that the weak with the sickly are thrown into the river to appease their offended deity.

In all diseases great power is shown by charms written by the Mallams or Mahomedan priests, consisting of extracts from the Koran, written on paper with ink made of burnt wood; the letters are washed off the paper into a calabash and drank by the patient; this is termed fetish water. As we advanced into the higher and mountainous country, as might be expected we met with fewer cases of febrile and dysentery, but as if a recompense for this diminution, ophthalmia and cataract prevailed to a fearful extent amongst those natives who inhabited the temporary huts built on sandbanks, on the falling of the river. The prevalence of these diseases arises most probably from the reflection of the rays of the sun from the sand.

At Egga I was applied to by hundreds suffering from cataract and ophthalmia; at Leyber, a small town at the foot of a mountain, forming one of that magnificent range named the Kong mountains. I was applied to by a young female, Oct. 22nd, the widow of a wealthy trader; she was suffering from inflammation of the cornea of the left eye, and inflammation of the coats of the right eye, accompanied with severe cephalalgia; the disease made its appearance five months prior to my seeing her; I expressed a wish to have her on board the ship for a short time, which was instantly complied with, so great was the confidence of these people in us. Their diet being simply yams and fish, only the higher orders being suffered to eat animal food, they do not bear much depletion; eight ounces of blood was taken from the arm; she was twice cupped at the back of the neck, blisters were applied to the back of each ear, and she was ordered to take the following pills. Pulv. Opii gr. iv. Hydrag. Submur. gr. xij. Confect. q. s. ft. pilulæ xij. Sumat j. tertiis horis; these pills were given until pyliasm was produced. This treatment proved very beneficial, the inflammation subsided, and in a short time she recovered the vision of the right eye, and the ulceration of the cornea was much diminished in size; after remaining until sufficiently recovered, she returned to her friends, bestowing (alburkahs), "blessings" for our kindness.

I am not aware that they use any remedial measures for the cure of ophthalmia; but judging from the numerous cases of blindness, I should suppose not.

For cephalalgia the natives scarify the temples with a large knife, and pinch the skin of the forehead with the fingers, each time cracking their fingers, as they state to extract or draw the pain away.

For some time I was of opinion that syphilis was principally confined to the sea coast, and the lower part of the river; but after a short residence in the countries of the interior, I met with several unfortunate creatures as bad as those I had seen at Brass.

The following case will shew the extent this disease attains when unchecked by art. Idiresa formerly King of the Nufic country, but at that time of only part of it, the rest of it being subject to the Felatahs, applied to me on board the Alburka at Egga, nearly six hundred miles up the Niger (the late Mr. Lander being the interpreter), and from his statement it was supposed to be a case of hæmorrhoids; but feeling dissatisfied and suspicious of the statement given, I requested an examination. His sable majesty attended on the following day for that purpose. I found it to be a case of syphilis of two years' standing, accompanied with secondary symptoms; he had a phagedenic ulcer of the penis, which was destroyed to the extent of two inches, surrounded with a large cauliflower excrescence; cicatrices in the groins from buboes, copper coloured eruptions, but in a much severer form than I had ever witnessed. Pains in the bones, deglutition difficult and painful, from two circular ulcers of the fauces, loss of appetite, restless nights, &c. He stated that one of his wives had communicated it to him two years before, and had died from its effects. Idiresa was a fine looking man about five feet nine inches in height, rather stout and marked with the small-pox; he wore a constant smile upon his countenance; his manners were mild and dignified, and very prepossessing. He was ordered to take the Compound Decoct. Sarsæ,* three times a day, pil. Plummer each night, and to use the black wash; he regularly sent for his medicines, during our stay in the country; I had not another opportunity of seeing him. A few months afterwards, during my stay at the confluence of the Ichadda, upwards of two hundred miles from his country, he sent a messenger, with a present of an elephant's tooth. He informed me that Idiresa was perfectly recovered, and regularly took horse exercise.

A slave of the principal Mallams came on board one morning having an encysted tumour on the os frontis, although he merely came on board like others from motives of

* I very fortunately had by me two bottles of Butler's of Liverpool's Essence of Sarsaparilla.

curiosity; he was asked if he would like to have it removed; he immediately consented, and with the assistance of my friend Lieut. Allen, it was removed without appearing to give much pain; the operation was viewed by the natives as something supernatural, and procured us an abundance of provisions, goats, &c.; and from the aged Mallam, the man's master, a remarkably fine carrier bullock.

During my stay here and in other parts of Africa (like Dr. Oudney) I was importuned for charms, medicines &c. possessing the power of removing sterility and barrenness.

The natives of the Nufic country attain a good old age; we met with several very aged people, said to be upwards of eighty years.

From Egga we got under weigh for Rabbah, and proceeded through the Nufic country, abounding in beautiful scenery, diversified with hill and dale, and anchored abreast of the city of Rabbah, in possession of the Felatahs, and tributary to the Sultan of Sockatoo; here we went ashore, to reside a short time, while the ship underwent repairs, &c. We engaged three horses belonging to the Sullikeen Doorkie (the master of the horse): the houses were built of mud, one story high, and very cool, situated in a large yard surrounded by a high mud wall. It is impossible to describe the scene at this place, the yard in a morning being filled with applicants; natives of different countries flocked for relief—Moors, Arabs, Mahomedans, Nufians, Yarribians, Timbuctoans, and natives of Housa—all sought us, to be relieved by our remedies.

The most prevalent diseases which came under my observation were large ulcers from the bites of moschetoës, diarrhœa, dysentery, variola, ophthalmia, and cataract; the farther we advanced into the interior, the more common we found cataract; at Rabbah I saw several hundred cases of double cataract: most of the natives were willing to undergo the operation; as we were not making a sufficient stay, it was not attempted. It was quite distressing to witness so many fine men and women totally blind, led into the yard daily; it is more common among males than females; the Arabs and merchants who cross the desert of Sahara are particularly liable to this disease; it is perhaps necessary to notice the practice of anointing the tarsi with sulphuret of antimony (toza), a custom which is supposed to beautify the countenance, and soften the appearance of the eye, prevalent among all classes, Pagans and Mahomedans, from infancy; may this be one cause? The period of our visit being in the rainy season, dysentery was very prevalent; the natives use large quantities of rice water, the astringent qualities of which appeared to give them great relief; the rice is of a superior kind, but badly cleaned, and forms the chief article of food in this part of the country.

I have before noticed the difference in the ages of the natives inhabiting the low and swampy country, and the fine open Nufic country; during our stay at this place (which is within a short distance of Borsa, where the unfortunate and intrepid Mungo Parke, surgeon, perished), Mallam Dando, formerly King of Rabbah, died; he was said to be one hundred and fifteen rivers old*; we had visited Mallam Dando a few days prior to his decease: he was a very old looking man, and very thin, with a long grey beard, and appeared to be in his second childhood; the natives imputed his death to my agency, by blowing magony (medicine) through the door of his house!!

I met with one case of phthisis in an Arab named Ali, one of the traders of Al Hadge Sali, the agent of the late Captain Clapperton at Kano. He had caught cold two years before, when on his journey across the desert of Sahara from Tripoli, with a large kofila†.

The natives of Rabbah and the neighbouring towns and villages high up the river, more especially where Mahomedanism prevails, are very cleanly in their habits, performing their ablutions twice a day; there were very few cases of cutaneous diseases among them.

The native women besmear their bodies with a red pigment made from red wood, brought from the Eboë country; it is supposed to possess tonic properties as well as to correct the fœtor of perspiration.‡

They attain puberty at eight and nine years of age; menstruation commences at this period; in several cases that came under my observation, the catameneia appeared every three weeks, from the seventeenth to the twenty first day, the females being in the enjoyment of perfect health. On my expressing my surprise to a very intelligent Fundah' woman, she assured me it was the usual time—that very few had them absent a moon (month); the quantity menstruated is small, and continues three or four days.§

* The Pagans calculate their hours by the position of the sun in the heavens, their months by moons, and their years by the annual rise of the river.

† A number of merchants with camels and merchandize.

‡ A full account of their manners and customs, with an account of the expedition will shortly be published.

§ Polygamy is carried to an incredible extent in western Africa. Lander has repeatedly informed me the number of the King of Boosa's wives exceed three thousand! It must be borne in mind, that the wives are the most extensive merchants or traders in the country, and therefore a source of profit. Vide the forthcoming Journal.

Parke correctly says, the negro women suckle their children until they are able to walk of themselves; three years' nursing is not uncommon, and during this period the husband devotes his whole attention to his other wives. To this practice it is owing, I presume, that the family of each wife is seldom very numerous.

Kraw kraw, is an inveterate form of psora; it was epidemic on board the the Quorra and Alburkah; the blacks suffered severely from it; the case of my esteemed friend Mr. Laird was very severe. After the decease of his valuable friend Dr. Buggs (in whose death science has suffered a great loss), and of nearly all the officers and men, he went to Fundah in a weak state of health, in appearance more like a walking skeleton than a living being.

While there he caught this distressing disease; he remained there more dead than alive for some time. Shortly after his return to the ship, I saw him; the disease had produced large ulcers all over the body, more particularly on the head, back, and left femur the latter being denuded to the extent of two inches; the irritation from these numerous sores occasioned great excitement. The vapour bath* and friction with the unguisulphuris relieved him wonderfully in a few days, the ulcerated parts being dressed with adhesive plaster.

Mr. Laird was one of the very few survivors of the expedition, (reduced, subsequently to four), who lived to return to his native country, which he reached twelve months prior to my arrival, and is, I am happy to state, at present in the enjoyment of perfect health.

SOCIETY FOR THE RELIEF OF THE
WIDOWS AND ORPHANS OF MEDICAL MEN.

ON Wednesday last there was a meeting of the Society for the Relief of the Widows and Orphans of Medical Men in London and its Vicinity. This Society was instituted in 1788, and has been much indebted to the patronage and assistance of the late Duke of York, and the Duke of Sussex. According

* I would strongly recommend the portable vapour bath to be taken on board every ship going to the coast of Africa, having experienced great benefit from it, and witnessed its good effects in many instances.

to its present regulations, the annual allowance to widows is 30*l.*, to which they are entitled if their yearly income do not exceed 50*l.* Children under the age of fourteen are allowed 10*l.* a year, from which an income not exceeding 12*l.* from other sources does not exclude them. When they have completed their fourteenth year, they may be further assisted by a contribution towards an apprentice fee. Orphans who have less than 25*l.* a year, and also the mothers and sisters of deceased members, can claim the assistance of the Society. The annual subscription is only two guineas; yet it is truly extraordinary, as observed by Sir James Macgregor, who presided at the last meeting, that not one fourth of the medical practitioners in London are members of this most excellent association!

The poverty of the medical profession is proverbial, and it is impossible to contemplate, without emotion, the life of care and anxiety which is entailed on too many of its most meritorious members, by the inadequacy of their pecuniary means to meet expenses which the present state of society in this country obliges them to incur; but it is still more melancholy to witness the state of destitution in which their families are often left by their death: ladies of cultivated minds and refined manners are suddenly immersed in the most abject and hopeless poverty, and reduced to beg, for themselves and their children, that aid which the members of the profession on which they have most claim, are generally in no condition to afford them. And what are the causes of this miserable state of things? They are manifold. Bad legislation is one of them. Know ye aught of the matter, men of Lincoln's Inn? Have ye not monopolised for yourselves, and your creatures, the means by which youthful talent may make itself known to the world? Have ye not turned the medical charities of this metropolis into

nests for your own cupidity to fatten in? Have ye not refused to interfere in behalf of the College whose ostensible heads ye are, to obtain for its members an equitable remuneration for their toil; and have ye not connived at, nay assisted, the sneaking artifices of the Rhabarbarians to soil the whole profession with their filthy jalap, and to leave the general practitioner no alternative but the pestle or starvation? Verily ye have done all this; and what is the result? The general practitioner, shut out from all professional means of advancement, is forced to seek his subsistence by trade, and the hybrid character thus thrust upon him acts doubly to his prejudice: considered as a tradesman, he is prevented from seizing his advantage, or enforcing his claim, by the "liberality" of his *profession*; considered as a professional man, he is lowered in the public estimation by his connexion with *trade*; so that he is left to choose between the benefits of a sordid reputation, and those of an empty purse; it would puzzle the arch fiend himself to invent a more vexatious dilemma than that in which the treachery of the men of Lincoln's Inn has placed their well-beloved brethren!

Another way in which bad legislation impoverishes the profession, is by allowing quacks and impostors to trespass with impunity on the field of medical practice; on this subject, however, we have so lately delivered our opinion, that there is no necessity for enlarging upon it here.

Independently of bad legislation, a fertile source of wretchedness to the profession is to be found in the prevailing sin, and the prevailing curse of this country—the lowest of low passions, the love of ostentation. In France, a medical man, if he be poor, may live according to his means, without forfeiting the respect of his fellow men; he may live in a garret, if he likes, till the exercise of his talents enables him to enter a better domicile; but in this land of free bodies and enslaved minds, the young

medical practitioner is absolutely compelled to incur an expenditure which he knows not how to meet; he must act the part of a knave as well as a fool, if he would not experience the contempt of many, and the neglect of all. Unfortunately this evil bears on men of other vocations besides our own, though certainly not so heavily: it is a universal and most pernicious humbug, pervading every class in England, from the highest to the lowest, and may happen, one day, to go down with a crash that will shake society to its foundations.

Such are the chief causes of the poverty under which so many of our brethren are at this moment labouring. These causes will not endure for ever; the ground is even now crumbling under the feet of the medical oligarchs, and the spirit of ostentation will fade before the progress of civilization, and the dictates of necessity; but in the meanwhile, hundreds of respectable families are rendered miserable by their influence, and whatever tends to circumscribe their effects, ought to meet with the cordial co-operation of the profession. Not only ought the society to which we have alluded to be generally supported by the medical practitioners of the metropolis, but efforts should be made to extend the benefits of this, or similar associations, to every part of the kingdom. Our profession has yet to learn the great truth, "that self-love and social are the same;" its recognition would give birth to a thousand noble and useful institutions.

THE LONDON UNIVERSITY—SLIMINGS OF THE LIZARD.

THE Green Lizard has sent forth some more slime against the London University, and has seasoned its ordinary vapiditv with a great deal of course personality against Mr. Tooke. If it were not that Mr. Tooke is a gentleman of established character, we should suppose that he had paid the reptile for abusing him, since, to incur the censure

of our high-minded contemporary is in itself an indirect testimonial of respectability: when we were in a less palmy state than we now are, we had ourselves some thoughts of hiring the Lizard to vilify us. We will not at present enter into the history of the University, which is abundantly familiar to everybody, and with the oft-repeated details of which the Lizard is everlastingly boring its readers, or rather load its pages—for its readers, we believe, are now reduced to ninety or a hundred superannuated practitioners, too stupid to be bored with anything. The true cause of our contemporary's hatred to the University is to be found in the following singular facts.

A temple has lately been reared at Hyde Park corner, to a medical deity, of whom all we know with any certainty is that he is neither Apollo, Hermes, Trismegistus, nor Æsculapius. This new divinity has, like Caligula, become high priest to himself; he is not, however, a Roman, but an Egyptian god, as sufficiently manifested by his love of darkness and mystery. Our green contemporary has managed, by a judicious mixture of bullying and cringing, to get itself installed as chief of the sacred crocodiles in the temple; and a great shame it is that a puny little reptile like itself, which has not the smallest pretensions to rank with real, proper crocodiles, should be thus favoured, when so many good lusty saurians are floundering about and weeping because they cannot get admitted in any capacity. Now, the aversion of our contemporary to the London University arises from his perceiving, pretty clearly, that it is one of those centres from which the light of intelligence will soon spread far and wide, penetrating the gloom of Egyptian temples, disconcerting the complacency of self-constituted divinities, and blazing in the small dim eyes of favourite reptiles till they are feign to hide themselves from the face of day for ever more.

The Lizard may slime as much as it likes, but the London University will yet obtain a charter; it will become the means of conferring incalculable advantages on the youth of England; it will stand and flourish when Oxford and Cambridge are in the dust; and for aught we know, the carcase of the Green Lizard may some day or other be stuck up

in its museum, to show what "delicate monsters" the world has produced!

—o—

ELECTION OF RESIDENT MEDICAL
OFFICER TO CHRIST'S HOSPITAL.

THE election for resident medical officer to that munificent institution, Christ's Hospital, is to take place on Friday, the 23rd inst. on which day we conjure the governors to discharge their duty conscientiously, by selecting the best qualified candidate for the appointment. The office of resident surgeon to Christ's Hospital is one of great responsibility; as to him is intrusted the health of the sons of our once opulent fellow-citizens, who have hitherto been sadly neglected, and most of them allowed to become sufferers from scalled head, a disease which has prevailed in the noble institution just mentioned a great many years past.

It appears from incontrovertible evidence, that the children, for several years, admitted into the branch establishment at Hertford, have been infected with the disease called ring-worm, from those who have been received before them. The evil resulting from this is, that their education has been impeded and rendered imperfect, as the contaminated have been, and are separated from the school, and subjected to some kind of medical treatment, which has never been sufficient to eradicate the malady.

The governors are now to choose a surgeon, and they are to elect the most experienced in the treatment of ring-worm, which has long marred the benefits of one of our best institutions; and they are morally bound to select the individual, whoever he may be, who can produce the best and most ample evidence of his skill in curing that disease. Were it in our power to address each governor individually, and say to him, "Sir, your duty to society is to vote for the candidate best qualified by long and careful observation, and successful treatment of scalled head," such elector would feel offended at our appeal to his humanity: though we grieve to indite it, there are some of the governors supporting persons whose names are unknown to the medical public in this capacity—we understand, some of whom are still in, and others have just emerged from

their pupillage!!! On looking over the list of candidates, there is not one of them, except Mr. Plumbe, who has ever distinguished himself in treating or describing diseases of the skin; and we beg to inquire, what claims or pretensions have they to the office of resident surgeon to a large establishment, in which cutaneous diseases predominate.

We reply, none whatever; and certain are we, that if the election rested with our profession, not one of them could have the slightest chance of success. We therefore contend that the governors of Christ's Hospital will, in our opinion, be guilty of a gross dereliction of duty, if they do not elect the gentleman who has devoted most years to the study and treatment of cutaneous diseases, one of the best living writers on the subject, and the best author on the identical disease which has so wrongly deteriorated the good of the institution in question. Plumbe's works on diseases of the skin, and on porrigo are known throughout the civilized world; and we boldly inquire, is their author to be passed over, and some inexperienced person elected in preference, by the governors of Christ's Hospital? Impossible! They will, we are certain, adopt the axiom "*detur digniori*," elect the more worthy, and never have it recorded, in 1835, that they, as the aldermen of London, would be capable of jobbing so important an appointment as that under consideration, and deprive the unfortunate children of their fellow citizens, placed by adversity under their care, of the best medical advice that can be procured.

In making these remarks, we need scarcely observe to our readers, or the medical profession, that we act as we have hitherto done, and ever shall do, on the principle that our hospitals and all charitable institutions ought to have the best medical aid that the country affords, and that medical appointments ought not to be filled through the corrupt source of private interest, family, and other connexions, open bribery by vote making, or the many other unworthy means of the grossest jobbing, to the incalculable injury of the children of poverty and misfortune. Our readers also know, from a careful observance of our principles for some years, that we have never allowed

any thing to influence our honest opinion of individuals or public institutions; and we make this observation lest it might be supposed that we would favour Mr. Plumbe, more than any one equally well qualified. We need not state that we should as readily advocate the claims of any one of the candidates, or of any member of our profession, whom we conscientiously believed to be most worthy of election, and most certain of improving and preserving the health of the children, and promoting the truly benevolent views of the founders of Christ's Hospital.

The following facts must convince every honest and really humane governor, of the superior claims of Mr. Plumbe, to those of the other candidates for the vacant office.

"Sir—I take the liberty of earnestly requesting your attention to the matter of the following petition, and to the testimonials I have deposited at the counting-house of Christ's Hospital. I am unassisted, to the best of my belief, by any private influence whatever, and therefore throw myself on the unbiassed opinions of the governors at large.

"I, am, Sir,

"Very respectfully and obediently, yours,
"S. PLUMBE.

"N.B. The election takes place October 23rd, 1835, at Christ's Hospital.

"To the right worshipful the president, the worshipful the treasurer, and governors of Christ's Hospital,

"The petition of Samuel Plumbe, Surgeon, of Southampton-street, Bloomsbury, to be appointed resident medical attendant of the hospital;

"Sheweth—That your petitioner was applied to in or about the month of June, 1834, by a special committee of governors, through their chairman; the object of which committee was to inquire into 'the efficiency of the medical establishment generally, and particularly as to the cause of the prevalence of ring-worm among the children;' and that that committee sought your petitioner's assistance and advice, although every member of it was utter strangers to him; and that he, your petitioner, declined and refused to give his assistance or opinion except in conjunction with the medical officers of the institution, and only consented to do so at last, because an opportunity for consultation did not occur.

"That your petitioner, having been thus led to interest himself in the health of the children, without the advantages of consultations with their usual medical attendants, recommended to the said committee a free allowance of vegetables to the children at each establishment, and that his recommen-

dation, handed by him to the said committee, was forwarded to the general court of governors, and by them acted on without delay; and your petitioner is confident that the health of the children in consequence has been materially improved.

"That your petitioner, having for many years assiduously studied 'the nature and treatment of DISEASES OF THE SKIN AND SCALP, because he found them, on entering on the practice of his profession, the least known of all diseases, owes, as he believes, to the reputation he has thus attained, the application of the committee alluded to for his assistance. He is the more sanguine in his hope that this is the fact, because he was flattered ten years ago by the award of the Jacksonian prize of the Royal College of Surgeons on this subject, and because his work, an octavo volume of 500 pages, has gone through three editions, with the general approbation of the medical profession.

"That your petitioner's claims on your consideration do not rest solely on the above-mentioned works, but that on the contrary he is able to prove to you, that he has given vast time and attention to the merits and demerits of vaccination, by laying before you a work, in the execution of which he has incurred much labour, and great expense.

"That he held the office, for several years, of senior surgeon to the Royal Metropolitan Infirmary for children, in which the cases of several thousands of children were brought under his care from year to year; and that for ten years he discharged the whole duties of surgeon and medical superintendent of the parochial infirmary of St. Giles in the Fields and St. George Bloomsbury, to the entire satisfaction of the vestry; and that in this latter institution there were seldom less than one thousand persons, many of them diseased, few in perfect health.

"Your petitioner respectfully solicits the attention of your honourable court to the above facts; and in justice to himself, and for the better information of your honourable court, he disclaims being a party to, or having a foreknowledge of, any publications in any way relating to Christ's Hospital, except such as have his name affixed, and in none of which has he ever used disrespectful language towards any member of that court, but in all has confined himself to the temperate advocacy, as a member of the medical profession, of his conscientious opinions, having no object in view except such as is common to every individual governor, namely, the good of the institution.

"That your petitioner finds himself labouring under great disadvantages on account of his confidence in the effect of his testimonials. Having passed his fortieth year, and with some claims to reputation in his profession, it appeared to him that the testimonials of teachers in different schools, (*always attainable, as a matter of*

course, by their pupils, where common industry only had been evinced) were not necessary, but that your honourable court would regard such as he laid before it, inasmuch as they proved his possession of the advantages of lengthened experience in all kinds of diseases, and his claims to the merit of improving the knowledge of that class, the prevalence of which has so much impeded the primary and vital objects of the institution, would have obtained for him higher consideration; and he was the more confirmed in that opinion, on seeing that, of the number of the certifiers themselves, few were his seniors in the profession, many his contemporaries as students, and many his juniors: there are several, he also perceives, whose names are almost unknown in medical science, and he is apprehensive that such testimonials may be considered by a few governors as deserving more influence, and to be of more value than the evidence of hard-earned reputation.

"Your petitioner further most respectfully (and disclaiming all intention to give to any personal offence), submits to your honourable court the indisputable fact, that two gentlemen whose signatures are affixed to a large number of the testimonials of his opposing candidates, were themselves his opponents in opinion, when his services were required for the hospital last year—that *their opinions were not acted on*, and that his, your petitioner's were.

"Your petitioner, in deference to the opinion of the governors, submits the following fragment, almost the last remaining, of his early testimonials!—

"I hereby certify, that Mr. Samuel Plumbe has attended my lectures, at St. Thomas's Hospital, and my practice at Guy's, for the last two years, with the utmost possible diligence and attention, and that he is highly entitled by his talents, and attainments, to the appointment he solicits.

"ASTLEY COOPER.

Guy's Hospital, 1826.

"Your petitioner begs to state, that the appointment to which the above certificate refers, was that of surgeon of a ship in the Honourable East India Company's service, the owner of which was J. W. Buckle, Esq. a member of your honourable court, whose good opinion your petitioner still retains, and of whose support at the forthcoming election he is fully assured.

"And your petitioner, as in duty bound, will ever pray, &c.

"Dated October 14th. 1835."

"P.S.—Since the above has been penned, the writer has obtained the best authority for stating, that the committee, as regards the selection of any individual candidate, was 'not a unanimous, but a divided committee,' each governor being thus called on to exercise *his own judgment* and discrimination. The writer therefore submits the foregoing facts, with renewed confidence. Aware, to

a great extent, of the participation on the part of many governors, in sentiments which have appeared in print, to the effect that the power of extermination of the contagious diseases alluded to, and the *accomplishment* of that object, ought to be the chief tenure by which your medical attendant should hold his office, he fearlessly and faithfully repeats the pledge he has before given. Advisedly and deliberately, with a professional reputation to lose, and a young and increasing family to support, dependent, in a great degree, on that reputation, he again declares, that at the expiration of one year, if the ringworm or other contagious disease remain, to the detriment of the children's education, he will resign his office, without waiting to be called on, into the hands of the governors, that they may avail themselves of such other assistance as they may think desirable."

We cannot entertain the idea that the governors, after this pledge, will fail to do their duty. Promises made under false representations, or in ignorance of merit, are not to be kept. Christian charity requires that every one of them should do his duty. Eight hundred friendless orphans look to them for health, as well as education and support; and the public demands justice at their hands. It will afford us sincere pleasure to put on record, for the information of our European and American contemporaries, that there is at least one of our hospitals in which merit is rewarded, and is preferred to incompetency, though fostered by private influence, family and other connexions; and and that the guardians of our public charities have at length adopted the just maxim—*"Palnam qui meruit, ferat."*

Hospital Reports.

—

WESTMINSTER HOSPITAL.

—

Stricture of Urethra—Calculus.

WILLIAM UNDERHILL, aged seventeen, was admitted April 29th, into Northumberland Ward, under the care of Mr. Guthrie. He is of a delicate complexion, and ruddy, a butcher by employment.

Four or five months ago, he first experienced a difficulty in making water, which now and then amounted almost to retention, and which gradually increased; at the same time he noticed a pain in the glans penis. He applied to Mr. Houlton for relief, who passed instruments, which he says did him great good. He states, that when the instrument was used, it could be distinguished passing over an obstruction, "when it got just above the testicles." Having left town,

he applied to a gentleman in the neighbourhood, who endeavoured to pass both catheters and bougies, but without success. On the occasion of the last attempt, a good deal of bleeding was occasioned, which in the afternoon was followed by the discharge of a "bloody matter," and which, from the boy's description, would appear to have been a mixture of blood and pus. This took place a week before his admission.

No adequate cause can be discovered for the production of the impediment in the urethra. He denies ever having had gonorrhœa or any syphilitic affection. Four years ago he fell across the side of a cart, and cut the glans penis and prepuce, the cicatrix of which now remains; but it does not appear that this has any connexion with the present symptoms. He has frequently hurt the perineum and penis by falls on the pommel of the saddle, &c., in riding, after which he has sometimes noticed small swellings in this situation, but he does not recollect there being one when he had the last catheter passed. His general health and appetite are good.

At the time of his admission, a catheter was passed, and the bladder evacuated, though not without some difficulty, from the obstruction in the urethra, as well as from its extreme irritability. His bowels being in a costive state, he has been directed to take a dose of the house medicine.

13th.—He has had at times great pain in the glans penis, and along its under surface, so as frequently to disturb his night's rest. The urethra is in so irritable a state, as hitherto to have altogether precluded the employment of any instrument to examine that canal, or to sound the bladder.

Rx. Ext. hyoscin. gr. xxxj;

Liq. potassæ. 5j;

Mist. camphoræ. ʒ viii, m. c. c. ji. t. d.

June 25.—Since the last report, he has, on the whole, continued much the same, until within a few days, since which he has obviously been worse. Several attempts have been made at introducing instruments, without success, except on one occasion, when a false passage was discovered in the membranous part of the urethra; the instrument being readily distinguishable in this situation, by the finger passed into the rectum. A mixture of pus and urine escaped through the catheter when it had reached this point. It seems that ever since his admission, he has passed a little blood mixed with his urine; but the most severe pain which he experiences, is in expelling the last drops; and that after this he has for a time comparative ease. During the last two or three days, however, he has almost constantly complained of excessive pain in the glans penis, and in its under surface, which is much aggravated by an extended state of the body, as in the erect or recumbent positions. A posture which he frequently assumes; is hence that on his knees

bending over a vessel, into which he passes, guttatum, a little bloody urine.

July 18th. Mr. Thomson endeavoured to day to pass a catheter, but without success, so irritable was the urethra; a warm bath was ordered him, which gave him some relief.

2nd. Considerable constitutional disturbance, indicated by the state of tongue and pulse, and the appearance of the countenance, has set in. Another bath was directed, and the following pills:

R. Ext. hyosciam. ʒj;

Saponis duri ʒij;

Sodæ carbonatis, ʒj. m.

Ft. pill. xxiv. Capt. iij. ter die.

4th. The distressing pain of which he complained so much, has been a good deal relieved since he has been employing the bath and taking the pills; he has, however, a good deal of it during the night.

11th. He passes his urine in a freer stream, and the pain, which remains in the same situation, rather to the right side of the under surface of the penis, is likewise less severe. The urine now dribbles away constantly.

Ft. pill. o. n. sumend.

28th. Mr. Guthrie to-day, with a good deal of difficulty, passed a catheter into the bladder, considerable obstruction having to be overcome, from a thickening of the under surface of the urethra, just within the scrotum. From this examination, Mr. Guthrie stated, that the opening of the false passage in the urethra, exists just in front of the triangular ligament, from which point it runs for some distance along the right side of the urethra. Upon the instrument entering the bladder, a little bloody urine was evacuated.

August 4th. Mr. Guthrie again passed the catheter, and evacuated a few drops of urine from the bladder. A shock was felt, as from a small calculus, on the instrument gaining the neck of the bladder. The boy looks better, and states himself to feel so to-day.

14th. General health and appearance improved, but he complains of pain in the region of the bladder, and tenderness, aggravated by passing his motions, &c.

28th. A small quantity of sabulous matter was passed, of a "soft and pasty character, and probably consisting of the double phosphate of magnesia and ammonia." The urine was also bloody.

29th. Goes on much the same. The urine continues bloody, and presents usually a deposit of pus, as well as of the amorphous calculus matter.

Omitt. pilul. alkal. n.

R. Ext. hyosciami, gr. iij;

Ft. pil. ter die, sumend.

September 1st. Leaves the hospital to-morrow, intending to return in a few weeks, after he has had a little change of air.

Serere Case of "Pott's Fracture;" Recovery without Anchylosis.

John Harper, aged forty-five, was admitted June 6, into Northumberland Ward, under the care of Mr. Lynn. He had been driving a phaeton to the coachmakers, and the horses taking fright and running away, he jumped out of the vehicle, and alighted on the inside of the right ankle, the foot being completely everted. In this way the fibula was broken, and the foot completely dislocated outwards, constituting the case generally known under the name of Pott's, but in addition, the inner malleolus was likewise fractured. There was not, however, notwithstanding the severity and extent of the injury, any wound of the integuments. Very extensive inflammation and tumefaction supervened, which precluded the employment of means for the reduction of the fracture. The treatment was hence restricted to the use of ordinary antiphlogistic means.

10th. Ten leeches were applied, which were useful in reducing the inflammation.

14th. To day Mr. Lynn reduced the fracture and dislocation, and placed the leg in the extended position, supported with "junks" on either side. In effecting the reduction, he noticed that the portion of tibia was quite separated from the body of that bone, and he afterwards expressed some doubts as to its perfect co-aptation.

16th. The inflamed and ecchymosed integuments over the inner malleolus, has become the seat of a sloughing sore, from which there is a discharge of nasty matter; the sore has a livid circumference, and there is a good deal of erythema proceeding up the leg. The piece of loose bone is felt immediately under the skin. There is a good deal of feverish irritability; the countenance is sunken and anxious.

R. Mist. diaphoret. ʒ viij;

Capt. ʒ j. ter in die.

It was agitated whether the better practice would not be to amputate at once, considering the peculiar difficulties of the case, especially as the habit of the patient was far from strong. Mr. Hale Thomson supported the affirmative of this question, but Mr. Lynn decided upon waiting the result of a few days.

18th. The patient is much the same, and the sore presents a similar appearance.

R. Ammonia carbon. ʒ ss;

Liq. ammonia acet. ʒ iss;

Mist. camphoræ ʒ viiss. M.

Capt. cochl. ij ter die.

Let him also have beef tea of double strength, and an egg, in addition to the usual low diet.

20th. Pulse 96, soft; the countenance is less sunken and anxious, and he eats his chop with a relish. The slough has separated, and

the bone is found very loose below, and will evidently be soon cast off. Mr. White, Mr. Lynn, and Mr. Thomson consulted on the case, when the former expressed his opinion, that at present there was nothing sufficiently urgent in the symptoms to warrant amputation, and he expressed the sentiment that it was more than possible that the leg might be preserved for the patient.

23rd. Pulse 100, feeble; countenance less anxious and sunken; tongue covered with a thick white fur; appetite pretty good. The bone has not yet separated, but is very loose, being only covered by sloughy ligaments.

Cont. medicamenta.

25th. Seems improved as respects the general health; countenance is less sunken; pulse 112 and full.

27th. Appetite improves. Let him have two mutton chops and four ounces of brandy daily.

29th. Not so well; an unhealthy looking, erythematous inflammation has set in in the skin around the sore, which has a livid character, and is creeping up the leg. There is a good deal of puffiness and pain about the ankle joint, and the sore has a very unhealthy appearance, being a fungous-like mass, protruding through the skin, and secreting a good deal of sanious-like pus, which has a most offensive smell. The countenance has a more anxious character; pulse 100, sharp and thready; has been sick after taking the mixture.

July 2nd. The cutaneous inflammation has a good deal subsided, except about the joint, where there is much swelling and redness; the discharge from the sore has less of a sanious character. General health appears somewhat improved; appetite is better.

4th. The inflammation, which was first observed around the ankle on the 29th ult., has terminated in suppuration. An incision was made above the joint between the tibia and fibula, which gave exit to a quantity of grey ichorous-like matter, which had been burrowing in the inter-muscular cellular tissue of the front of the leg. Another incision was also made over the outer malleolus, some suppuration having likewise occurred in that situation. The large fungous sore, in the situation of the broken malleolus, which it surrounds, continues in much the same state. The man continues much better than could have been expected from the severe and extensive nature of the local mischief; he is looking even better; his appetite is good; tongue clean; pulse 96, pretty full.

9th. The sore discharges a less ichorous and much more healthy pus; some inflammation is still going on in the front of the leg; but he is much better, as far as the countenance and appetite indicate.

11th. To day Mr. Lynn removed the dead piece of bone, by dividing some of the ligamentous fibres which connected it to the shaft of the tibia, and which had not sloughed. It

was found to consist of the whole of the malleolus, with the greater part of the articulating surface of the tibia, obliquely fractured. The operation gave him a great deal of pain, to the irritation of which he appears morbidly sensible. The inflammation about the leg is a good deal subdued, and the matter discharged assumes a more healthy appearance, becoming, at the same time, less abundant. Pulse 96, rather feeble.

14th. Not so well. On the evening of the 12th he began to have feverish symptoms, and since that time he has been very poorly; he lost his appetite, the tongue became furred and tremulous, and pulse small and frequent. At the present time he has great thirst, pulse is 144, feeble; bowels are open. The leg looks very irritable; a large fungus-like sore projects at the inner ankle, covered with large pallid unhealthy-looking granulations, and having in its centre some sloughy ligaments. There is a deep red erythematous-like blush, extending up the leg, two thirds of the way to the knee. Upon pressing in the inter-osseous space, on the front of the leg, a quantity of matter escapes from the opening over the ankle.

15th. Seems somewhat better to day. The countenance is less anxious and sunken. He is taking a mixture of tartarized antimony and liquor opii sedativus.

17th. There was more tumefaction and inflammation of the leg yesterday; but it has subsided a good deal to day, leaving, however, an abundant discharge of healthy-looking pus, from the anterior opening. There is a hectic flush on the cheeks; appetite has been very indifferent since the removal of the bone, but is somewhat improved. Takes four ounces of brandy, and the like quantity of port wine daily.

18th. Several superficial absorbent vessels are seen passing up from the leg along the front of the thigh, in the form of delicate red streaks, and terminating in the superficial lymphatic glands of the groin, some of which may be felt enlarged and rather painful. In other respects the leg is much the same. Pulse 120, feeble.

20th. The absorbents are less inflamed than they were yesterday, and there is less swelling and inflammation in the leg. His general health is also somewhat improved; pulse 120, stronger and fuller than at last report; bowels confined.

R. Olei ricini ℥ ss;

Tinct. cardam. comp. ℥ iij;

Ft. haust. c. m. p. s.

21st. The oil has operated two or three times, and the patient seems relieved by it; appetite is better. Mr. Lynn made a small opening into a collection of matter, which has formed on the front of the leg, and evacuated a quantity of pus.

23rd. A good deal better to day.

28th. The discharge has almost ceased from the inter-osseous space, and that from the outer

side of the ankle joint has improved much in quality. The entire leg appears to be going on very well, and is likely to terminate favourably, with the exception of a little deformity at the ankle joint, the relation of the tibia to the astragalus being somewhat too internal. The patient's general health improves rapidly.

30th. The extensive breach of surface over the inner ankle is granulating and healing in a very favourable manner.

Aug. 1st. The general health continues to improve. The local mischief is likewise becoming repaired.

4th. The leg has been to day put up in splints, and the patient states that he feels comfortable.

6th. Goes on very well. General health in a fair way to be perfectly re-established. He has extra bread, and half a pint of porter daily, in addition to his wine and brandy.

Sept. 1st. During the last fortnight the leg has been out of splints, and he has merely had a roller applied. The various sinuses and sores about the ankle are now quickly healing; all tumefaction has now nearly disappeared; and there does not appear so much deformity in the leg as might have reasonably been anticipated, and was at one time threatened. The general health is now pretty good.

22nd. Made an out-patient to day. There is very little deformity about the ankle, excepting only a little tumefaction; no anchylosis has taken place, and he hobbles about with the assistance of crutches. His general health appears quite established.

—o—

NORTH LONDON HOSPITAL.

Lithotomy.

MR. LISTON performed this operation last week, on an old man, aged 80. He had suffered from stone in the bladder for fifteen years. He has experienced great pain in the region of the bladder, and has not been able to retain his urine, which constantly keeps dribbling away from him. The curved staff was introduced, and a stone of supposed large size detected. The operation was performed in the usual manner; there were some difficulties in the case, however, worthy of notice. On the introduction of the forceps, the operator had some difficulty in grasping the stone, which, when he succeeded in doing, broke to pieces in the blades of the instrument; he succeeded, however, in removing the various portions of the stone in a few seconds; the searcher now evidenced the existence of another stone of larger dimensions than the first; this constantly eluded the grasp of both the short and long forceps, but a hold being obtained by the last instrument, it was found, on attempting to withdraw the stone, that the incision was not large enough for

that purpose; the knife was now introduced, and the right side of the prostate divided; the stone was then removed without difficulty.

Previous to operating, Mr. Liston observed, that though this case was unfavourable in some respects, from the extreme age of the patient, and the considerable size of the stone or stones, yet he was induced to operate, from the circumstance of almost all the very old men whom he had cut for stone, having made very good recoveries. Mr. L. said, after the operation, that the difficulties of the case were owing to the patient not having been able to retain his urine; he therefore felt great difficulty in seizing and disentangling the last stone from the fundus of the bladder. There were however no parts cut more than was necessary, and the loss of blood was very small, being scarcely more than two ounces.

The stones were of the lithic acid formation, with an outer coating of triple phosphate; the first about $1\frac{1}{2}$ inches long, $\frac{1}{2}$ broad, the second about 2 inches long, and 1 broad.

Oct. 12. Doing well.

The excellent arrangements in the way of clinical instruction, the regular attendance of the medical officers, and the lowness of fees, make this hospital a most advantageous one to the student. Both physicians and surgeons are indefatigable in their endeavours to assist the pupils.

—o—

ST. GEORGE'S HOSPITAL.

Colica Pictorum.

W. FAREBROTHER, aged 30, was admitted under the care of Dr. Seymour, August 19th ult. He complained of severe pain in the abdomen, constipation, loss of appetite, and furred tongue.

R. Hydrag. subm. gr. iij;

Opii pulveris gr. ss.

Fiat pulvis singula nocte sumendus, et cras mame ol. ricini.

Utatur balneo tepido omni nocte, et enemate communi.

Foveatur abdomen.

He continued these remedies until Sept. 3rd, when he complained of giddiness and indistinctness of vision.

C. C. ad $\frac{3}{4}$ xij.

6th. Pain in the head diminished, bowels open.

Habeat haust. salin. efferv.

8th. Headache relieved, tongue still white, countenance improved.

23rd. Dismissed cured.

Chronic Rheumatism.

Mary Bradford, aged 26, was admitted under the care of Dr. M. Leod, Sep. 2, 1835. She stated that she had suffered from rheumatism for the last twelve months.

She now complains of slight swelling in the knees and ankles, slight cough, general health impaired, pulse weak, and appetite bad.

Rx. Haust. cinchonæ, \bar{z} iss ;
Tincturæ guiaci, \bar{z} j ;
Fiat haustus ter. in die sumendus.
Habeat ext. conii, gr. vi. om. n. h. s.

Let her have ordinary diet.

She continued these remedies until the 19th, when she was much better; but she now complains of pain in the right arm and shoulder.

Rx. Tinct. guiaci ammon., \bar{z} ij ;
Aquæ \bar{z} iss.

Lit haustus ter. quotidie capiendus.

Sumat pulv. ipecac. comp. $\bar{\text{D}}$ ss. o. n. h. s.

Omitantur alia.

She continued this remedy until the 25th, when a blister was applied. She now complained of a glandular swelling under the left lower jaw, to which six leeches were applied. In a few days more she was free from rheumatism.

Diabetes.

James Birch, æt. 55, was admitted August 19th, under the charge of Dr. Seymour. He states that about nine months ago he observed his urine increase in quantity, and it at present amounts to nine pints during the night. Previous to his attack he was subject to perspiration of the feet, which ceased, when his present complaint commenced. He suffered from severe pain in the loins, extending along the ureters, and to the glans penis. He was ordered aperient medicine.

24th. Ammon. hydrosulphuret. mv ;
Aquæ fontis, \bar{z} iss ;
Sit haustus ter. de die sumendus ;
Habeat opii, gr. j m. vespereque.

Extra diet without vegetables or beer; milk for breakfast and supper.

26th. Urine diminished, two pints in the twenty-four hours.

Sep. 4th. States that he weighed 17 stone a year ago, and at present only 10 stone 2 lbs.

He continued his medicines until the 14th, when his urine had diminished 6 pints in the day. From that time to the present the quantity of urine has scarcely varied, and the only addition made to the treatment was the use of the vapour bath. He wished to leave the hospital, and confessed himself grateful for the relief afforded him.

—o—

Inerate Syphilis treated with Phosphoric Acid—By Dr. HEINECKEN.—An individual had been affected with syphilis a year or eighteen months, and had, without success, submitted to the employment of various remedies. His disease, at this time, consisted of ulcers in the neck, exostosis of the cranium, and over one orbit, tumefaction and pain of

the nose, accompanied with the discharge of an acrid bloody ichor, and pain of the antrum highmorianum. He had also a kind of herpetic exudation from nearly the whole surface of the body, and extreme pain of his bones and eyes, at night, which rendered it almost impossible for him to move. Under these circumstances, Dr. Heinecken prescribed phosphoric acid in as large doses as the stomach could bear, together with a strong decoction of the solanum dulcamara. The continuous employment of these means, brought about a complete and permanent cure of the disease.—*From Pierré's Allg. Med. Zeitung.*

—o—

CHAIR OF BARON DUPUYTREN.

SINCE the death of Baron Dupuytren, the chair of this celebrated surgeon, by the change of attendance of Professors Roux and Velpeau, has been transferred to the Hospital of La Pitié. The concours for this professorship will be held in 1836. Whilst waiting the appointment of the successful candidate, the lectureship has been confided by the Faculty to two equally distinguished surgeons, M. Blandin, surgeon to the Hospital Beaujon, and M. Berard, Jun., of the Hospital of La Salpêtrière. M. Blandin has given lectures for six months. M. Berard, who commences on the 1st of November, will continue the course for the winter months. We doubt not that this young surgeon will have the same success as his predecessor, and be also prepared to dispute the chair of the great master with a very favourable chance. The Royal Council of the University have authorised the commencement of a course of lectures on Dietetics at Paris, for the preparatory instruction of nurses.

—o—

BOOKS.

A Series of Botanical Tables, and Tables of the Materia Medica, designed for the use of Students preparing for Apothecaries' Hall; illustrated with numerous Engravings on Wood, and four coloured Medico-Botanical Maps of Europe, Asia, Africa, and America; shewing the Geographical situation of all the Plants in the Pharmacopœia. By W. K. TOASE, T.L.S., Lecturer on Botany and Anatomy.

An Introductory Address, delivered at the commencement of the Tenth Session of the Manchester School of Medicine and Surgery, Pine Street. By JAMES L. BARDSLEY, M.D., Lecturer on the Principles and Practice of Physic, and on Materia Medica and Therapeutics, at that Institution.

In consequence of the illness of our engraver, we are unable to give a plate this week, but we shall make amends by furnishing one the two following weeks.

SELECT LECTURES,

FROM

M. BROUSSAIS'

*Course of General Pathology and Therapeutics;
translated and revised*

BY JAMES MANBY GULLY, M.D.

LECTURE XX.

Question of the Essentiality of Fevers—Revolutions in the Theories of Fever—Inflammation, Bilious, Mucous, Entero-mesenteric, Ataxic, and Adynamic, or Typhoid Fevers.

We proceed to examine another assertion. Some have maintained that the name fever should be adopted as representing the most general phenomenon of febrile disorders, and they have based their assertion on a distinction long since made between fevers and inflammations. Say they, we daily see fever manifested without any sign of local inflammation, and diminish in proportion as the latter develops and takes a locality; fever and inflammation are, therefore, two distinct things, and the former is the principal one. Such would then call all febrile conditions fevers, instead of calling them inflammations; and in order to keep in mind the inflammation, when such exists, they adjoin to the generic term an epithet drawn from the organ that is inflamed; in this manner we have cerebral fevers, pulmonary, catarrhal, bronchial, pleuritic, gastric, rheumatic fevers, &c. Are we bound to adopt these denominations, and the presumption on which they are grounded? I think not. In fact, inflammation may exist, and even produce vast mischief, without there being any fever; whereas fever can never exist without some existent shade of inflammation: the latter is the fundamental fact, and the former a circumstance, an accident, a mere effect. You have no right to make inflammation subordinate to fever, nor should you habituate yourselves to the recognition of the first by the second alone—a plan that would lead to serious errors of diagnosis and therapeutics. Considering inflammation as independent of fever, you will not wait to assault it until the fever appears; you will oppose it as speedily as possible, in order that this destructive phenomenon,

tending as it ever is to extension, may not be propagated. On the other hand, seeing the approach of fever, you may, without any fear of deception, assert that there is an inflammation somewhere: you have then only to find the seat of it; you pass the different functions in review, and when once you have discovered it, you put a stop to the fever by attacking the inflammation. The fever persisting, you seek in some other organ for the stimulus that maintains it, and you put an end to it in the same manner.

By regarding fever and inflammation in this way, we are led to establish a line of demarcation between inflammation with, and inflammation without fever—a point of serious import in the treatment; for it often happens that a phlegmasia, previous to being acute and febrile, remains for a long time latent and apyretic, and that if we wait to attack it until fever has appeared, it is sometimes too late; disorganization has taken place, and the patient is lost. Thus the natural order of things obliges you to make fever subordinate to inflammation, and not inflammation to fever; and you find this advantage in it, that inflammation once well conceived, leads you to seek out the exact position of the disease, its causes, and the determination of the most effectual modifiers in its cure; whereas, fever being placed foremost, and made the ground of your treatment, exposes you to the most prejudicial mistakes.

Since we are speaking of fever, it may not be amiss to investigate the various acceptations of the term. With Hippocrates, fever was a state of the system characterized by a violent tumult of the blood and humours, a sort of general blaze. In his relations of cases, he tells you, "I went to such a patient: he had fever, more or less heat, delirium, &c.," but he does not specify the fever. Hippocrates was wise, and did not prejudge: he simply related what he saw; to have a proper judgment of him, we should separate what he has written from what he has been made to say; it would then be seen, that of all the ancient writers, he was the least prejudiced. He placed in the foremost place the observation of facts, and put into execution, without saying so, the very thing that Descartes and Bacon recommended so many ages afterwards: this it is that gives him

so high a place in the hierarchy of the sages of old, and a right to be considered at the head of them. For some time, all went in his footsteps; then came the school of Alexandria. Erasistratus established a difference between fever, properly so called, and other fevers. Galen took the expression previously in vogue, for the character of particular fevers; but between him and Hippocrates several doctrines had made their appearance, and among these, was more especially distinguished that of the four elements taught by Plato, who retained the principal divisions of Erasistratus, referred fever to the four elements and the symptoms, and called one essential, the other symptomatic: the former of these have descended to our times, and are in fact, phlegmasiæ, whose seat had not yet been determined. They then made use of scholastic divisions, apparently clear, but which at the bottom had no meaning whatever. In this manner they recognized simple fevers, synchous fevers, putrid, sanguineous, containing, or without exacerbation, continuous with exacerbation, but with no rigor nor sweating, remittent or exacerbations, with rigor and sweating, intermittent or regular accessions, separated by a complete apyrexia—and all these they explained by affections of the fluids, the bile, the blood, the phlegm, the atrabilis—an imaginary humour—or by the disturbance of the corporeal spirits. These divisions are in direct accordance with the march of the human mind, which first of all rests on the most prominent objects, but as these are far from responding to all the forms of fever, others, founded on the symptoms, came to be established. There were bilious fevers that were explained by an excess of bile (bilious synocha), or by excess of blood in the small vessels (sanguineous synocha); fevers in which the evacuations predominated, and which were termed colliquative, a term that may be traced to Galen. At the time when I was a student on the benches of the lecture-room, and when these colliquative fevers were matter of great speculation, they could form no idea of them—of fevers, in which the body was represented as melting like a lump of butter in the sun. It was I who first announced that these colliquations, accompanied with copious diarrhoea towards the close of diseases, were nothing but consecutive entero-colites supervening in individuals on their last legs. I know not whether some learned Theban has found this announced elsewhere, but, for myself, I most certainly have not seen it in any author.

Other symptoms we have, that might well call attention. We have fevers, in which shivering and cold predominate; these were called algid, horrific, and were explained by the mixture of the bile or blood with the phlegm, the latter being cold, the others hot; the phlegm fights it out with the bile and blood, and if victorious, cold remains master of the body. Asodes fever

is a fiery or acrid principle, acting on the nerves. Elodes fever is the sweat exhalng through the pores. Syncopal fever, says Galen, is the bile stimulating the orifice of the stomach; producing syncope. All these fevers correspond to unknown local phlegmasiæ. Even now-a-days they would persuade you that in many of them the inflammation is general; but this is nothing but the corruption or putridity of Galen. There is no more inflammation of the whole sanguineous system, than there is general inflammation in consequence of the bile, the blood, the sulphur, putrid humours in the vessels, &c.—the whole is alike false.

The ancients frequently saw putridity in fevers, and the few autopsies they made, might very well keep them in this error. For the rest, you cannot wonder at it, knowing that these fevers are inflammations; for the elements of the supposed putrescence are heat and moisture, and the more inflammation is fierce, and fluids are accumulated in a part, the easier is putrefaction after death. Cadaveric exudations, and quickly effected humoral alterations, appeared to them to be general, although they were really confined to certain parts, more disposed, from their inflammatory condition, to chemical dissociation. This doctrine, absurd as it may appear, is still spread abroad; they have put another cloak over it, but still it remains the same, as I shall show in the course of this examination.

Passing from the barbarous times, we approach the seventeenth century, when science began to take her flight. At this epoch you have a crowd of classical writers that are continually quoted; the chief of which are Vanhelmont, Buerhaave, Baillou, Willis, Baglivi, &c., who had derived their doctrines from Galen, who tended towards localization. After them came the observers, who practised autopsies at the same time that they endeavoured to take from the ancient systems—Bonnet, Riviere, Glisson, Sydenham, Pringle, Lind, Mead, and all the epidemists. They were eclectics, who gradually modified their method, and set aside explanations, only to stay by the mere descriptions, in imitation of Hippocrates, around whom they rallied as round a sacred beacon. They ceased to attribute fevers to the humours, and nothing but epidemics, caused by some extraordinary and incomprehensible agent went down. Looking closely at diseases that bore the nearest resemblance to each other, they saw differences between them, which gave to each a particular physiognomy, and they accordingly multiplied the forms of them to an extraordinary extent. This might be said to be the epoch of the inbreaking of light, for error was pushed to its utmost limit, and fell by the very exaggerations of the epidemists. To the diseases of seasons they added those of latitudes, then those of localities, which they at length even substituted for epidemics; and had ridicule not stopped them, they

would finally have described the fevers of every little village, as they had already done those of Hungary, Dalmatia, &c. Such were the fevers of the epidemists, groups of symptoms without end, entities that cannot inspire regrets.

These diseases again underwent a change in the reign of vitalism. The irritability of Haller brought back the *strictum and laxum*; and Baglivi's treatise, "*De fibrâ Motrice*," consolidated his ideas. Hoffman maintained that reference should be had to debility and spasm, without, however, altogether renouncing humorism. Then came Cullen, who swept away the remnants of humorism, and beheld nothing but strength and debility. Later on, the mechanical theories of which Borelli was the propagator, replaced these ideas; it was no longer the conservative principle, or *natura medicatrix* of Hippocrates, but the power of the heart which impelled the blood forwards, to the overthrow of all obstacles: to this Boerhaave leaned. Then came the animism of Stahl, the duration of which was short, especially among physicians, who could find no profit in sounding words and hypotheses, in souls and abstract principles. The "vital force" became allied to the "irritability" of Haller; "nervosism" was added to these, and the whole passed into "sthenia and asthenia" in the hands of Brown. Fever was excluded, and no longer explained anything. But this doctrine is more dangerous than that which admits fever, for it gives you two weapons, weakening and stimulating; if you stimulate the patient when he ought to be quieted, you enact a homicidal part; if you remain inactive when you ought to be acting, the disease gets on, and may prove fatal by excess of power and irritability; if you debilitate when there is already too much debility, you may in like manner cause death. The most mischievous trait in this system is, that by it the characteristics of debility were mistaken, and too much stimulation employed: on this, however, we need not now dwell; suffice it to say, that it was adapted to the subject of fevers, and held its ground down to our times, when in this very school appeared Pinel, the celebrated nosologist, the true eclectic classifier, proceeding in the footsteps of Sauvages his predecessor and model, and like whom, he wished to adopt and conciliate all the previous ideas. There are men indeed, whose organization leads them to recapitulate and classify objects: such men scarcely invent at all, and sum up the discoveries of others in order to form a nomenclature: of these, Pinel was one. He reformed the classifications of Sauvages, and passed through life in the painful condition depicted in his phrases, scarcely ever knowing, amid the incoherences consequent on his eclectism, on what opinion to fix; yet he did good service by provoking investigation, from the doubt in which he plunged physicians. Had

he not written at too early a date, before he had sufficiently studied pathological anatomy, his ideas would have been much more judicious and fixed, and his influence more salutary. Now, on the very question before us, what remains have we of him? Six fevers which he had not the courage to *disessentialise*, and in place of which, as they were falling away, others have been substituted. These fevers of his, as well as his hesitation in announcing them, I attacked in my *Examen*, and I showed how prejudicial it would be to partake of his doubts and amalgamate, as he had done, several systems together. In fact, almost all the modes of treatment of his predecessors are adopted by him, particularly emetics and tonics, to which he assigned a prominent place, while purgation seems almost to inspire him with horror. I showed that he dared not think that all fevers are referable to inflammations, that is to say, that all febrile states not having the name of symptomatic fever, should be placed in the same category as the symptomatic fevers of catarrh, of rheumatism, pneumonia, &c.; and though every one is not yet convinced of this truth, yet the general opinion has done justice to very many fevers, in spite of the disguises they would impose on the reform effected by us. Thus mucous fever has given place to the entero-mesenteric, and has been lost in dothinentery; bilious fever has disappeared and been lost also in dothinentery, when prolonged; adynamic fever remains as the type of the latter, so that definitively, almost all fevers are, as it were, merged into dothinentery. The plague has been respected, as has also been yellow fever, because as they do not reach us, there has been no way of investigating them. On these a silence has reigned, but they have pertinaciously held by inflammatory fever: they find our refutation of it insufficient, at least they tell us that though we have proved that certain inflammatory fevers depend on inflammation of the viscera, there are others of which we have given no relation; and to support this, they have lapsed into a string of vague expressions. At present then, little more than two fevers are proposed to our faithful adoption, into which all the others glide: these fevers are the inflammatory and the typhoid, or dothinentery. And first of the inflammatory.

Inflammatory fever presents itself with frequency of pulse, halituous heat of the skin, moist tongue, no local pain, but only a feeling of fatigue and bruising of the limbs, and some headach: thus it is in young adult and sanguineous subjects. You may clearly see that this is only an affair of constitution and shade. What would you make of this group of symptoms? a catarrh? You have not all the characters of it. On the other hand, you can gain nothing from an autopsy, for the patient cannot die in this state: to kill him the disease

must become considerably worse, become a serious phlegmonous or membranous inflammation; take, for instance, the form of a gastro-enteritis passed to the typhoid state, with ataxic and adynamic symptoms—or a cerebral congestion supervene—or pneumonia, pleuritis, peritonitis, &c. come on; in one word, this state, which they give you as representing inflammatory fever, must degenerate into one of greater gravity, in order to become mortal. *Then what do you find?* A visceral inflammation. What, then, is this inflammatory fever? The dawn of this same inflammation not yet sufficiently intense to satisfy the desire of beholding the local symptoms. But think you that such are altogether wanting? Undoubtedly not, and you may find them by analyzing the functions and interrogating the organs. In the first place, you will find that the stomach no longer digests, and that thirst has taken the place of hunger, indicating that the gastric mucous membrane is more than ordinarily irritated; you will see prostration of strength, necessity for the recumbent posture, proving, not a general affection, but an irritation of the nervous centres which are now more stimulated by blood; and so true is this, that if you bleed the patient, in two hours afterwards he gets up and walks freely. Is there, then, a general inflammation of the blood-vessels, as has been asserted? Is it an angiotonic fever? Be it so; but if this inflammation exist, most assuredly it can only be momentarily existent, for I should perceive the marks of it in the circulating apparatus, in the heart or the vessels, and I should at length behold signs of carditis or arteritis. But this is only seen in a small number of cases, and never in the ephemeral inflammatory fever, that lasts twenty-four or thirty hours—never in the non-putrid synocha of Galen, that ends in sweating or hæmorrhage. What will most frequently be met with is a beginning of inflammation in some viscus or other, not yet sufficiently serious to cause great disorder, and, in the present instance, evidently resident in the digestive canal. It is not in the lungs, else we should have bronchitis, or pneumonia, or pleurisy: it is not in the peritoneum, else we should have peritonitis, nor in the cellular tissue, without a phlegmon: neither is it in the articulations, nor the skin, nor the liver, nor the brain, &c., since we have neither arthritis, nor cutaneous phlegmasia, nor hepatitis, nor encephalitis, &c. Where, then, is it? In the internal gastric surface, principally in its sanguineous capillary network, in consequence of plethora. This sanguineous capillary superexcitation may, no doubt, exist elsewhere: but it predominates there, not in the most intense degree, although if it does not terminate by an evacuation or crisis, it will rise. It is therefore a gastro-intestinal phlegmasia in the first degree, such as is seen in youthful subjects, or as it

is exhibited in the onset of paroxysms of intermittent fever. It may even be only an irritative congestion, not yet passed into the properly so called inflammatory state—a congestion occurring in a visceral apparatus, chiefly in the gastric or in the capillaries of the mucous membrane of relation, shared in more or less by the encephalon and spinal cord, and which, therefore, is not general.

Pass we to bilious fever. It is agreed to consist in a phlegmasia of the digestive mucous membrane, with supersecretion of bile. But this supersecretion is a circumstance of individual constitution, of temperament, season, and previous regimen. Moreover, bile is not always secreted to the same extent throughout the whole course of the disease; most frequently it is at the commencement, when inflammation develops in the stomach, that the bile flows thither, accumulates, and is vomited or produces jaundice; or else, being rapidly poured into the intestines, it irritates them, causes increased peristaltic movements, and gives rise to bilious motions. But if you allow the inflammation to go on for a few days this secretion is changed, or even ceases altogether. This has been felt, and the name of bilious fever suppressed: still they have stayed by a state as the basis of a particular indication requiring evacuation of the bile when it is superabundant. Such indication may possibly exist to the eyes of some, but, for my part, I do not consider myself conscientiously bound to make use of evacuants, and I almost always dispense with them. I limit myself to the quieting of the irritation, and then the bile may go whither it pleases: at the most, I endeavour to assist its departure by warm water: if it hurries upwards or downwards, so much the better, but I do not force the already irritated stomach and duodenum to expel it violently. My colleagues and myself have, at Val-de-Grâce, frequently two hundred patients in this state, and we get them out of it, not by striving to evacuate the bile, but by calming the irritation. Besides, after this bile has been evacuated a fresh quantity forms, and this only lasts a few days, after which the time for evacuations is past. It is true we cannot fix the duration, but we can do very well without lavishing antibilious remedies. So true is this, that in jaundice I mostly make use of none at all, although in it the bile acts a predominant part: I calm the irritation of the duodenum and liver, and that is sufficient; occasionally, but very rarely, I give a purgative when the bile does not find exit by the bowels, but only to bring it into that track, and when there is no phlogosis. I therefore do not see what they would make of this bilious state. It is a fact, say they: no doubt it is: but it should be reduced to its just value. There are simple and there are complex facts: this secretion of bile is a complex fact that

must be decomposed: it depends on an irritation situate in the duodenum and liver: put a stop to this irritation and the bile ceases to be secreted in excess. Still, you may say, suppose it obstinately returns? Very well, be more obstinate than it. Instead of purging in these fevers, persist with antiphlogistics: this is applicable to chronic gastro-enteritis: I have lately treated an individual who, for about fifteen months, had every five or six days excessive bilious evacuations, with chronic gastro-duodenitis, and an enlarged liver projecting beyond the ribs. I had no notion of following up the so-called antibilious indication: I combatted his gastro-duodeno-hepatitis by regimen, leeches, and revulsives. This treatment was continued in for a year, and was followed by a cure. This person, whose perseverance deserved the reward of health, previous to consulting me, thought himself under the necessity of evacuating his bile, and he even felt relieved after every such evacuation: I however was not caught by this false indication, and I contented myself with putting a stop to the irritation that produced the bile.

Thus, then, is the bilious state decomposed: the same may be done with the mucous state. In fact, what is that state? An irritation of the mucous follicles which secrete overmuch and bathe the organs with mucosities; allay this irritation and the mucosities disappear. But, you will tell me, when these are excessive and conjoined with the bilious state, would it not be well to free the digestive canal from these oppressive matters? This is a question of the greatest importance, and to answer it one should be well versed in irritations; if it be slight you may evacuate; but if fierce your duty is to calm it. To sum up: these bilious or mucous fevers, these bilious or mucous states, are entities that signify nothing, except as symptoms, and are manifested at one period, but not throughout the whole course of the disease.

What shall we say on entero-mesenteric fever? Here something more exact presents itself, though the fever is still put forward as the principal object. The zeal with which medical men receive it, proves how great is their thirst for truth. This fever is nothing but a gastro-enteritis, subsequent to which we find redness, ulcerations, swelled mucous follicles in the small intestines, and tumefied mesenteric glands in the neighbourhood. In all times similar disorders existed, but were not appreciated, showing how tenacious of error men are, and how easily deceived. Since dead bodies have been inspected, no one has thought of taking this coincidence of intestinal lesions and mesenteric alterations as the basis of a particular fever: all at once appears a man to whose idea it occurred, and behold a new disease created. It is only a fact of pathological anatomy

ill explained: the word fever, substituted for that of inflammation, is not admissible: the mesentery is only secondarily effected, consequently this entero-mesenteric fever must be considered as "not proven."

As to ataxic and adynamic fevers, we know well what they are. At a certain period of gastro-intestinal phlegmasiæ, nervous phenomena, which I have already pointed out, appear; attention is directed towards them, and from them they take the name of the disease, which they consider as a nervous fever, with two different forms. It is certain that at the period in question there is an affection of the cerebral or cerebro-spinal system; the patient has the symptoms of ataxic fever with or without gastro-enteritis. If he has them without primary gastro-enteritis, he has encephalitis, and the ataxic fever must change its name. As to adynamic fever, I do not believe that it can be owing to the brain alone; its source is always in the digestive canal, as the symptoms indicate—dry, red or black tongue, mouth filled with blackish, bloody exudation, prostration of muscular power, supination, subsultus of the muscles which are not in a violent or permanent convulsion, but agitated from time to time, taciturn delirium, brownish colour of the skin, as in demi-asphyxia, fetid state of the mucous exhalations, considerable diminution of the feelings of any want, frequently laborious fatiguing respiration. This group of symptoms is the same that has borne the name of typhus since the time of Hippocrates; I attribute it to gastro-enteritis arrived at a degree that produces in the gastro-intestinal mucous membranes the alterations that I have described as corresponding with it; whatever cause may have brought it to this state, whether it has been irritated by good wine and food, or by bad drinks and indigestible, corrupted aliments, by miasms, moral affections, dry or wet weather, &c.—the symptoms are always the same. Hence the necessary confusion of adynamic fevers that depend on infections and those that do not, since in both cases they may be developed. In a word, typhus may belong to all the causes that produce gastro-enteritis, when not arrested, and when extended in the digestive canal. It then produces more invariably typhoid than ataxic symptoms—the latter accompanying inflammation of the gastric portion, which is with predominant irritation of the brain, and the former inflammation of the middle portion, which threatens great part of the mucous membrane with disorganization.

The whole, therefore, of the divisions of typhus, according to seasons, ages, climates, &c., may be reduced to the simple proposition that, arrived at a certain degree of intensity, gastro-enteritis invariably produces adynamic or typhoid symptoms, whatever the causes may be. And this fact renders

comprehensible all the accounts of epidemics that have been transmitted, or that may be hereafter produced.

This group of symptoms constituting typhus has furnished matter of much dispute. It has been said that it depends on something other than gastro-enteritis; that it may be induced by a latent suppuration, by a phlegmon, the pus of which has been retained under an aponeurosis, by the highest degree of peripneumony, by infection (particularly), subsequently to small-pox, absorbed deposits, &c. The proof, it has been said, that all these causes may produce typhus is, that it is found consequent on them, but without any traces of gastro-enteritis after death. I respect these facts, whencesoever they originate, but I confess that I have in vain, for a long time, sought for similar ones. I think that there wants some agreement as to the character of inflammation in the digestive canal, and that the disorders therein produced by it are badly appreciated. I shall repeat to you, that frequently after inflammation has prevailed in that canal, it goes elsewhere, so that the blood leaves it and accumulates in other organs—the lungs, for instance. In that case redness no longer exists in its former situation; but there is always either an anormal coloration, or ulceration, or softening, in fact, some alteration of the tissue of the membrane.

As to the objection, that peripneumony produces adynamic fevers as well as gastro-enteritis, I deny it: in that case the latter must exist, and there is complication of peripneumony and gastro-enteritis.

In the case of hidden suppuration, it is indeed possible that there may be a febrile affection resembling adynamic fever; but hitherto no satisfactory distinction has been established, nor has ever the slightest difference between these states been sketched out. I believe them to be identical when the disease has commenced by the phenomena of inflammation of the digestive canal; in short, I believe that when the group of adynamic symptoms exists, there is gastro-enteritis.

So much for ataxic and adynamic, or typhoid fevers.

—o—

A Sketch of the Medical and Statistical History of Epidemic Diseases in Ireland, from 1798 to 1835, with the Method of Prevention and Cure, as practised in the Fever Hospital, Cork Street, Dublin. By WILLIAM STOKER, M.D., Hon. Fellow of the King and Queen's College of Physicians in Ireland, &c. &c.

[Few physicians have had such ample opportunities of observing fevers in Ireland as Dr. Stoker. This will appear by the perusal of the following historical Sketch of these diseases for a period of thirty-seven years. The subject of which he treats is of

immense importance, as there are few countries in which fevers are so prevalent as in Ireland, and as a history of these diseases is replete with instruction to all who practise in that country; while it enables others to institute a comparison between the characteristics of febrile complaints in that and other sections of the kingdom, as well as of other countries. It also throws great light on the pathology of fevers, and amply proves that their causes are not always to be discovered by dissection or by auscultation. It favours humoralism more than solidism, and manifestly proves that both doctrines are applicable to different varieties of fever.—ED.]

Introduction—Period from 1798 to 1816 inclusive.—Increase of febrile disease, gradual but constant, sometimes symptomatic sometimes idiopathic—but more generally these forms combined.—Instruction derived in all cases from the morbid changes in the blood, especially in distinguishing between inflammatory and typhoid disease.—Great value of these distinctions evinced by successful results.

Close and almost daily observation of the constant increase of epidemic diseases, in Dublin, since 1798, and of pestilence periodically within the last twelve years, has led me, in continuance of my public engagements, again to attempt a sketch of the medical history of that period*. By faithfully detailing the events I have observed, and as they are recorded in the annals of the institutions in which I have been engaged, and arranging them in the consecutive order in which they occurred, I hope to present an incontrovertible statement of facts, which, if duly considered by those devising means of prevention and cure, would, I am convinced, have rendered their efforts more successful. At least that much of the prejudice of preconceived opinions, which has hitherto been the source not only of failure but also of mischief, in the otherwise valuable institutions of Dublin, would, I believe, have been obviated†.

Materials thus collected for others better qualified to compile them, may also aid in the task of tracing effects to their true causes; and I am persuaded, that however difficult that may be, it can in no case be more indispensable, and hardly more important, than in inquiring the causes of the

* Physician to either the Dublin General or Meath Street Dispensary from 1798 to 1803—to the Fever Hospital and House of Recovery, Cork Street, from 1803 to July, 1834, 100,000 patients being received in that time—and to the Molyneux Asylum for blind females since 1815.

† See the Medical Reports of the Dublin Fever Hospitals from 1803, and those of the Cholera Hospitals since they were opened for the reception of patients, in 1832.

rapid advance of disease in the Irish metropolis, as if in defiance of the extensive apparatus, and of the numerous means provided there to check the progress of contagion. The extraordinary phenomena, both moral and physical, which *pari passu* have accompanied that long-continued progress of disease, have been noticed since 1804, in the annual reports from the Fever Hospital and House of Recovery, Cork Street*. That parallel may be found traced at the eighth and twenty succeeding pages of the second part of my "Pathological Observations," published in 1829†, and still further extended in the Practical View of Ireland, published in 1831, by James Butler Bryan, Esq., Barrister at Law‡.

But other motives, which also influenced my previous efforts, induce me to renew them; namely, to promote a sounder pathology than is likely to result from contests between exclusive solidists and exclusive humoralists. Desirous, as on previous occasions, to draw the notice of pathologists more closely to the constant connexion which I observed as our epidemics have advanced to pestilence—between morbid changes in the blood, and debility or derangement of the vital functions—and to the important question, "Were these synchronous phenomena merely accidental, or were they ancillary?" Also, "How far were they mutually dependant at the beginning, and during the progress of disease?" Questions which have become, yearly, more and more interesting as successive systems have failed in generating a practice, effectual as it should be, in preventing and curing diseases. The comparative value of successive speculations, too, during their temporary application to transient changes, can be best shown by placing them in the order in which one was proposed on the destruction of another; and the fitness of what remains of their debris for a more enduring structure can be more fully estimated. (Vide note A, Appendix.)§

Proud to acknowledge the aid which my former attempts similarly and arduously directed, met with on the Continent, (especially in a critique by Dr. Steinheim, in the Magazine of German Literature, and in Great Britain||, I beg to give the following extracts with that view, as well as in justification of myself, viz.—

* See Annual Reports from the Cork Street Fever Hospital for 1806, 7, 11, and 16.

‡ A Practical View of Ireland, by J. B. Bryan, Esq., 1831.

§ See a dissertation on the Institutes of Medicine, particularly relating to the Pathology of Fever.

|| Med. Chirur. Review, new series, No.

"About forty years ago, (Dr. Steinheim's Critique continues,) Cullen first advanced in Edinburgh the doctrine of Sthenia and Asthenia; which had extended itself over Europe for half a century under different names, and manifold shapes. Its intellectual course passed two points of Culmination; the former in Brown, the latter in Broussais. And now comes the second extinguishing blow from a quarter near that from which the theory of solids, as a first flash of lightning, blasted the old fabric of the pathology of humours. A new, although not unheard of appearance.

"This last meteor of the solidists, whose elegy Doctor Stoker has already sung in Ireland, will soon be extinguished.

"It would be incredible how far almost all our fellow artists across the sea suffered themselves to be enticed into that quagmire, the theory of solids, by the appearance of the solidity, as by an *ignis-fatuus*, if their writings did not prove it. One may even see the disjointedness of false explanation, and the wildness of their madly forced applications at the bed of sickness. The adherents of the pathology of humours were regarded with real pity, disdain, and contempt; and the gestures of those persons are ridiculous, when nature presents them with an explicable problem as a barrier on the theoretical highway, and forces from them a reluctant acknowledgment, (*un eveu arraché par la verité*) as Broussais often expresses himself against Ontologists."—pp. 35, 36, 37.

"Stoker now opposes himself to this physio-pathology of his countrymen, and with the danger of having all that applied to him, which was said against humoral pathology in modern times. Every well-intentioned person will praise him for his courageous love of truth. The manner in which he conducts his new doctrine proves this at once, for he prepares and conducts the reader by practical cases as they occurred to himself. This method is certainly practised by his countrymen, and is formed on the fundamental principles of Locke, being peculiar to observers, who wish to deviate but little from direct evidence, and retire quickly to it again*."—pp. 40, 41.

"The next part (continues Dr. Bostock), ('Pathological Observations,' part 1, &c.) consists in observations on the connexion supposed to exist between the appearance of the buffy coat on blood, and the time re-

1, p. 155, June, 1824; London Med. and Sur. Jour. Oct. and Nov. 1829; Med. Chir. Review, Sept. 1, 1820.

* Magazen der Auslaudeschen Literatur der Gesamnter Heilkunde, &c. &c., Von Dr. G. H. Gerson, and Dr. Nichol, Henri Julius, Juli, August, 1824, Art. 2. Pathological Observations, &c. &c., by William Stoker, M.D., 1824.—Translated by I. G. Abellshauer, Professor of Languages.

quired for its coagulation. It is well known that pathologists in general have looked upon this as a merely physical operation, and have explained it by the slow coagulation of the blood in the cases in which it presents itself, and by the time thus allowed for the precipitation of the red globules. Dr. Stoker rejects this explanation, as being incapable of being reconciled with the results of actual observation. He has given a tabular view of the state of the blood drawn from twenty-seven patients; the time required for its coagulation, with notices of the presence or absence of the buffy coat, &c. We do not think it necessary to transcribe this, but shall contrast one or two of the cases which appear to fully support the doctrine Dr. Stoker has advanced!!”*

The following remark of M. Duges on the creeds of the solidists and humoralists, was extracted for the *Medico-Chirurgical Review*; from the *Revue Medicale, Mars, 1824*; that the reviewer of my *Pathological Observations*, might thus express his unqualified approbation of both: “Il ne serait pas moins de raisonnable d'adopter des idées toutes contraires, et de nier les alterations du sang, ou de le croire indifferentes aux phenomenes de la santé et de la vie. Un juste milieu entre ces deux extremes est, sans doute la veritable route a suivre.”†

“Dr. Stoker (says the *London Medical and Surgical Journal*) has drawn his conclusions from the best of all premises, from observations at the bed-side of the sick, and he has found the present theories of Cullen, Brown, Darwin, Clutterbuck, Marcus, Plouquet, Broussais, Bretonneau, and others, all inadequate to their explanation. The ardent admirers of necrotomy are now convinced of the inutility of endeavouring to discover the causes of febrile and other diseases, by the scalpel; and they are once more very rapidly returning to the other modes of investigating the causes of these diseases, which cannot be explained by localising them, or referring them to different organs. Dr. Stoker is the first writer in this country who has assailed the modern theories, and endeavoured to direct attention to the condition of the fluids in disease.”

But I must conclude these extracts with another, by way of reference to Dr. William Pulteney Alison's “*Outlines of Physiology and Pathology*,” as they ably support the difficult position which, though unknown, it seems, to this distinguished pathologist, I have felt it my duty, *since the beginning of this century, to maintain* through evil report and through good report, and I would feel wholly inexcusable to shrink from it at this critical period.

The “moving powers of the animal economy,” and especially the province of the nervous system (see *Outlines of Physiology and Pathology*), in producing the phenomena of life, which were long neglected in certain schools of medicine, have been erroneously conceived in others; by Stahl, by Hoffman, by Cullen, and Whytt*, and to a certain degree by Bichat, by Legallois, and even by Dr. Wilson Philip; and were more accurately understood by Haller, than by any of these authors.

“Besides the misconceptions which seem to have prevailed (continues Dr. Alison), and still prevail, among many physiologists, as to the essential condition of vital movements, and particularly to the influence of the nervous system, in determining these movements and their immediate effects; it seems now pretty generally admitted, that the influence of the truly vital properties of the blood, and other animal fluids, on many of the most important changes of the living body in health and disease, has been *until lately* very much overlooked. When these vital properties of the fluids are better ascertained, and their importance duly appreciated, there is every reason to believe that the distinction so often drawn in the schools of medicine between solidity and fluidity will be effectually obliterated by the admission that most diseases originate in that part of the system (the capillary vessels) where the animal solids and fluids are most intimately blended together, and are continually interchanging particles, and therefore necessarily extended to both†.”

The early and terrific effects of the causes referred to in the introduction, appear in the synoptical tables of the Rev. Dr. James Whitelaw's *Essay on the Population of Dublin*. In 1798 (he states) there were in Dublin 16,401 houses, and 172,091 inhabitants; and in 1804, but 15,645 houses, and but 167,899 inhabitants; so that the return of 1798 exceeded that of 1804, by 756 houses, and 4,192 inhabitants.

Now, if it is borne in mind that it was in 1798 Dr. Jenner published his “*Enquiry into the Causes and effects of the Variola Vaccina*,” and that his recommendation of infection with that virus has been since very generally adopted in Ireland, and its beneficial effects as widely extended, it follows necessarily from this singular depopulation of Dublin since, notwithstanding the most fatal of epidemics, had been thus arrested, that other epidemics must have become more

* Edit. Edin. 1773.

general and malignant. Besides this valuable addition to prophylactic medicine, there was simultaneously in operation in Dublin the most extensive apparatus in the British dominions for checking the progress of contagion. The sources of malaria, too, and hence of ague, were nearly removed. This, I conceive, imperatively calls for a closer investigation into the causes of disease, not alone by the faculty, but the community. The public safety at least would be thus promoted. It is now quite clear that evident causes have either been overlooked in contriving preventive and remedial measures, or that they have overwhelmed the inadequate means in use.

The type of epidemic fevers at the close of the last and beginning of this century, was in most cases very nearly described in Dr. Cullen's definition. "*Febres sine intermissione nec miasmate paludum ortæ; sed cum remissionibus et exacerbationibus, parum licet notabilibus, perstantes paroxysmis quovis die binis.*" The diurnal paroxysms, however, distinguished them less every year, as the sources of malaria were dried up, and perhaps, too, as famine, mental depression, and consequent pestilence, assisted to obliterate the vital energy or efforts (*Conamina*, as Sydenham calls them), to repel the encroachments of disease, struggles on which these phenomena in some measure depend. These struggles, I remember, were pointed out to us, who were his pupils, in 1796, by Dr. Perceval, in his lectures on the cases admitted into the clinical wards here, and afterwards in the Edinburgh Infirmary, in the years 1797 and 1798, by Drs. Gregory and Rutherford; and notwithstanding a more rapid growth of disease for several years before, the cases then did not differ materially in their external character, nor essentially in their nature from those described at a much earlier period of the 18th century by Drs. Boate, Rogers, and Maurice O'Connell*. At these periods, it appears too, as continued fevers became more typhoid than inflammatory, symptoms of debility in the functions, with corresponding lesions in the circulating mass supervened. Re-action, however, was better marked by increased force and velocity in the pulse, and higher degree of temperature at the close of the last, and beginning of this century. It was also more frequent at the commencement of diseases than since, and in mixed cases continued through a more considerable portion of the disease. The prevailing fever was very generally denominated Synochus. Dr. Cullen's definition of that species, however, was not wholly unobjectionable; for *synocha* or the *causa* of Dr. Mason Good, was then, as

since, a very rare occurrence; but if *pyrexia* be substituted for *synocha*, it would in many cases be found admirably suited to the mixed fevers that prevailed; and in many still more so, if rendered thus—*Phlogosis initio et versus finem Typhus*.

Continued fevers, however, of any species, could neither have been so prevalent nor so severe before as since the beginning of this century, no hospital being expressly provided for their prevention and cure in Dublin before 1803. And that, notwithstanding the subsequent increase in extent and aggravation of symptoms, no changes in their nature or essential characters had then taken place, will appear more clearly by comparing the reports published from the fever hospitals of Great Britain and Ireland at the commencement of this, with the descriptions in the first and second quarters of the last century, already referred to.

The principles and practice adopted in the treatment of fever at that period were very generally founded on Boerhaave's system of pathology, or, more properly speaking, on the same eclectic plan as his system—that is, upon the rational opinions of others, whether antecedent or contemporary, connected together so as to mould them into a consistent and uniform theory. Consequently, morbid changes in the vital fluids, and morbid actions in the living solids, in whatever degrees they were found conjointly or reciprocally affected, were duly studied and promptly prescribed for, without fruitless inquiry into the *primum punctum saliens*, or *postremo moriens*, and with still less hesitation preferring allopathy to homopathy.

In intermitting fevers emetics were employed on the supervention of the rigors, to relieve the oppression at the stomach, and because spontaneous or excited vomiting had been noticed previously to abate or shorten them. Costiveness having been observed in the intervals to render the succeeding paroxysms more severe, and accidental purging beneficial, laxatives were always directed for the due evacuation of the bowels; but Peruvian bark was directed still more empirically, and, as at present, when not contra-indicated, was employed at all stages of the disease*.

Continued fevers were treated upon nearly the same principles, and according to the most obvious indications, whether the signs were observed in either fluids or solids, or in both. In dynamic or inflammatory fevers, means, especially general and local bleeding, were employed proportionately to the increased strength and velocity of the pulse, the pain of the part affected, and the derangement of the function most engaged; the prescriber being guided by the external character of the blood taken from a vein,

* An Essay on Epidemic Diseases, by Joseph Rogers, M.D.—*Morborum acutorum et chronicorum quorundam observationes*. Auctore, Mauritio O'Connell, M.D.

or accidentally effused. If the crassamentum was firm, colour not darker than natural, and surface sizy, the evacuation was continued or repeated, as otherwise seemed necessary for the patient's relief; but if these indications were wanting, remedies likely to be successful, without detracting so much from vital power, were prescribed*.

On the treatment of adynamic or typhoid fevers at the period under consideration, reserving a more complete catalogue of remedies, selected with that view, until epidemics became more pestilential, and when the contrary indications to those in dynamic fevers became better marked—a few remarks here, and chiefly on the adaptation to transient changes of disease. (e. g.) Purgatives were very generally resorted to soon after Dr. James Hamilton's able treatise in 1799, but were for some time much abused, owing, chiefly, to neglect of his salutary cautions. The growing malignity of epidemics, however, in some measure demonstrated the extent of these abuses, and therefore led to a more guarded and less frequent administration of purgative medicines in the treatment of febrile diseases, and to confine them strictly to the due evacuation of the intestines. Dr. Hamilton's predilections in favour of purgative medicines, however, were so strong as to lead him to oppose other remedies. Owing to his high authority, he in some measure proscribed sudorifics, more particularly antimonials. Having contributed my aid to prevent the abuse of purgative medicines adverted to, by re-publishing Dr. Hamilton's cautions, and by publishing some cases of mixed fever, in which James's powder, especially when the head was affected, and others in which tartarized antimony was eminently useful, to restore antimonials to their due rank in the *Materia Medica*, I am the more desirous, on an occasion like the present, to refer to adjustments in the practice of physic which have been crowned with success†.

Warm or cold affusion, as recommended by Dr. Currie, was much employed at that time, if the circumstances he pointed out, namely, if vigorous re-action and high temperature justified it. These indications, however, as diseases became more pestilential in the same degree, became less and less observable‡. This, as well as the consequent disuse of that remedy, will be seen more clearly in the sequel. In mixed cases of fever, when inflammatory and typhoid symptoms, as often happened, were intimately blended, it was of the highest importance to have a remedy not contraindicated by either, yet consistent with the

ratio medendi in both—and barm or yeast, on account of some reports of its efficacy in putrid fevers, as tried by the Rev. Dr. Harwood and then published by the lamented Dr. Beddoes, seemed to me to promise favourably. The results of the extensive trial I had made among the sick poor of the Dublin General Dispensary, being decisive, I stated them in 1800, to Dr. Whitley Stokes, then a Fellow of Trinity College, and Professor of the Practice of Physic; and on reviewing the general and beneficial adoption of this remedy since, I trust I may be excused in adding, that I was the first physician who gave it an extensive trial and published the cases thus remedied*.

The principles and practice then generally taught in the public lectures, and adopted by the classes, though founded, as stated, on the eclectic method, and Hippocratican doctrines, were soon after as violently opposed as the most restrictive and arbitrary that preceded them; but the questions most constantly agitated were chiefly between those who held opposite sides with the rival systems of exclusive solidism and humoralism. Still, however the contending parties might affect to be wholly directed by Lord Bacon's method of induction from facts, to avoid those errors which they thus pretended to have detected, they continued to be guided in secret to a later period by a mixed pathology, based alike on morbid changes in the vital fluids, living solids, and some uninfluenced by either theory, prescribed remedies, wholly because they had been employed with advantage for similar symptoms.

The failure of the attempts to establish consistent theories on any exclusive system of pathology will become more manifest as we proceed with this sketch, as well as the idle vanity of disputes on the *prima et sola sedes morbi*, which have likewise retarded the improvement of the practice of physic. Morbid actions in the solids and morbid changes in the fluids were duly noticed, and were examined through the entire course of disease, without respect to the particular system in which they commenced. The nature of the disease, and the means of relieving it, were thus sufficiently ascertained for safe practice.

In thus, for the present, briefly touching on my objections to exclusive solidism, I mean to advocate the great advantages from unrestricted autopsy, before and after death, and should observe that stethoscopy was not wholly unknown to the practitioners of Dublin, that auscultation, unaided by an intermediate apparatus, was then found beneficial in exploring the morbid contents of

the natural cavities, particularly of the thorax. It was practised, in 1796, by Dr. Perceval, in the Clinical Hospital, and by the late Dr. Wright, in the Meath-street Dispensary. Neither were the advantages common to it and cranioscopy neglected—such, I mean, as examining the external deformities of structure on the surface of the head, chest, and abdomen, and comparing them with the natural inequalities on these surfaces, so as to ascertain whether or not these were the result of morbid changes in the solids.

Autopsy, however, was not then limited to mere alterations of structure, either during the course of disease or after death, but, both here and in Edinburgh, was extended to morbid changes in the fluids. In 1797 and 1798, I witnessed in the Edinburgh hospitals the great advantages of such modes of inquiry into the nature of diseases, directed by Drs. Gregory, Rutherford, Hamilton, &c., whose accurate diagnoses, prognoses, and successful treatment must be recollected; likewise, how cautiously these eminent physicians noticed morbid changes in the fluids.

As the principles and practice just described nearly resemble those most generally adopted by the faculty during the succeeding years of this section, in following the progress of disease it will be only sufficient, in that entire period, to notice the theories by which these principles were assailed, or the modifications of practice which alterations in the characteristics of disease rendered indispensable.

(To be continued.)

—o—

Observations and Experiments upon the Function of the Cæcum. By Dr. Schultz, Professor of Physiology in the University of Berlin.

—

THE objects of this learned Professor in making his experiments were to ascertain; 1, the function of the cæcum; 2, the digestibility of the different articles of food; 3, the manner of the dissolution of the fleshy fibres in the stomach, according to microscopical observations; 4, the degree of acidity in the stomach and cæcum; 5, the degree of alkalescence of the food in the stomachs of ruminating animals; 6, the nature of the acids in the stomach; 7, the coagulation of milk by the saliva, stomach, &c.; 8, the saliva; 9, the nature of the bile.

He maintains that there are two digestions, one in the stomach, the other in the cæcum, and that the latter is more especially active when vegetable food has been ingested.

From the first experiment he learned that the degree of acidity in the cæcum is not always the same, that it is not always present, and that the food may even become alkaliescent. From the second, that this acidity was neutralized by long fasting, and thus allowed pure bile to enter the cæcum and neutralize its contents. From the third, that there is always bile in the course of the small intestines. From the fourth and fifth, that all the bile secreted by the liver during fasting, is by no means contained in the gall bladder, and that that part is very small compared with the large quantity that flows into the intestine during the empty state of the stomach. From the sixth, that though bile is always flowing, it never passes the cæcal valve during fasting, but collects on the upper side of it; it is only after perfect acidification, and at the beginning of the peristaltic motion of the intestines, that this bile flows into the cæcum. From the seventh, eighth, and ninth, that the degree of acidity and alkalescence of various parts of the digestive canal, vary with the length of time that has passed after feeding, and the degree of perfection of the gastric digestion, as also with the length of time which animals have fasted before feeding. From the tenth, that the quantity of digestible matter which is contained in the food has a great influence upon the degree of acidity in the cæcum. From the eleventh, that in carnivorous animals, when the cæcum and colon are but little developed, the food is for the most part digested by the stomach and small intestines, and the acidity in the cæcum is in general very weak, since the food, when it is here collected, contains little or no digestible matter.

The general results from the whole of the experiments we give in the author's own words; they are of the highest interest and importance.

Results of the experiments upon the cæcal digestion.—It may, therefore, be gathered from my observations and experiments, that the food in the cæcum becomes not only a second time sour, but that the acid chyme is there neutralized by the access of bile, in the same way as in the duodenum; so that after the employing of the intestines very different reactions may be produced according to pleasure. On account of this twofold consumption of bile in the stomach and cæcum, there is an antagonism between the two digestions, for when the bile is consumed by the diges-

tion in the stomach, the cæcal digestion cannot be perfected, and, on the other hand, when the bile flows into the cæcum, the neutralization of the acidity in the duodenum cannot take place. In those animals in which the cæcal digestion is most perfectly developed, this antagonism appears to be so arranged, that each digestion has its particular period of action, so that when the one is in action, the other is either lessened or at rest. In ruminating animals, it is very evident that the gastric digestion takes place more particularly during the day, and the cæcal at night, so that I think the gastric may very properly be called the diurnal, and the cæcal nocturnal, digestion.

"In carnivorous animals, however, the cæcum is so little developed, that the stomach alone furnishes nearly the whole process of digestion. These animals, therefore, have a preponderating diurnal digestion. This agrees with the fact, that carnivorous animals rest for the most part during the day, and at night become hungry, and seek their prey, and are, therefore, nocturnal animals, since their digestion takes place during the day.

"As the formation of the feces follows the perfected cæcal digestion, herbivorous animals are accustomed to discharge the greatest quantities in the morning and evening, and but very little during the day, and the healthy course of digestion. There appears to be something similar to this in man, in those ages where the cæcal digestion is most developed; in childhood, on the contrary, when the digestive apparatus resembles that of carnivorous animals, repeated discharges of excrement take place at indefinite periods of time.

"*The use of the valvula cæci in cæcal digestion.*—That the cæcal digestion may take place, it is necessary that the still digestible remains of the food should be rendered acid and changed into chyme, as in the stomach, before its mixture with the bile. This could not happen if the bile flowed continually into the cæcum, and it is therefore probable, that its opening into the small intestines is closed during chymification, as the stomach is closed during its digestion, only with the difference which the different state of the matter required. The stomach is closed during digestion at its pyloric orifice, to prevent the egress of the food, and the cæcum at its iliac opening, to prevent the ingress of the bile. This is my view of the use of the valvula cæci. I have not only found in general at the lower end of the *ileum*, an alkaline reaction, while the upper is still either sour or neutral, but at certain periods of digestion, a collection of pure bile at the iliac orifice of the cæcum. The contents of cæcum are at this time nevertheless sour. This would be impossible if the mouth of the cæcum were not closed during chymification. After the collection of the food, therefore, in the cæcum, its opening, like that of the bladder, uterus and stomach,

appears to be strongly contracted by its muscular fibres, and with the help of the valvula cæci, to be perfectly closed. The contrary is the case at the beginning of the peristaltic motion of the cæcum, and upon the opening of its iliac orifice the collected bile flows in. This agrees with the sensation of the ceasing of the peristaltic motion after the collection of the food in the cæcum, which I observed upon myself, and have described in my work (*de Alimentorum Concoctione Experimenta Nova.*) It appears to me, therefore, that the generally admitted explanation of Fallopius, according to which, the use of the valvula cæci is to prevent the return of the food from the cæcum into the *ileum*, is quite unfounded; for it may be easily seen that during excretion this backward motion is very possible.

"*Concerning the times for eating corresponding to the periods of digestion.*—The simple rule to eat as often as one is hungry, appears no doubt the most natural. I shall be able, however, to show that this rule is by no means universal, and in many instances even pernicious. I shall succeed best if I prove that one is often hungry without having the least real need of food, and that this hunger is better allayed by fasting than by eating.

"Hunger is the feeling of need of the nourishing parts of the blood, and is situated in that organ through which it is satisfied—the stomach. This appears to be the reason, why, when the stomach is empty, we hunger, and not when it is full, even when it is filled with perfectly indigestible matter, which cannot satisfy the true feeling of hunger. We cannot judge from hunger whether the food be digested, and the proper source of hunger satisfied; and, therefore, this feeling cannot be the only rule for eating, since a perfect and undisturbed digestion is necessary for the true allaying of hunger, and, therefore, when digestion would be disturbed thereby, it would be improper to eat, notwithstanding hunger may be felt.

"If we consider under this point of view the antagonism between the gastric and cæcal digestion, it follows, that, if both be excited at the same time, they will reciprocally disturb each other, and that for perfect digestion, and the proper formation of the blood, they must take place at different periods of time. My experiments show that, for the completion of the cæcal digestion, the bile flows through the small intestine into the cæcum, and the whole intestine becomes thereby more or less alkaline; but they also show, that if, during the cæcal digestion, the stomach be put in action, the flowing of the bile to the cæcum is stopped, and its digestion consequently hindered, since the chyme cannot be neutralized, and all the contents of the canal as far as the excrement become sour. The formation of the blood in the lower parts of the canal is hereby disturbed, and the gastric digestion is also rendered imperfect; so that the two digestions cannot take place

in their integrity at one and the same time. The completion, therefore, of the cœcal digestion is indispensably necessary to perfect digestion in general, and it becomes very important so to regulate the periods for eating, that the activity of the stomach may not disturb the digestion in the cœcum.

"If now, the cœcal digestion be considered more particularly as a nocturnal digestion, the meals should be so regulated, that, when this begins, the stomach may no more be put into action, or at least not overfilled. It is generally admitted that a man digests a moderate meal within three or four hours. My experiments, however, upon carnivorous animals, which digest much more quickly than the omnivorous, to which class man belongs, show, that six or seven hours are requisite for the digestion of a moderate meal, and that when dogs are allowed to eat as much meat as they will, twelve to fourteen hours are hardly sufficient for perfect digestion. The animals must even then be allowed to rest, for if they are made to exert themselves, the digestion is still further delayed, at least half the time longer. The observations which I made upon myself during the intermittent fever agree with this fact, and it may safely be assumed, that six hours are necessary for perfect digestion, that is, till all sour chyme has disappeared from the stomach. If now it be admitted, that, in the common mode of life, the nocturnal digestion begins about from seven to eight o'clock in the evening, the last meal ought to be taken so early, that by this time it may be for the most part digested in the stomach. In general, therefore, one should not eat after four o'clock in the afternoon, and evening meals should be altogether avoided: for, in proportion to the lateness of the hour and the quantity eaten in the evening, the more will the cœcal, and therefore also the gastric digestion, be disturbed, seeing that both must take place nearly at the same time.

"That this rule is not so applicable in youth, (as long as the gastric digestion resembles that of carnivorous animals, and for the most part finishes the process of digestion alone), as in riper years, follows from what has been already observed.

"The more the digestion is disturbed by continued large and late evening meals, the less perfect will be the preparation of the blood, and the more will the need of its nourishing parts, or hunger, be felt, particularly in the evening when the stomach is empty. This is the reason why those people who should eat least in the evening are most hungry at this time, and here more particularly does the feeling of hunger not correspond with the period of digestion; for the more such people eat in the evening, the more imperfect is their sanguification, and the greater the consequent hunger, since the food goes almost entirely unchanged through the alimentary canal, and the nourishment it

contains is lost to the body. The only means, therefore, by which this hunger may be properly appeased, is that by which the digestion may be restored, and sanguification amended, and that is, notwithstanding hunger, to abstain from food in the evening, that the gastric and cœcal digestions may not reciprocally disturb each other.

"The source of hunger will ever increase, by continually appeasing it by late evening meals, and in this way, therefore, it is as easy to starve from too much eating as from fasting: and no doubt in this way has many a person eaten himself to death, and most probably will still. We find in general that the meagerest and most sickly persons are the greatest eaters, and, on the contrary, the well-nourished and powerful eat less. That in the different condition of the digestive organs of different people, and according to the quantity of food which is taken during the day, there may be various changes and exceptions to this general rule, is self-evident. Where the youthful condition of the digestive organs is still vigorous, and the cœcum not as yet much developed, it is not necessary to be so particular about the smallness of the evening meals; and where there is in general but little taken during the day, and the quantity of food in the cœcum, therefore, small, more may be eaten in the evening, as there still remains a quantity of bile sufficient for the perfection of the cœcal digestion. The longer the fasting after meals, the more bile can flow into the cœcum after the ending of the gastric digestion, and the less fear need there be of evil consequences."

Reviews.

A Statistical Inquiry into the present state of the Medical Charities in Ireland, with Suggestions for a Medical Poor Law, by which they may be rendered much more extensively efficient. By Denis Phelan, Surgeon to the County Tipperary Gaol, and to the House of Industry and Lunatic Asylum, Clonmel, &c. 8vo. pp. 324. Dublin: Hodges and Smith. London: Longman and Co. 1835.

(Continued.)

WE now resume our review of this instructive and important work, and proceed to give some statistical details which show the comparative number and extent of English and Irish infirmaries and dispensaries. The author must have incurred a vast deal of trouble and expense in collecting his information, but the good which will result from it, both to the profession and public, must afford him the most gratifying compensation for his labours. The work is similar to

Mr. Lee's on Foreign Hospitals, which we also lay under free contribution.

The following report will be read with interest.

"Number, Extent, &c. of English Infirmaries.

"1st. The London hospitals for mere medical and surgical patients, exclusive of those for fevers, ophthalmic, venereal, and lying-in cases, contain at least 2,600 beds. If we suppose that these afford sufficient infirmary accommodation to the population of that city and those counties immediately adjoining it, viz. Surrey, Hertfordshire, Buckinghamshire, and Berkshire, (in which I am not aware that there are any such institutions), the remaining population of England will be about 10,811,000, that of the metropolis and these four counties being about 2,280,000, which is one bed for every 877 persons.

"2nd. From the Rev. Mr. Oxendon's valuable tables, and other sources of information, I find that in twenty-six English counties, whose population is 9,423,175, there are, at least, 3,573 infirmary beds, exclusive of others of which we have no correct returns. This gives one bed for every 2,692 of that population. Dr. Walker informs me, that the English provincial hospitals, not including houses of recovery or lunatic asylums, contain above 4,000 beds, 'probably,' he adds, 'not less than 4,500.' If taken at 4,250 there will then be one infirmary bed for every 2,543 of the above population of 10,811,000; and the proportion of beds which the London and provincial infirmaries altogether contain, viz. about 6,850, is to the whole population of England (13,086,675) as one to 1911. And let it be recollected, that these are independent of the numerous parish workhouses, a species of charities of which there are only eight or ten in Ireland, (but which here are county workhouses), which admit a great number of bad surgical and medical cases, generally chronic and incurable it is true, but such as I shall show, often occupy the too scanty wards of our Irish hospitals.

"3rd. The infirmaries of twenty-six English counties admitted 21,145 intern patients in 1828, being one for every 403 of the whole population.

"4th. The expenditure of the twenty-seven infirmaries of twenty-four English counties, (all that are given in Mr. Oxendon's tables), which admitted 20,705 interns, was 82,975*l.* in one year. Their population is 9,010,575, and were each individual equally assessed for the payment of this sum, it would be about 9*l.* 3*s.* 4*d.* for every 1,000 persons.

"Number, Extent, &c. of Irish Infirmaries.

"5th. The population of the city and county of Dublin is 386,694. Excluding, as in London, the hospitals for fever cases, lying-in women, &c., the Dublin hospitals

contain about 685 beds, or in the proportion of one bed to 564 persons. By this it appears, that, compared with the population which they have to accommodate, there are more infirmary beds in Dublin than in London. But the Irish provincial infirmaries contain only 1,262 beds, or one for every 5,827 of the population of Ireland excluding that of Dublin city and county. The total of infirmary accommodation in all Ireland is only 1917 beds, which is in the proportion of one bed to every 4000 of the population. And let it be borne in mind, that there are no institutions like the English parish workhouses, to act as temporary substitutes here, the few county workhouses, eight or ten, being on too limited a scale, and chiefly appropriated to other purposes.

"6th. The Dublin hospitals, (of the infirmary class), admitted 7,114 interns in one year; of these 4,795 were residents of the city, and a circle of about five miles around it; the remaining 2,319 came from beyond that distance; several from the more remote counties. Taking the population of Dublin, and of the country for five miles around it, to be 315,000, there was then one hospital intern for every 66 persons residing in the city and within that circle.

"7th. On an average of three years' returns, (1825, 1828, and 1832), all the Irish county infirmaries admitted 7,846 interns annually, and the others belonging to cities and towns, 2,104, making a total for all the provincial infirmaries, of 9,950 interns in a year, which is in the proportion of one to every 746 of the population. But if we add to this number those admitted into the Dublin hospitals, and who resided in the country, viz. 2319, we shall have a total of 12,269, which is in the proportion of one to every 608 persons.

"8th. A population of about 120,000, that of the city and suburbs of Cork, supplies the north and south infirmaries with 337 interns yearly; that of Waterford and suburbs is about 33,000, and it sends an average of 430 interns to the leper hospital yearly. About 66,000 in Limerick and its liberties, supply the Barrington (city) hospital with 457 interns; the cities of Kilkenny and Londonderry, and the towns of Wexford and Mallow, whose joint population is about 62,000, supply the four county hospitals with 328 interns annually; whilst from the remaining population of the counties of Kilkenny, Londonderry, Wexford, and Cork, viz., 1,514,777, (excluding that for the city of Cork and suburbs), only 958 patients were admitted. This gives 1,552 intern patients for a total population of 281,000, of seven cities and towns, or in the proportion of one to 181, whilst the remaining population of these six counties, amounting to 1,695,000 is only accommodated with beds for 1,254 patients, or one for every 1,351 persons.

"9th. Ten Irish county infirmaries ad-

mitted 2,679 intern patients in one year. The total population which supplied this number was about 2,591,000. I have ascertained that no less than 1,390 of these patients were residents of the districts included in a circle of five miles around these hospitals; and that the population of these ten districts is about 334,000. The remaining 1,289 interns resided in different parts of these counties, at a greater distance than five miles from the infirmaries. Those who resided contiguous to these institutions, therefore, supplied one intern for every 247 of the population, whilst the more distant only furnished one in 1,751.

"10th. The only governors of an infirmary in Ireland, that I know of, who publish an account of the number of *fit objects which they are obliged to refuse annually for want of funds*, are those of the Queen's county. In four annual reports of that institution, which now lie before me, for in the years 1828, 1830, 1831, and 1832, the governors state in each report, that '*applications by objects in extreme want of the benefits afforded by admission into the infirmary were made, and the board reluctantly compelled to reject them in consequence of insufficiency of funds for their support, and from that cause alone.*' The number so refused was 2,212 in four years; that admitted 2,406. With the exception of three infirmaries, all those from which I have had reports are stated to have refused a considerable number annually, but no account of the numbers refused has been kept, except at Maryborough.

"11th. There are only thirty-six cities and towns in Ireland in which there are any infirmaries. Their joint population is about 736,638. Twenty-two of these places contain a population under 10,000 each; and and fourteen under 5,000 each. There are 230 other towns in Ireland varying in population from 17,000 to 1,000 each, in which there is no infirmary, and containing a population of 532,086; and the greater number of these are so remote from any county or other infirmary, that those who reside in, or contiguous to them, derive very little benefit, many none whatever, from these institutions, as I shall prove in a subsequent part of this work.

"12th. The total annual expenditure of all the provincial infirmaries is 27,990*l.* 17*s.* 8*d.* on the average of three years. This, for a population of 7,356,200, is at the rate of 3*l.* 15*s.* 10*d.* for every 1,000 persons, not quite one penny for each.

"The conclusions to be drawn from the above facts, and from many of a similar kind, which will be given in the progress of this work, are:

"1st. When in a rich country, hospital accommodation is found necessary in the proportion of one bed for every 1,911 of the whole population, one bed for 4,000 must be insufficient in a poor one, such as Ireland, even admitting that considerable less acci-

dents must occur in the latter, from want of manufactories, collieries, &c.

"2nd. That when in England the provincial infirmaries contain one bed for every 2,543 of the population, and are usually fully occupied, one bed for 5,827 of a poorer people cannot be sufficient.

"3rd. That when a rich country supplies its provincial infirmaries with one patient for 403 of its population, those of a poorer, which only admit one in 746, must be insufficient.

"4th. That when a population of about 315,000 of the city and neighbourhood of Dublin, supplies the metropolitan hospitals with cases considered serious enough to be made interns, in the proportion of one to sixty-six, and that of Cork, Limerick, Belfast, &c., in the proportion of one to 181, the sick poor of other towns and districts which are very extensive, and very populous, cannot be done justice to, when only one in 1,351 is admitted.

"5th. That Irish county infirmaries, though receiving patients from all parts of their respective counties, are chiefly useful to the population of the district within eight or ten miles of them; and that such must necessarily always occur under the present system, when more than two-thirds of the population is at such a distance from the hospital, that the most serious surgical and medical cases either cannot bear removal, or if removed, cannot be admitted for want of room, or of funds, or both."

The next two sections of the work relate to fever hospitals and dispensaries in Ireland, and conclude the introductory remarks. They are well worthy of perusal.

"Facts respecting Fever Hospitals.

"1st. Doctors Barker and Cheyne, in a work published by the authority of the Irish government, state, that during two years and an half of the epidemic fever of 1816, 1817, and 1818, no less than one million and an half had fever in Ireland, or nearly one-fourth of the whole population; and that the deaths amounted to 65,000 during the same period. By a careful examination of this valuable work, I find, that though the epidemic raged in all parts of Ireland, and the most laudable exertions were made by the government, and a great portion of the wealthier and middle classes, only seventy-two fever hospitals were established throughout the kingdom, though the idea of contagion haunted every mind, and houses of recovery, and whitewashing, were looked on as essentially necessary to check the epidemic. The population of the seventy-two cities and towns in which these hospitals were got up, and of a district of three or four miles around them, was about 1,455,168, so that there still remained, as I shall afterwards shew, at least 4,317,248 persons who were unable to avail themselves of fever hospital

accommodation for such amongst them as became affected.

"2nd. Fever has been seldom less prevalent than in the three years ending 1831; yet, during these years the Cork-street and Hardwicke fever hospitals, in Dublin, and the fever wards of the new Meath hospital, admitted 5,702 fever patients annually, giving a proportion of one to 66½ of the whole population of the city and county of Dublin, *from which alone, with so few exceptions as scarcely to deserve notice, they were sent.*

"3rd. The forty-six provincial fever hospitals given in the parliamentary report of 1832, admitted 7215 cases annually, on an average of three years. I know of sixteen others, from which, though then established, no returns were given, and which are on as extensive a scale as the former. We may, therefore, fairly assume, that these sixteen hospitals admit fever patients in the same proportion as the forty-six; the total admissions for the sixty-two must then be about 9,724 annually, and including those received into the Dublin fever hospitals, 15,426. The county fever hospitals, therefore, admit one patient for 760 of the population.

"4th. By very accurate returns with which I have been favoured by the medical officers of twenty-three provincial fever hospitals, I find that these twenty-three admitted 5,516 in one year (1833), *of whom 4,499 resided within five miles of these institutions, and 1,017 came from a greater distance, but very few beyond eight or ten miles.* The population which supplied these 4,499 was not above 300,000, and that which furnished the 1,017 about 250,000, which gives one fever patient for every sixty-six persons *within five miles of a fever hospital, and one for 236 beyond that distance.* To these facts I request the reader's attention, for reasons to be hereafter explained.

"5th. The population which supplies these 5,516 patients to twenty-three fever hospitals being about 550,000, that from which the sixty-two are chiefly supplied cannot be above 1,483,000. Add to this the population of the county and city of Dublin, (380,165), we have the total of that which, from its contiguity to fever hospitals, is enabled to derive any advantages from them; leaving about 5,284,000 persons, whose remoteness from these institutions, with other causes to be explained, render it quite impossible for them to derive any whatever.

"6th. Calculating the number of fever cases that annually occur in Ireland in ordinary seasons, from data which will be hereafter given, I am of opinion, that it cannot be under 107,800, or one in seventy-two of the whole population: and as only about 15,436 of these get fever hospital accommodation, 92,274 must pass through the disease in their own residences.

"7th. As Leinster contains twenty-eight fever hospitals, Munster twenty-nine, Ulster seven, and Connaught two, the relative

number relieved and unrelieved in each province may be readily estimated; especially if the reader bear in mind, that fever patients rarely come to these institutions from beyond a distance of six or eight miles; the greater number only from within four or five.

"The conclusions to be drawn from these facts, and others of the same nature, are too obvious to require that they should be fully stated here. They prove that when fever becomes epidemic, *there has not been, and there is not, any machinery at the command of the public authorities at all adequate to meet the emergency—that even on ordinary occasions wherever there are fever hospitals, it is found that fever does occur in the proportion of one patient, at least, to every sixty-six of the population—and that a vast number of persons are so circumstanced as to be totally deprived of any of the advantages attending fever hospitals.* These, with other circumstances, to which I shall hereafter more particularly refer, prove how very inadequate our fever hospitals are, as at present managed, or indeed however well managed, to answer the purposes for which they were intended, to meet the wants of the sick poor labouring under fever.

"Facts respecting the Inefficiency of Dispensaries.

"1st. Numerous as these institutions are, I could point out many populous districts of eight, ten, and twelve miles in extent in which there are none.

"2nd. In a great many counties the number of these charities is too few for the population. For instance, in the county of Down, they are to the whole population only as one to 35,000; in Leitrim, as one to 23,000; in Longford, one to 27,000; in Galway, one to 28,000; in Monaghan, one to 24,400; in Antrim and Fermanagh, one to 21,000; in Carlow, one to 20,000. *In Mayo no Dispensary has been presented for these two years.* As each Dispensary has usually only one medical officer, it is impossible for him to attend the sick poor of such large populations, as I shall explain in a future chapter.

"3rd. A considerable number of our dispensaries are attended by non-resident medical men, many of whom live at such inconvenient distances from their respective districts, that with all the attention I know some of them discharge their duties, it is often physically impossible they could do so efficiently, or that the sick could obtain that prompt medical attendance so essentially necessary in dangerous cases."

The facts accumulated by Mr. Phelan, will enable the legislature to form a correct conclusion as to the present state of hospitals, infirmaries, fever hospitals, and dispensaries in England and Ireland. This was the object of the author, and he has successfully attained it. His work will materially contribute to the cause of medi-

cal reform; and to the improvement of public charities in Ireland.

Our author now commences his work, and his first chapter is entitled "Classification of Irish Medical Charities." This is brief, and is as follows:

"Classification of Irish Medical Charities."

"The medical institutions intended for the relief of the sick poor of Ireland, may be classed under the following heads:

"1st. Those which are entirely supported by annual parliamentary grants; of this class I know only of four, viz., the Westmoreland Lock Hospital, the Richmond Surgical Hospital, Whitworth Medical Hospital, and the Hardwicke Fever Hospital, all in Dublin,

"2nd. Those entirely supported by funds left in trust by individuals, as the Leper Hospital in Waterford.

"3rd. Such as obtain parliamentary aid in addition to the properties willed by individuals, but for which, neither county presentments, nor private subscriptions are had, as Stevens' Hospital in Dublin.

"4th. Such as obtain parliamentary aid in addition to private subscriptions and donations, as the Cork-street Fever Hospital, and the Hospital for Incurables in Dublin.

"5th. Charities supported by parliamentary grants, by private subscriptions, and by the income arising from properties of various kinds, as the Rotunda Lying-in Hospital, in Dublin.

"6th. Charities whose funds are chiefly supplied by subscriptions, by county presentments, and by parliamentary grants, as Mercer's and Jervis-street Hospitals, in Dublin, all the county infirmaries, and the Limerick Fever and Lock Hospital.

"7th. Those entirely supported by county presentments, as all the district lunatic asylums.

"8th. Those supported by county presentments, and by private subscriptions and donations, as all the fever-hospitals (except the Cork-street and Hardwicke) and dispensaries.

"9th. Charities whose support arise from properties left in trust, and from the fees paid by the medical pupils, as Sir Patrick Dun's Hospital; or by private subscriptions and such fees, as the Baggot-street Hospital.

"10th. Charities entirely supported by private contributions, as many ophthalmic and lying-in institutions, in the large cities and towns, and a considerable number of dispensaries, for which, latterly, presentments have not been obtained.

"From this variety in the mode of obtaining funds for our medical charities, it is evident, that there must be considerable diversity in the constitution and management of the different classes, even of those hospitals which are all equally intended for the admission of surgical and non-contagious medical patients."

Relating to Irish Medical Charities;" and contains a correct and full account of the various legal enactments upon the subject. These we must quote at length.

"Acts relating to Irish Medical Charities."

"A short account of the principal clauses of the acts of parliament which regulate our county infirmaries, fever hospitals, dispensaries, and lunatic asylums, appears necessary to enable the reader to perceive the advantages as well as the defects of these valuable charities; especially as I shall have to shew, that some of the chief defects of the first depend on particular clauses of these acts, which, if I am right, require to be revised and amended before any great improvement can take place in respect to these institutions.

"Acts relating to County Infirmaries."

"The 5th and 6th Geo. 3, (of the Irish parliament,) made provision for the erection and establishment of one infirmary for the relief of the infirm and diseased poor in each county in Ireland. In twenty-three counties, the act directed that the hospital should be built in or near the county towns, without any reference to the convenience or inconvenience of such situations to the majority of the population; many of these places being at the extreme end of the county.

"In seven counties, a site remote from the assizes town was specified. The counties of Dublin and Waterford were entirely omitted, probably, because there were hospitals in each, viz., Stevens', the Meath, and Mercer's, in the former, and the Leper Hospital in the latter. The primate, lord chancellor, bishop of the diocese, and the rector or vicar (of the parish in which the infirmary was directed to be built), along with donors of twenty guineas, and annual subscribers of three guineas, form a perpetual corporation, for the management of such infirmaries.—The act states, that "no person shall be capable of being elected, (surgeon) who shall not have served a regular apprenticeship of five years to a surgeon, and have likewise undergone an examination before the surgeon general, the visiting surgeon, the two assistant surgeons, and the resident surgeon of Stevens' Hospital, and the five senior surgeons of Mercer's Hospital," and that he shall produce their certificate, "that he is qualified to be a surgeon to said infirmary." The election of the surgeon was then, as it still is, in the hands of this corporation.

"By this act, the sum of 100*l.* a year is ordered to be paid each infirmary surgeon by the public treasury, a provision which is still in force; and grand juries were authorized to present from 50*l.* to 100*l.* a year on each county, for the use of its infirmary. The north and south Cork infirmaries, which before were supported by voluntary subscription, were allowed 50*l.* a year each, by grand jury presentment, and a similar sum from the treasury; and a like provision was made

in respect to the Inn's Quay Hospital, (Jervis-street,) Mercer's, and the Incurable Hospital, in Dublin; the county presentments for these being limited to 150*l.* a year.

"The next act, 7 and 8 Geo. 3, provides, "that no person shall be appointed physician to any county infirmary, who shall not be examined and certified to be duly qualified, under the seal of the King and Queen's College of Physicians in Ireland." This was the origin of the exclusive privileges enjoyed by Dublin medical and surgical graduates, in being alone eligible, as physicians and surgeons to county infirmaries in this kingdom.

"The act of the 36 Geo. 3, extended this exclusive privilege to the members and licentiates of the Dublin College of Surgeons. It provides, that 'no person shall be capable of being elected surgeon to a county infirmary, who shall not previously have obtained letters testimonial of his qualification, under the seal of the Royal College of Surgeons in Ireland, and that no other qualification or examination shall be necessary.'

"The 45 Geo. 3, enabled grand juries to present 600*l.* a year on each county for the infirmary. In this act provision was first made for the establishment of dispensaries in Ireland. It states, that '*the distance of many parts of each county from the infirmary therein established, does not allow to the poor of those parts the advantages of medical aid and advice, which such infirmary was proposed to afford*;' a state of things, which I shall just now shew, applies to the present as well as to the period at which that act was passed.

"The 46 Geo. 3, makes provision for obtaining information respecting county infirmaries, and the application of their funds, by making it imperative on the governors of each infirmary, to transmit an annual statement to the commissioners of imprest accounts, detailing all such circumstances as might be supposed necessary to be communicated to the government, or the legislature. And the same act provides, but in a very inefficient manner, as the result has shewn, for the inspection of county infirmaries. It directs, that on a representation being made to the Lord Lieutenant of Ireland, by the commissioners of imprest accounts, '*it shall and may be lawful for him to give directions to the inspector general of prisons in Ireland, or such other person as the Lord Lieutenant may deem most eligible*,' to visit, inspect, and report on, the state, management, &c. of these institutions.

"The 47 Geo. 3, extends the infirmary acts, which before were only in force in counties, to such counties of cities, and counties of towns, as no local act had been passed for.

"The 49 Geo. 3, extends to counties of cities, and counties of towns, the provisions of the forty-fifth of the same reign, relating to raising any sum, not exceeding 500*l.* a year, in counties at large; and it provides,

that if there are two infirmaries in any such place, the 500*l.* shall be divided between them in equal shares.

"The 54 Geo. 3, made provision for enabling grand juries to present an additional sum of 100*l.* a year, to be paid the surgeon of each infirmary, whether of a county, city, or town, in addition to the 100*l.* a year to which he was entitled from the public treasury. The preamble states, 'and whereas the said sum,' (of 100*l.* paid by the treasury,) 'from the great increase in the necessities of life, and other circumstances, is inadequate to the fair remuneration of the services of such surgeon; and in consequence thereof, it has been found impossible in some counties to procure persons properly qualified according to law, to accept such situations.' It also directs that a certificate of good conduct, and a copy of the letters testimonial of the surgeon, shall be laid before each grand jury so presenting this additional 100*l.* And, as a condition on which the salary is to be presented and paid, the infirmary surgeon is, by this act, required to give 'his attendance and professional assistance, without any other, or further fee or reward, to the prisoners and others in the gaol of the county, to the infirmary of which he is surgeon, if such gaol is within five miles of such infirmary.'

"Hitherto subscribers of three guineas were empowered to vote at all meetings of governors, the power of doing so commencing on the 25th of June next following the payment of their subscription. But by this act, no annual subscriber is permitted to vote at any election of an officer in an infirmary, unless his subscription has been paid two years before such vacancy occurred; a regulation which it would appear has greatly affected the funds of these institutions though it had not the effect of preventing the practice of new voters taking a share in such elections, the object contemplated by the framers of the act.

"This act contains another, and a very important clause, but one which must have been, as it has been, inoperative, in consequence of the machinery by which it was directed, or rather permitted, to be put into execution. It provides, that, 'whenever the governors of any county infirmary shall deem it expedient to establish a second within the same county, it shall and may be lawful for them to do so, taking care that such infirmary shall not be situated within ten miles of the first,' and it further adds, that whenever two such infirmaries are established, the surgeon and apothecary of each, are entitled to receive one half of the emoluments provided for surgeons or apothecaries of infirmaries; that is, each surgeon is entitled to 100*l.* a year in place of 200*l.*; each apothecary to 15*l.* in place of 30*l.*, marked out by the same act as the maximum of his salary. And the surgeon of such second infirmary must also be

a graduate of the Dublin College of Surgeons.

"I shall, hereafter, shew how little probability there could be, that under this act, additional infirmaries should be built, as the only parties intrusted with the power of deciding on the erection of such second hospitals, are those that have the greatest interest, that there should be only one infirmary, and whose feelings must be most adverse to any additional one.

"The clause which provides for the payment of a *maximum* salary of 30*l.* a year, to the apothecary of an infirmary, makes it imperative, that he 'shall have duly served an apprenticeship,' by which wording, licentiates of the London Apothecaries' Company are qualified, as indeed they ought to be, to hold such situations, though otherwise disqualified by the Irish apothecaries' act from practising in this kingdom.

"By the 1 and 2 Geo. 4, those provisions of acts which vest in commissioners for building gaols and lunatic asylums in Ireland certain powers for the valuation of any fit premises for such institutions, is extended to the governors of infirmaries, who are thus enabled to select the most wholesome and convenient sites, paying only according to the valuation of a jury empaneled by the high sheriff.

"The act of 1833, called the Marquis of Westmeath's, though differing widely from that most extraordinary, and I may well add, most injudicious one, introduced by that nobleman, provides, that life-governors of infirmaries—donors of twenty guineas—shall not have the power of voting at any elections of medical officers for twelve months after the payment of such donations. This act, as well as the grand jury bill of the same date, continues the monopoly of the Dublin colleges.

"The Irish grand jury act of 1833, makes it imperative on the surgeon of each county infirmary, to send, before the special sessions assembled for the consideration of presentments, an account of the number of intern and extern patients treated since the date of the preceding presentment: and the treasurer is also obliged to lay before them a certificate, signed by five governors, that such surgeon has faithfully executed his duty, and is a graduate of the Dublin College of Surgeons; without which, the additional sum of 100*l.* a year, (which the Marquis of Westmeath's act makes it imperative on the governors to apply for the use of the surgeon exclusively, and which before it was optional with them either to give or withhold), cannot be granted.

"An act of the Irish parliament, the date of which I forget, made a very strange alteration in the financial affairs of the Queen's county and Tipperary infirmaries. Leaving the donation for a life-governor still at twenty guineas, it enacted that the sum to constitute an annual governor should be only one guinea; and that on the pay-

ment of the latter sum for ten years in succession, such subscriber of only ten guineas in the course of ten years became a life-governor, though one paying down a lesser sum than twenty guineas at one time would not be entitled to the same privilege. I have reason to know, that both institutions have suffered considerably from the effect of this unaccountable act."

(To be continued.)

—o—

A Series of Botanical Tables and Tables of the Materia Medica, designed for the Use of Students preparing for Examination at Apothecaries' Hall; illustrated with numerous Engravings on Wood, and Four Coloured Medico-Botanical Maps of Europe, Asia, Africa, and America, shewing the Geographical Situation of all the Plants in the Pharmacopœia. By W. K. TOASE, F.L.S., Lecturer on Botany and Anatomy. 4to. London: 1835. Longman and Co. Four Coloured Maps. Price 4*s.*

THIS is an exceedingly useful work to medical students, and ought to be in the possession of every one of them. The tables are most instructive, and the coloured maps contain the names of the medicines which each country supplies.

Table 1 contains a key to the Linnæan system, with a corresponding arrangement of medical plants. Each class is illustrated with a wood-cut, and all the medicines belonging to it enumerated.

Table 2 contains a key to the Jussieuian system, with a corresponding arrangement of medical plants, illustrated with wood-cuts. Then come four coloured medico-botanical maps of Europe, Asia, Africa, and America. These maps alone are worth the price of the whole work.

Table 3 shews the parts used, properties, doses, active principles, pharmaceutical preparations, and forms of exhibition of medical plants, with a reference to their Linnæan and Jussieuian classification.

Table 4 shews the atonic compositions, properties, doses, pharmaceutical preparations, and methods of obtaining these articles of the materia medica, which are not contained in the preceding table.

Thus the student has, in a concise form, what he requires on botany, materia medica, doses of medicines, forms of prescribing, and atonic composition. The book is an excellent one for those preparing for examination at Apothecaries' Hall. It only requires to be known to be encouraged.

MEDICAL INSTITUTIONS IN IRELAND.

To the Editor of the London Medical and Surgical Journal.

Statistical Inquiry into the Present State of the Medical Charities of Ireland, with Suggestions for a Medical Poor Law. By DENIS PHELAN, Surgeon to the House of Industry and Lunatic Asylum, &c. Clonmel, &c.

PERMIT me, as one of your constant readers, to draw your attention, and that of the profession at large, to a work which has just made its appearance, on the present state of the medical charities in Ireland. The author, Mr. Denis Phelan, was one of the few Irish county practitioners that were examined before the medical education committee last year; but since that period he has collected together, not without great expense and immensity of labour, a vast mass of documents from every part of Ireland, shewing the many glaring defects under which most of the Irish medical charities labour: a work of this nature was long wanted, and will prove of the highest value to those members of the legislature who feel an interest in such subjects, as well as to the medical profession, and to such governors of hospitals and dispensaries, &c., as are anxious to improve their respective institutions. It seems, from a variety of causes, the want of adequate regulations, neglect of governors, and a vicious system of management, that numerous as the medical charities in Ireland are, and large as the sums appear which are annually expended in their support, a *vast portion of the sick poor of that country neither do, nor can obtain relief by their means.* Many curious statistical facts are here for the first time noticed; and some of the highest importance, as shewing that the present system of medical relief is highly objectionable; that the infirmaries have not dispensaries connected with them; that though considerable sums are expended in fees to medical officers of infirmaries, yet that the system of visiting the home patients, who cannot attend the infirmary, is very rarely practised; that such is the locality of the Irish county infirmaries, that often more than two-thirds of the population are at such a distance from the hospital, that they cannot avail themselves of its aid, and that above all, there being only one medical officer to such hospital, the duty is usually most imperfectly discharged. It will sound curious to those familiar with the character of English hospitals, to learn, that in the county infirmaries of the sister kingdom, no competent medical officer permanently resides in these hospitals, and that in every county in Ireland (Limerick and Louth excepted), there was only one medical officer or surgeon to the infirmary. Most of these medical officers or surgeons are in *full private practice*, and are often called

many miles distant to visit a private patient; and where (as must often be the case) any of these casualties occur which require prompt assistance, where is it to be found? Nay, in a great many hospitals, the apothecary is non-resident; he has a shop in the town, has his own private business to look after; and when, in the surgeon's absence, an unfortunate patient comes in with a bad compound fracture, or an aneurism bursts, or hemorrhage suddenly takes place from a stump after amputation, he also, perhaps, is as difficult to be found as his superior. Even two medical officers, if they have only a moderate share of private practice, would be insufficient to attend to an hospital with forty or fifty beds, and devote a reasonable portion of time to attendance on the out-patients, and visit them, when necessary, within a reasonable distance. The non-appointment of a second medical officer is shewn by the able author of the present work, to be fraught with the greatest injury to the poor, as well as an unjust attempt at monopoly. Of the truth of this, the present work abounds with ample illustration. The poor of Ireland, as well as the profession and public at large, owe a deep debt of gratitude to our talented author for the uncompromising manner in which he probes the many abuses to the bottom. The work abounds with a large body of evidence relating to every branch of medical charity, and with a detail of many very useful suggestions and enlightened observations on the best mode of removing the various defects and abuses now existing. It is impossible, even in a cursory manner, to glance at the multitude of objects comprised in this most useful volume, which ought to be in the hands of every person engaged professionally or otherwise in the superintendence of medical charities. On the subject of gratuitous attendance on the part of medical officers, our author has the following observations, which seem to coincide with the opinion maintained with great ability in one of your late numbers:—"Is it ever found, he asks, that duties which require considerable personal and mental exertion, day after day, and month after month, are well performed gratuitously? Do lawyers, attornies, or even clergymen, give their services on such conditions? why then should medical men be expected to do so? But if from competition and other causes, some young and comparatively inexperienced person offer to fill such situations, is it in human nature that they will toil and search without the prospect of any compensation?" He gives the Dublin Lock Hospital as an illustration of this, which was at first attended gratuitously, but it was found expedient to alter the system. "When a daily and laborious duty is required," he adds, "as in hospitals combined with dispensaries, it should always be borne in mind, that it must be entrusted to the youngest and least experienced, for

the medical man of character and standing will not undertake it. He does not require such adventitious aid, he has already reached a certain rank in his profession, and though such may not be the case in England, it is a well known fact, that in Ireland the physician or surgeon that is known to devote much of his time to visiting the poor, or that attends a dispensary, I mean in a town of any considerable population, *is sure to be least employed, and to suffer in a pecuniary sense for his humanity.* Gratuitous attendance, therefore, must always have this effect, and the services of those of more mature judgment cannot often be made available for the poor under such a system." Among other improvements, he enters largely into his plan of establishing district dispensaries, and gives a succinct view of the probable expense of erecting and establishing such district general hospitals and dispensaries, as well as the sources from which funds may be raised for their support. There is also a useful chapter on the mode of ascertaining the objects entitled to receive relief from medical institutions, together with suggestions for a medical poor law for Ireland. Nor does he omit an account of the district and other lunatic asylums, and the statistics of houses of industry. In short, this able writer has neglected no department of his subject, and his suggestions are such as must command attention. There will not be wanting interested men in the profession in Ireland who will maintain existing abuses, but let the present work be read in both countries, and it will not be long before the exposure of abuse will be followed by correction and removal.

MEDICUS.

A REMARKABLE CASE OF GALL-STONES,
CONNECTED WITH DELIRIUM TRE-
MENS.

To the Editor of the London Medical and Sur-
gical Journal.

SIR—If you consider the following case worthy of notice, perhaps you will give it a place in your valuable journal.

I am, Sir, your obedient servant,

H. S. CALDWELL, M. D.

Camberwell, Oct. 23, 1835.

Mr. B., who is about fifty years of age, was formerly an officer in the navy, and has, for some years past, been living upon a comfortable independency. His habits were generally considered sober, although not unfrequently, he had recourse to spirits to aid digestion.

About the beginning of May last, I was called up in the night to visit Mr. B. His countenance was then pallid, although agitated, tongue white, clammy, and tremulous, hands very unsteady, pulse and skin quite natural, the whole system free from pain.

But what had produced the present alarm was, a distressing delusion, under which he had been labouring for several days, that his wife was endeavouring to wean from him the affections of his son and daughter, by a former marriage. The absurdity of this was evident, and reasoning had a momentary effect of quieting him on the subject. But after a day or two, he became so ungovernable that it was requisite to place him under restraint. For about two months he derived much benefit under the judicious care of Dr. Uwins at Peckham Asylum, and his mind having become more composed, he was allowed to return home. After Mr. B. left the asylum, I occasionally attended him, and his general health, which was greatly debilitated, seemed to improve, but there were at times symptoms about him which threatened a relapse.

On Monday, August 30th, Mr. B. was seized while at church with severe pain in the epigastric region, which was relieved after taking some ol. ricini. On the following evening the pain returned. I then saw him rolling upon a sofa in great agony. The pulse and skin were natural, the pain *not* increased by pressure. Anodynes and antispasmodics were administered, but produced no relief. In a short time, the urine became exceedingly high-coloured and muddy, while the feces, on the contrary, were remarkably pale. As some obstruction appeared to exist in the biliary ducts, Mr. B. was treated accordingly. Previous to the 6th of September, there was no fever; the pulse then rose to above a hundred, and an acute pain was now felt under the edges of the ribs in both sides, as also under the scapulæ. After the application of leeches, the pain subsided, and the pulse fell to eighty. After this, the white of the eyes became yellow, and gradually in succession, the whole surface of the body. The tongue, as usual, was clammy and tremulous, but except in the commencement of the attack, there was neither nausea nor sickness, and during the intervals of pain, the patient relished his food as usual.

On the 8th, while under the influence of medicine, something was heard to rattle in the night-pan, which proved to be nine gall-stones, the colour of verdigris. Next day he passed five more, and on the following day, one.

A favourable change now took place in Mr. B.'s appearance and feelings, which was very evident to all who knew him. An aperient mixture, containing hydriod. potassæ, as previously prescribed, was taken daily, and all went on well until the 29th, when the pain again returned, and continued violently for six hours, without intermission. Next day he passed ten more gall-stones. On the following day, October the 1st, three; and on the 2nd, two; in all, 29 calculi, which are at present in my possession. Ten of them are as large as a middle-sized hazel nut; the

others somewhat smaller, and nearly of a triangular form; the whole weighing 163 grains.

After passing these calculi, the excretions gradually became natural, and a very remarkable improvement has since taken place in Mr. B.'s health, both in body and mind. His complexion is now clearer than it has been for years past; and his *temper*, instead of being irritable and captious, has, to the great comfort of his excellent wife, become mild and agreeable.

P. S. This case is also well known to — Phillips, Esquire, surgeon, Albion-street, Hyde-park Terrace.

—o—

CAPSICUM IN VARIOUS DISEASES.

To the Editor of the London Medical and Surgical Journal.

SIR—I shall feel much obliged to you for an early insertion of the following communication in your valuable journal.

I am, Sir, your obedient servant,

A. TURNBULL, M. D.

48, Russell-square, Oct. 13, 1835.

Having used capsicum in various forms in amaurosis, weakness of sight, and deafness, with great benefit, I am desirous of imparting this information for the benefit of others. I shall not at present relate any cases, but reserve them for a future period, when I have accumulated still further experience upon this subject, upon which I have been engaged for the last eighteen months.

The first form is that of tincture, made by macerating one pound of powdered capsicum in two pounds of alcohol for seven days, and filtering. In diseases of the eye, this tincture is to be rubbed over the whole of the forehead and temples for fifteen minutes once a day, and should not be washed off before the expiration of six hours. For diseases of the ear, the same tincture is to be rubbed over the mastoid process, and in front of the ear, and to be allowed to remain for the same length of time.

The second form is made by evaporating the tincture to a thin extract, and is to be used in the same way by friction and allowed to remain for the same length of time. The third form is made by mixing one dram of the extract above mentioned with one, two, or three drams of lard, and to be used in the same way.

In some cases I have first rubbed the tincture for five minutes, and then applied the extract or ointment immediately afterwards, and allowed it to remain for six hours.

The effects of these applications are great heat and redness, which continue for some hours, when they disappear, leaving the part upon which they have been rubbed in a perfectly natural state.

DEFENCE OF THE NEW POOR LAW.

To the Editor of the London Medical and Surgical Journal.

SIR—Although a shelf of my library begins to groan under the weight of the London Medical and Surgical, yet have I never found occasion to protest against the reasoning of its editor until now. The following remarks on the report of the poor law commissioners I cannot pass over without saying a few words:—

“They (the commissioners) advertise for the lowest bidders, and obtain young and inefficient officers. They seem to consider disease among the poor unworthy of the best treatment.” Presuming to appoint myself pleader for the defendants, *i.e.* the young men of inexperience, let us proceed to argument.

The fact, sir, is notorious, that when an old practitioner is parish surgeon, the paupers are invariably consigned to the care of his assistant. The great man may now and then condescend to see one of the “*interesting cases*,” but his calls are “*like angels’ visits*,” nor is it to be wondered at—how is it possible that one in extensive practice can visit a number of private patients scattered east, west, north, and south; and see also a host of parish poor. Now, supposing the assistant to be equally skilful with a young man who has just begun to practise in a parish—which think you is most likely to exert his talents for the benefit of the sick? he who is seeking a practice and knows that the good name he obtains among the poor will lead to his future advancement, or he who has no spur of action but his (too often pitiful) salary, and who in many, very many instances, is glad to run over the paupers as fast as he can, in order to get home, and compound a formidable list of draughts, &c., for his master’s patients of a more profitable class. I am utterly at a loss to conceive what is to become of the juniors should the commissioners ever adopt your mode of procuring for the poor “the best treatment:” the worthy gentlemen would hardly like to trust themselves in the hands of those whom they had declared unworthy to treat the poor, and their elite friends would certainly have the same feeling, so that the raw youths just stepping from the hospital in all the pride of conscious power, would have but this alternative, either to turn their hands to some other craft, or to advertise that they undertook to cure for love, not money. Doubtless they would be happy enough to catch a few outcast souls who had no parish, and a few also of those demihonest thrifty beings of a somewhat higher grade, whom we see so frequently stealing the benefits of our abused charities. Well then, Mr. Editor, tell us how many years do you think the youngers ought to do “all for love?” how long before they would be worthy

to presume upon the treatment of a decentish sort of a respectable patient? say a substantial green-grocer—"any thing you like to begin with"—how much longer before they might safely undertake the care of a lawyer's wife without incurring the hazard of an action for damages if the gentlewoman died? Of a surety you do not think of dooming the rising generation to a perpetual "love-feast:" you intend that in the course of years, even when the snow of time begins to fall upon their sapient heads, that then they shall be free to touch the fees, and find, after all their lengthened fast, it has not been "love's labour lost."

It is pleasing, however, to turn from the opinion of the reviewer, and find the strong answer to his false notions thus furnished by the commissioners themselves. "With respect to the general professional qualifications of the medical men who come within the words of the act, we have relied on the diplomas of those who are charged by the legislature with the duty of examining the qualifications of the candidate for practice, being assured that the recent improvement in medical practice and education are such as in general to render the later diplomas certificates of a degree of competency *equivalent to much practice* on the parts of those who have had an earlier education." I need not add one word more; the answer is complete, and I am sure the gentlemen of the jury will find a verdict for those "young and inexperienced officers," conscientiously concluding from what they have heard, that though in many instances "their poverty, and not their will has led them into the presumption of competing with older men, and offering their labour at a lower rate, still they are deserving of much consideration, seeing that every man has a right to fix the price of his own work, whether it be good, better, or best; and that science is not always to be measured by the length of a beard, nor wisdom by grey hairs.

There are some other disreputable points in the said Review, and as the subject is one of importance, at leisure I may return to it again.

I am, Mr. Editor, sincerely yours,

JOHN C. W. DYER.

Liverpool Road, Oct. 29th, 1835.

We beg to ask, would Mr. Dyer, if dangerously ill, select his client the youngster as his medical attendant? or does he suppose that youngsters who have received diplomas are competent to treat disease? The law presumes so; but the profession is of a different opinion.—REV.

The London Medical

AND

Surgical Journal.

Saturday, October 31st, 1835.

DEGRADATION OF THE PROFESSION— STATE OF OUR MEDICAL LITERATURE.

NOTHING can bear stronger testimony to the degraded condition of the medical profession in this country than the present state of medical literature. Foreigners remark with justice how few scientific works are published, and they naturally attribute this to the dearth of talent or the want of industry; they suppose that there are few men among us capable of producing such works. They are mistaken. We venture to assert that no country in Europe gives birth to more individuals adequate to the achievement of great works in medicine than our own. It is not ability that is wanting, but the stimulus to rouse it into action: the pure love of science is like disinterested patriotism—a vision of the imagination; and the light of genius will wax dim and the sinews of labour will be unstrung, unless something more substantial than "the bubble reputation" be held out as the reward of exertion. Scientific books are not published, because they will not sell; that is, because they are not read; for if the pure love of science cannot make doctors write, still less is it to be expected that it will make booksellers publish. And why do the greater part of the profession never read? Because the infamous corporations have so crushed them down by their hateful tyranny, that they can hardly be brought to regard themselves otherwise than as servile hacks and mere *routiniers*; literature and science can aid little in drenching people with abominable liquids, or making them pay bills for the same. It is thus, ye pompous noodles of Pall Mall, and ye uncharitable curs of Lincoln's Inn and

ye sordid pill-mongers of Blackfriars, it is thus that ye, whose duty it is to uphold the honour and to guard the interests of the profession, have reduced it to a state of abasement that banishes all self-respect, to a state of penury that banishes every consideration but the means of obtaining a beggarly subsistence! If doctors do not read, however, patients do; and what sort of medical books are most likely to suit those who are necessarily ignorant of medicine? Why, trashy treatises on diet and digestion, to make people who eat too much have a reverend care of their stomachs, and consult the authors of the said treatises as a matter of course; and an infinity of other humbugs, among which those calculated to excite "high moral feeling" are not to be forgotten—such as disinterments of headless kings, and the deaths of the great unchanged (*eminent persons*)!

It is but justice to add, that the world is chiefly indebted to the "heads of the profession" for such contributions to the literature of science.

If a man wishes to bring out a really scientific work on medicine in this country, he must do it at his own expense, for no bookseller will undertake it, and he must look for readers on the continent, for he will not find them at home. It is true that he may even here be gratified with the praise of critics, who declare every book not absolutely execrable to be the best ever published in any age or nation, and with the vituperation of hireling prints, which will abuse both his writings and his character if he chance to be personally obnoxious to the Dons of their slavish idolatry, or to awaken the malignity of conscious turpitude by the expression of a single manly and generous sentiment.

The above-mentioned causes render the appearance of scientific works on medicine so rare amongst us, that if any member of the profession produces such a work, he has much reason to apprehend that a hue and cry will be

raised against him for not being a *practical man*—the wise-acres having conceived the luminous notion that a man who reads largely and thinks profoundly cannot by any possibility *act* with ordinary judgment.

Such are the present encouragements for scientific medicine in the native land of Harvey, Cullen, and Hunter. But set the mind of the profession free; let the villainous oligarchies be swallowed up in one faculty, and we shall soon see if Great Britain be inferior to other countries in original genius—in scientific ardour—or in the power of exertion, without which both are ineffectual.

—o—

LATE APPOINTMENTS IN THE CITY— ELECTION OF A RESIDENT SURGEON TO CHRIST'S HOSPITAL.

THE medical appointments attached to some of the venerable institutions of the good city of London have lately been most strangely disposed of. A little while ago the professorship at Gresham College was given to Dr. Southey, a very gentlemanly man—none more so in the profession—but who has done about as much for medical science as we have for Sanscrit philology. Nobody who knew that Dr. Copland was a candidate could have entertained an idea that Dr. Southey had a chance against so distinguished a man.

We have now to announce that a youth named Stone has been appointed resident surgeon to Christ's Hospital. The only objection we have to this gentleman is, that we never heard of him before, and therefore have no ground of confidence in his qualifications for so important an office, to which, indeed, his experience can scarcely be considered adequate. This Mr. Stone is, we believe, the son of the apothecary at St. Thomas's Hospital—Ah!—St. Thomas's—now we only hope that King Harrison may have had nothing to do with the matter. We know well that there is a formula of *sovereign*

efficacy in use at Guy's, which begins thus:—"We, Harrison, by the Grace of God! King of Guy's and All-round-about, do ordain," &c. We trust that no such *ordonnance* has been the means of flinging this Stone so unexpectedly into Christ's Hospital, where the services of an able and experienced man are seriously called for. What is done, however, cannot be undone, and we wish that Mr. Stone may fill the situation creditably; we have no earthly exception to take against him but the simple impossibility of his being at present as competent as Mr. Plumbe, who was unsuccessful.

Academy of Medicine—Reproduction of Leeches.

M. GUIBOURT read a report on the work of M. Fleury, of Rennes, on the reproduction of leeches. The author recommends, in order to preserve the species, which threatens to become extinct in France—first, to interdict their being taken during the season of reproduction; secondly, to interdict the taking of those below a certain size or weight; thirdly, to subject the right of taking them to a certain remuneration; and fourthly, to place the taking of them under the management of keepers. M. Guibourt considered that these means are insufficient, and proposes that the leeches which have already been used, should be placed in tanks devoted to the purpose, in order to be taken again at a time more or less distant. The experiment has already been made by M. Desportes, director of hospitals; who caused the leeches which had been used in the hospitals to be put into a tank in the country. Six months afterwards they were furnished gratis to the people in the neighbourhood, who made use of them with much benefit, in spite of the repugnance they at first manifested for these animals, which they knew had been before applied to other patients. In the hospitals of Paris there were annually employed five hundred thousand leeches, valued at sixty thousand francs.

M. Amussat, in the name of M. Thomson,

presented an instrument for the treatment of artificial anus. It is a kind of metallic tube, which the patient may open and close at pleasure.—*Journ. Hebd.*

The Therapeutic Influence of Atmospheric Heat By Dr. Guyot.

The first question which Dr. Guyot proposes to resolve is, "When is the temperature most favourable to the cicatrization of wounds?"

Hippocrates remarked that warm weather is more favourable than winter to the greater number of wounds. Ambrose Paré, drawing a practical conclusion from this observation, recommended that wounds of the head, in winter, should be treated by vibrations of iron heated before the fire. Since that time, most surgeons have understood the favourable influence of an elevated and uniform temperature; but this fact still remained as a simple observation; and even the essays of Ambrose Paré were almost forgotten. Dr. Guyot has just brought them forward again in a new form; and by giving to his experiments the greatest degree of accuracy, he has arrived at results, which ought to engage all the attention of practitioners.

He has experimented on thirty rabbits; and many of these having been employed a second and third time, the number of experiments amounted to sixty-four. Let us first give an idea of the apparatus, and mode of experimenting.

The principal apparatus consists of a case of wood, with four compartments one above another; each of which will contain two rabbits easily. Each is closed behind by a slide, which may be drawn out laterally; and has in front a contrivance for holding food. A vertical pipe passes through the middle of them all, and opens into each by a mouth, through which the heat passes, and which may be more or less opened at pleasure. The inferior extremity of this pipe incloses the upper part of the lamp, which burns throughout the twenty-four hours, and which heats all the compartments at once, to the degree that may be wished for. An aperture in the side of each compartment, allows the introduction of a thermometer, which constantly indicates the temperature. A strong curtain, pierced with two holes, each capable of admitting

the head of a rabbit, is nailed before each compartment, leaving the food-trough outside, so that the rabbits may have their bodies plunged in the hot air, while their heads are free.

A second apparatus is constructed after the same manner; but the rabbits are here enclosed entirely. Four windows are adapted to it, to permit a view of what passes in the interior. The first apparatus, then, gives a heat diffused over all the body except the head; the second, a heat diffused universally; lastly, topical heat is applied in the following manner. On a large bench, seven rabbits are fixed, by means of ribbons, fastened to the feet; each rabbit being furthermore enveloped in a piece of linen fastened all round him; so as to leave no part uncovered except the head, and the wounds which had been made on the buttocks. Between every two rabbits, opened a pipe, passing through the bench, and having beneath an inverted funnel, to receive and concentrate the heat of one or more lamps placed below. Superiorly the pipe opened in such a situation, as to give an equal degree of heat to the wounds of both rabbits. Let us now see the results.

Two rabbits plunged wholly into a heated atmosphere, presented nothing unusual till the temperature reached 25 degs. (of the centigrade thermometer), when the respiration began to be accelerated. At 35 degs. there was faintness, with commencing perspiration; at 40 degs. prostration, with the escape of saliva from the mouth; at 50 degs. the respiration was so much hurried, that the movements could scarcely be counted; and at 60 degs. the animals ceased to give any signs of life, after an immersion of two hours. Removed into the surrounding temperature, they gradually recovered, and were well in twenty-four hours.

Two other rabbits, one of which had suffered amputation of the thigh, and the other with a penetrating wound of the chest, were plunged into an atmosphere at 40 degs. The first died at the end of an hour; the second after eight hours.

With respect to temperature diffused over the body alone, by means of the first apparatus, the results were very strange; and one can scarcely avoid thinking that some accidental circumstance had occurred to inter-

fere with the results. Thus the rabbits supported very well a temperature from 25 to 35 degs.; but from 35 to 45 degs., the depression was constantly extreme, the appetite gone, and the respiration quickened. Above 45 deg., on the contrary, to 50, 60, 70, and even 76 degs., they remained very well; without any other general perturbation than a slight acceleration of the breathing, which often did not remain long. The author confines himself to the statement of the fact, without even attempting an explanation.

The following is the result of the observations made on the wounds submitted to this diffused temperature. Of four simple incisions in the thigh, an inch and a half in length, constantly heated to 60 degs., two were united in from four to six hours; the two others, remaining open, furnished for twelve hours a serous exudation, which gradually dried up in the form of a shining varnish, red and transparent. In the twenty-four hours which followed, a white solid matter appeared under the varnish, while the borders of the wound were drawn towards each other. The third day the wounds were reduced to a line in breadth. On the fourth the crust which remained was renewed, and the cicatrization was complete. It appeared to have taken place without inflammation; and as for suppuration, it certainly did not occur. Of four other wounds of the same dimensions exposed to a temperature of 14 degs. only, (two exposed to the air and two dressed) the first were not cicatrized till the twelfth day, the others not till the fourteenth or fifteenth, all having suppurated.

Dr. Guyot afterwards experimented on wounds with loss of substance involving the aponeurosis, an inch and a half in length, and three quarters of an inch in breadth.—Two of these wounds, submitted to a temperature of 50 degs., poured out for twenty-four hours a viscid and scanty serous fluid. They afterwards became covered with the kind of red varnish already mentioned. At the third day were perceived points on which were deposited a white solid matter, which appeared to be the "plastic matter" of M. de Blainville. This layer extended gradually, and by the seventh day appeared to form a true membrane over all the surface of the wound. At the same time the wound

contracted. On the tenth day it was not more than two lines broad; and by the eleventh or twelfth the cicatrization was complete. Two wounds of the same kind, involving the muscular tissue to the depth of two lines, exposed to a temperature of 40 degs., were cured by the fourteenth day. Others, at the ordinary temperature, suppurated, and were not healed till the nineteenth, or even the twenty-second day. The influence of a high temperature was not less beneficial in the case of wounds which had previously been treated in the ordinary manner, and which had thus been already brought into a state of suppuration.

The amputations were less successful in their results. All the rabbits died, either with tetanus, or from perforation of the intestines. The same fate attended others, in which the chest was opened by an incision in the side; but one, submitted to a temperature of 36 degs., was completely cured in sixteen days; the wound being perfectly cicatrized without having suppurated.

The experiments with the third apparatus did not succeed. The rabbits deranged it, and burned themselves at the orifice of the tube. It became necessary to abandon it; but Dr. Guyot experimented in another manner on the local application of heat. He injected into the head of a rabbit water at the temperature of 8 degs.; and into the head of another a similar quantity of water at 32 degs. Both at first gave evidences of being stunned, and of great prostration of strength; but after the interval of an hour the rabbit in which the cold water had been used appeared completely recovered; while the other remained ill and suffering for forty-eight hours. The same difference was exemplified in comparative injections of water at 8 degs. and at 32 degs. into the abdomen of two rabbits. Ultimately all the four animals recovered.

Much controversy has arisen on the action of instruments at different temperatures. Dr. Guyot says that in the great majority of cases he observed less muscular trembling, and the absence of cries, when he operated on these rabbits with instruments heated to 25 or 30 degs. But still in a great number of cases he could not perceive any difference in the action of hot and cold instruments.

Hitherto the experiments had been made only on the lower animals. It was desirable

to try them upon the human subject. M. Magendie having been made acquainted with the results obtained, and having ascertained for himself that a wound of a rabbit, round and the size of a five-shilling piece, submitted to a temperature of 45 degs., did not present at the eighth day either inflammation or suppuration, and yet tended nevertheless to cicatrization, requested Dr. Guyot to try the effect of heat first upon ulcers. It was in the wards of M. Breschet that the first four patients were treated; two others in those of M. Roux, then surgeon at La Charité; and lastly one at Val-de-Grâce.

The apparatus consists of a rectangular box, ten inches square, and twelve inches long, closed at the two extremities by a cloth nailed all round, and presenting in the middle an opening, which can be enlarged and diminished at pleasure, by means of a cord passing through a hem in the cloth, and entirely surrounding the aperture. The affected limb is passed through these two holes in such a way that the wound is placed in the middle of the box, and a door, which opens above, permits us to examine it. Into the side of the box is fixed a tube, which passes horizontally across the lid till it reaches the side of the latter, then descends perpendicularly, again becomes horizontal, and lastly vertical, in order to adapt itself to a lamp. Above the last portion of the tube is a groove, by means of which may be opened or shut at pleasure an orifice destined to allow a part of the heat to escape. An aperture in the top of the box permits the introduction of a thermometer, the tube of which being external, allows the temperature to be noted. The limb rests upon cushions.

By the assistance of this machine, and a heat of 45 deg., two patients at the Hôtel Dieu, affected with ulcers of long standing, were cured with a very firm cicatrice. Two others received only an amelioration. It is worthy of remark, that in the case of one of these last patients, the heat having reached 70 or 80 degs., the ulcer suppurated abundantly, and gave forth a very disagreeable odour, until the temperament was lowered. Of the two ulcers treated at La Charité, one healed very well, but the other did not go on to complete cicatrization. At Val-de-Grâce the treatment was interrupted before the cure.

Dr. Guyot also tried his apparatus on a white swelling. He removed the lancinating pains; but having raised the temperature to 60 degs., the tumour was found next day to be increased in volume. In another patient, operated upon for popliteal aneurism, by ligature of the femoral artery, two hours of immersion, in a temperature of 35 degs., sufficed to calm the painful cramps which had prevented sleep. The author likewise obtained remarkable relief in a case of sciatica, by a temperature of from 35 to 50 degs. But all these cases are incomplete; since either the apparatus was not applied long enough to effect a perfect cure, or the patients are still under treatment.

The local application of heat, then, has not succeeded so well with the human subject as with rabbits. But the circumstances were very different in the two cases; and it is easy to conceive that a remedy very proper for curing a recent wound, or a simple ulcer, may fail when applied to a complicated ulcer. In other respects the results are sufficiently encouraging; and during the cold season especially, in the extensive wounds produced by certain operations, the application, prudently directed, may acquire an importance of which experience alone can reveal the extent. It is for hospital surgeons to ascertain for us its value.—*Gazette Medicale*.

Observations on a Case simulating Rheumatism, with Fatty Degeneration of the Muscles and general Softening of the Bones. By M. Dechambre.

A woman, 61 years of age, of a dry and meagre habit, had been subject for a twelvemonth, without any appreciable cause, to intense pains, first in the left inferior extremity, and then in the false ribs of both sides. For six months they have been felt in the right inferior extremity and the two shoulders. There was neither redness nor swelling. While she was at rest the pains were generally not felt, but a touch, and the least movement, gave rise to them in an excessive degree. She went into the hospital (La Salpêtrière) under the care of M. Hourmann, and remained for seven months without any great improvement. At the end of that time she died.

On examination, there was found a re-

markable firmness of the cerebral substance, but no other appearance worthy of note, either in the head, the spine, or the nervous trunks. The muscles were universally of an extreme paleness, bordering a little on yellow. A great portion of the muscular tissue has disappeared, and was replaced by adipose tissue, which could be followed among the smallest fibres. The whole mass of flesh was inconsiderable: the woman appeared to have been reduced, during life, to great emaciation. The vertebræ, the humerus, the clavicles, the femurs, and the iliac bones, could be cut with the greatest facility. A smart impulse given to the left thigh fractured the neck of the femur. The interior of the bones presented universally a highly rarefied cellular structure, of a greyish white colour, and containing a great quantity of gelatinous fluid. In some places, as in the neck of the femur, and in the left iliac bone, the osseous tissue was reduced to a reddish-coloured detritus, which occupied the centre. The last of these bones alone appeared sensibly augmented in thickness, and the buttock of that side was more prominent. Nothing particular was observed in the articulations, except an erosion of the osseous tissue, of slight extent, on the internal surface of each olecranon process, and on the head of the left femur.

The author appends to this case some observations. To what cause ought we to attribute this remarkable degeneration of the muscular and osseous tissues? He ascribes the first to the long state of inaction in which the patient had lived; but as for the second, it has been observed in cases so dissimilar, that he refers it to a general disposition, whatever that may be, to deterioration of the organism. "Analysis has proved," he observes, "an unusual abundance of gelatinous matter in the bones, which have undergone this softening process; and as it is gelatine which, in the fetus and young children, supplies the place of the oily fluid which fills the osseous cells in adults, so it is observable that in the preceding case, in proportion as one organic element disappeared, it was replaced by another not so high in the scale; the muscular tissue by the adipose and the oily fluid of the bones by gelatine." It appears to us that the terms which the author has

employed do not express his meaning. Analysis has discovered in softened bones, a greater quantity of *animal matter*, but not of *gelatine*. On the contrary, this animal matter is almost wholly composed of oily fluid—which we are far from regarding as an element less elevated in the scale than the gelatinous web in the bones of young subjects. We may also observe, that if there be more medullary matter in adults than in young subjects, that does not prove the gelatinous web to have disappeared. The chief difference between the bones of the child and that of the adult, is, that in the latter, the earthy salts are more abundant, with scarcely a trace of oily fluid.—*Gazette Medicale*.

Académie des Sciences—*New Classification of the Animal Kingdom*. By M. Ehrenberg.

M. de Humboldt, in the name of the author, M. Ehrenberg, Member of the Academy of Sciences of Berlin, and Correspondent of the Institution, presented a table of a new classification of the animal kingdom into 28 classes, founded on the organization and similarity of type which pervades the apparatus of sensation, circulation, locomotion, nutrition, and propagation. The table is German.

In the system of M. Ehrenberg, said M. de Humboldt, 22 of the 28 groups belong to animals without vertebræ, and the author distinguishes these into those which have a heart, and those which are without it—into *cordata* and *vasculosa*. In the latter the vessels exhibit no pulsation. The rapid motion of the liquids they contain is often favoured by the oscillation of the internal walls of the vessels. The digestive apparatus is either simple and single, as in the *tubulata*, or divided and multiform, as in the *racemifera*; of which the last class, with hermaphroditism almost always evident, comprehends the *polygastrica* or *infusoria*.

M. Ehrenberg, in the course of two expeditions (the one in Syria and Nubia, to Dongola and the Red Sea, the other in the north of Asia and to the Caspian Sea), has had opportunities of observing the organization of a great number of animals. He has continued without remission, in Europe, his microscopical observations; but he presents his general table only as an essay capable of improvement and gradual development.—*Journal Hebdomadaire*.

Hospital Reports.

WESTMINSTER HOSPITAL.

Malignant Disease of the Antrum—Excision of the Superior Maxillary, Malar, Palatine, Lachrymal, and Part of the Ethmoid and Sphenoid Bones.

MARY BROWN, aged 46, a widow twelve years, and having had six children, residing at Codicote, Hertfordshire, was admitted, July 7th, into Queen Anne's Ward, under the care of Mr. Guthrie. She has for some time been subject to a severe face-ache, on the side affected with disease, but it was not until about nine months since, that she first noticed a little swelling of the right gum on the outer side of the alveolar process, after which the pain became more severe and stationary. She attributes this to catching cold about the time in question. The swelling gradually extended and became visible; the lower part of the cheek, from which it ascended towards the orbit, filling up the fossa canina, and at present it involves the whole right cheek, disfiguring it in a very extensive degree. The tumour is found by examination to be of a dense and hard consistence, apparently of considerable thickness, and overlaying the surface of the upper maxilla. It encroaches on the nose anteriorly, and on the ear behind; inferiorly it extends below the angle of the mouth, and above, the eye is evidently raised by the elevation of the floor of the orbit, as well as by the presence of the external tumour, which is most prominent near the outer canthus of the eye. At this point the integument of the face is thin and livid, but over the rest of the tumour it has a pretty healthy character. Soon after the appearance of the tumour in the gum, she was advised by a surgeon whom she consulted in the country, to have one of her teeth extracted, but as the tooth was sound, she deferred submitting to the operation until January last, when the last molar was removed, but without alleviating the pain, or otherwise checking the progress of the disease. Two months since, the canine tooth was likewise removed, and the gum freely lanced, by which means the pain was a good deal relieved, and the progress of the disease was rendered less rapid. Upon looking into the mouth, the tumour is seen to involve the gum, and to have numerous veins ramifying over its surface. At the situation of the last molar tooth which was extracted, an opening is seen with ulcerated margins, and extending into the palate. From this opening occasionally some black and congealed blood distils into the mouth, as well as a little unpleasant matter. Upon passing a probe through this opening into the cavity of the bone, it meets with numerous obstacles in the shape of dense but elastic substances, which appear to grow from the entire extent of the inner surface of the antrum. A little bleeding was

occasioned by making this examination: she says that at all times there is more or less of a "pricking pain" present in the tumour; but she likewise describes a severe lancinating pain, which only makes its invasion in paroxysms. Her countenance is of a yellow sallow colour, and she says it has become so since she has suffered from this disease. The appetite has generally been bad, but is better at present; bowels are costive; tongue reddish, and slightly furred; pulse 96.

18th. Since admission the tumour has increased somewhat in size, especially towards the eye, upon which it is encroaching with rapid strides. The paroxysms of pain have latterly been a good deal aggravated. She has suffered a good deal from sickness.

R. Morphæ acetat., gr. ss.

Ft. Pil. horæ somni, p. r. n. sumend.

R. Mist salin effervesc. ter die.

Appr. cataplas. panis feciei.

Mr. Guthrie having come to the conclusion that the only chance of removing the disease consists in excising entirely the bones of the face, has proposed it to the patient, who has given her consent to its being performed. A few doses of the Mist. salin. cathart. have been prescribed for her during the ensuing week.

21st. During the last two days, there has been a good deal of vomiting or constipation. Various aperients were rejected by the stomach, until a solution of sulphate of magnesia in a state of effervescence was tried, which was at last retained. This morning the bowels have been relieved two or three times, but the vomiting still continues. The tongue is furred; anorexia; thirst.

R. Liq. opii, sedativ. gtt. x;

Mist. camph., ʒ iss.

Fiat. haust. statim sumendus.

25th. The sickness has continued, although not quite so severely, nearly up to the present time, but it is now a good deal relieved. The tongue however is red, and there is a good deal of constitutional irritation.

Contr. haust. effervesc.

28th. The tumour has increased so much, especially at its upper and outer angle, that the eyelids are generally kept perfectly closed. As a little fluctuation was distinguishable at the prominent part of the tumour, Mr. Guthrie introduced the point of a lancet, and gave exit to a few drachms of pus. There is now a greater discharge of offensive ichor into the mouth, than when she came in.

30th. The face is a good deal easier than before the opening into the little abscess was made. Pulse 84, feeble; countenance has a depressed, anxious character.

August 1st. She is still confined to bed, being very weak, and subject to occasional severe attacks of sickness. The tumour remains as before, the eye being kept entirely closed by it.

8th. A very small and superficial collec-

tion of pus has formed on the surface of the tumour near the inner angle of the eye, which very much resembles a phlyzaceous pustule. The place where the incision was made in opening the small abscess, has become fistulous, and discharges a thin, glairy, brown ichor over the face.

Contr. cataplas. panis.

13th. Has less pain in the tumour, and she states herself to feel better.

15th. The face has not been exposed entirely, for the purpose of examination, for some time, and the threatening aspect of the disease was surprising to day in the extreme. A large conical tumour covered by a livid and purple integument with a fistulous opening in its centre, discharging an offensive sanies, pushing upwards the eye by the elevation of the roof of the antrum, as well as by the growth of the external tumour in front of the orbital margin; causing, by its development towards the median line of the body, a deflection of the nose to the left side; extending almost to the angle of the lower jaw below, and externally, apparently becoming lost in the substance of the parotid glands; such a state of parts as this, would, we think, be sufficient to induce even the most tenacious surgeon to inquire, whether any operation, even the most desperate that could be suggested, would not be justifiable, if it held out the least chance of success.

20th. The general health is better; has no vomiting; bowels are opened once at least daily, without the aid of any medicine; pulse 96, feeble. She has not had so much pain of late; the discharge from the fistulous opening in the face has become more abundant, and is of almost a black colour.

September 29th. During the last month the disease has not made very rapid progress as regards extent; the opening in its surface only discharges a few drops of a serous fluid, but a very considerable quantity of fœtid glairy fluid finds its way into the mouth, which however is doubtless much augmented by an increased and sympathetic secretion of saliva, as she regularly spits a pint or two daily. She has likewise had frequent attacks of diarrhœa and vomiting during the last month, which have at times been very severe.

October 5th. Upon examining the mouth to day, the opening in the gum communicating with the maxillary sinus, was found considerably enlarged, and upon passing a probe into the antrum, that cavity can be readily distinguished to be much larger than when the patient was admitted. The general health appears a good deal better, although she seldom passes a week without a return of the gastro-enteric irritation, as indicated by diarrhœa and vomiting.

24th. Mr. Guthrie having concluded to perform the operation by excising the diseased bones, and having obtained the patient's consent, her general health having likewise become in a good degree established, a

great number of pupils and visitors assembled in the operating theatre. Amongst the visitors we noticed Mr. Keate and Mr. Stanley. Mr. Hale Thompson assisted Mr. Guthrie in the various steps of the operation. The patient was placed in a chair, having the head supported on pillows, and kept steady by an assistant. A vertical incision was made through the integuments, extending from just below the tendon of the orbicularis palpebrarum muscle, to about half an inch within the angle of the mouth, and dividing completely the upper lip. By this incision the coronary branch of the facial artery was divided, and a little hæmorrhage was produced, which however soon ceased. Another incision was carried somewhat obliquely outwards and upwards, so as to avoid the parotid duct, towards the lobe of the ear, and a square flap of skin was then obtained by making a third incision from the outer extremity of this to the temple. This flap was then speedily but carefully dissected as far as the lower eyelid, from the surface of the tumour, which was thus exposed, having the remains of the zygomatic and other muscles of the face stretched over it. As the tumour had a somewhat loose connexion with the posterior part of the maxillary bone, and from its protuberance was likely a good deal to impede the further steps of the operation, Mr. Guthrie removed it at once, by making a few incisions around it with the scalpel. A large mass of dense scirrhous structure, of almost a cartilaginous hardness, was thus removed, which proved to be the anterior paries of the antrum, which had become the seat of this form of heterogeneous formation, attended with the absorption of all traces of the bony tissue. By this means, the maxillary sinus was of course laid open, and its posterior wall exposed, which was found involved in a similar state of disease. Mr. Guthrie now divided the zygomatic process of the jugal bone, by a stroke or two of the mallet and chisel, and by the same means separated its ascending orbital process from the external angular process of the frontal, which did not require any great degree of force, from the softness of the osseous tissue. In this way, the bone was perfectly freed on the outer side from any attachment to surrounding parts. Directing his efforts in a similar manner to the inner side, the maxillary and palatine bones were separated from their fellows in the line of their palatine suture, by insinuating the chisel between the two front incisor teeth. An opening being made into the right nostril by piercing the cartilage of the ala nasi, the nasal bone was separated by the chisel from the nasal process of the superior maxilla; and the lachrymal bone, and the orbital plate of the ethmoid, were then cut through with the blunt pointed knife. The superior maxillary nerve, where it lays in the sphenopalatine fossa, having been first

carefully incised with the scalpel, Mr. Guthrie, by insinuating his fingers behind the diseased mass, was enabled to raise it from its situation, but it still adhered by its posterior border to the pterygoid processes. The employment of the scalpel was here again necessary to divide the connexions, which was only effected with considerable difficulty, from the impediment caused by the motions of the tongue. When it was brought away, part of the posterior angle of the diseased sinus, where it often communicates with the ethmoid cells, was found to be left behind, and required separate and rather tedious dissection, as did also part of the glandular structure of the soft palate of the amygdala, which had participated in the disease, as well as a portion of the pterygoid plate. Here, of course, the greatest care was employed by the operator, from the proximity of the carotid, which he afterwards stated he was in great fear of wounding. Upon the division of the branches of the internal maxillary artery, and the removal of the diseased mass, some hæmorrhage occurred, which occasioned a good deal of distress to the patient, from the blood accumulating in the fauces. It was however expelled by the expiratory efforts, which were increased in violence as the blood accumulated. The mouths of the divided arteries very soon contracted, very little blood being lost during the operation, and not a single ligature being required. Mr. Guthrie now requested Mr. White to examine the surface from which the diseased mass had been removed, in order to ascertain whether any vestige of it remained behind. A little was detected at the upper and posterior angle of the cavity, most probably in the walls of the sphenoidal sinus, which being seized with a hook, was with a little tedious dissection removed. The bone was afterwards scraped.

The removal of the disease now being accomplished, and forty-five minutes having elapsed, the patient was allowed to rest a little, and some wine was administered. Her wet and bloody linen was removed, and she was placed on a bed which had been brought into the theatre for the purpose. The edges of the divided integuments were now brought together, and retained so, in the situation of the outer incision, by means of two or three stitches of interrupted suture, metallic wire being employed in place of silk; whilst the incision in those parts of the cheek and lip which were unsupported, were closed by means of the twisted suture, about five hare-lip pins being altogether employed. A little simple dressing was laid over the cheek, and a bandage lightly applied. The patient bore the operation almost without a murmur, and although the pulse after the operation was very small and feeble, yet it had fallen very little from 120, which it was before she was taken into the theatre. A little brandy and water was

administered upon the patient being removed to the ward, where the strictest quietude was enjoined.

7 P. M. Has had a quiet sleep during the afternoon, and expresses by signs that she is free from pain; there being great difficulty in articulating, as well as in deglutition: the pulse 126, is rather fuller and stronger than before.

25th. Has passed a very comfortable night, and has no pain either in the face or elsewhere: she takes boiled milk for nourishment, which however she can only swallow in small quantities. In the afternoon the bowels not having been opened, a domestic enema was administered, which in a few hours produced a free evacuation from the bowels. Pulse the same as yesterday. In every respect she appears to be going on as favourably as could possibly be desired.

26th. Passed a good night. A little tumefaction has arisen about the lower eyelid, which has a rather dark colour. Union by the first intention is taking place very quickly in the wounds of the cheek. Upon examining minutely the diseased growth, it was found to consist of grey semi-transparent tissue, apparently not highly vascular, and having its general characters more of the appearance of medullary sarcoma than of scirrhus. No remains of osseous tissue could be detected in its substance; one or two of the teeth remained impacted in the mass, the osseous alveolus being totally absorbed. The schneiderian membrane of the outer side of the nose, which was in close apposition with the diseased mass, preserved its normal character.

NORTH LONDON HOSPITAL.

Lithotomy.

Mr. LISTON last week performed the operation for stone on a little boy, aged six years and a half, who had suffered from infancy with most of the distressing symptoms of calculus. The patient having been sounded, and the presence of a stone detected, he was placed between the knee of an assistant, a small curved staff, with a groove a little to one side, was introduced—the incisions were made with a common dissecting scalpel—and the stone removed in 40 seconds from the first incision.

21st. Quite comfortable.

The patient, aged 80, whose case we reported last week, appeared to be going on very well until the 15th, when, on the unexpected copious operation of some medicine he had taken, he rapidly sunk.

Cataract.

Margaret Lake, aged 65, was admitted, Oct. 15, under the care of Mr. Liston, with cataract of both eyes. The right eye was operated on. The pupil being previously dilated by dropping in a little solution of

extract of belladonna. The left eye being covered with a bandage, the operator steadied the right one with his left hand, then with his right hand introduced the cataract needle about a line from the junction of the sclerotic coat with the cornea, and pierced the cataract: he then disentangled it and withdrew it cautiously. The eyelids were then closed, and a pledget dipped in cold water and a bandage applied.

MEDICAL BOTANY.

PLATE VI.—COLCHICUM AUTUMNALE.

(THE systematic name of the common meadow saffron).

C. autumnale, as a medicine, has been known since the days of Hippocrates. It possesses diuretic, purgative, and narcotic properties: and on the Continent, where it was recommended to notice by Baron Stoeck, it is a favourite remedy in dropsy, particularly hydrothorax, and in humoral asthma. But it does not differ in its mode of action from squill, and is more uncertain in its operation; it has not been much used in that complaint in this country. In gout and rheumatism, however, its efficacy has been fully ascertained; and in allaying the pain it may be almost said to possess a specific property. It operates on the bowels chiefly, and the nerves, and diminishes the action of the arterial system.

It is to the enterprising spirit of Stoeck, that we are indebted chiefly for the virtues of colchicum, whose experiments were made principally on his own person. The fresh root, which is the part he preferred, is highly acrid and stimulating; a single grain wrapped in a crumb of bread and taken into the stomach, excites a burning heat and pain both in the stomach and bowels, strangury, tenesmus, thirst, and total loss of appetite. The acrimony is best corrected by vinegar. The tincture and wine are now found to be a controllable formulæ, and the best. Baron Stoeck began with a drachm of the latter twice a day, and gradually increased its dose. In France it is a favourite remedy in the case of gout; for it is supposed to be the active ingredient of a celebrated quack medicine prepared by M. Husson, and by him called *Eau Medicinale*. In this country it has been very extensively used, both that as prepared in France, and a tincture and wine, as ordered by the College of Physicians, in the cure of rheumatism as well as gout.

The sensible qualities of the fresh root vary, according to the place of growth and season of the year. In autumn it is almost inert, but in the beginning of summer highly acrid: hence some have found it to be an active poison, whilst others have eaten it in considerable quantity without experiencing any effect. When it is possessed of acrimony, this is of the same nature with that of garlic and some other plants, and is entirely destroyed by drying.

M. BROUSSAIS'

*Course of General Pathology and Therapeutics;
translated and revised*

By JAMES MANBY GULLY, M.D.

LECTURE XXI.

*Cerebral Fevers—Petechial, Miliary, and
Nervous Fevers—Strictures on the Numerical
Method, as applied to the Pathology of
Typhoid Fevers.*

THE existence of a cerebral fever has been advanced: Pinel describes one, which he calls apoplectic; it is a complex entity that needs to be decomposed, a cerebral phlegmasia with or without apoplexy, complicated or not with gastro-enteritis, and which may kill at any age, though more especially at the two extremes of life, for in them encephalic inflammations and congestions are more frequent and more violent. Of course this cerebral fever was unravelled on the inspection of dead bodies: under the names of encephalitis, meningitis, or arachnitis; what belonged to the brain was attributed, and what to the digestive canal was thereto assigned. But as men unfortunately are not exempt from passions, a coterie sprung up, overflowing with fury against the physiological doctrine, that has caused this unravelling of the fever in question: they appealed to observations that were due to the sagacity of Professor Lallemand, and according to which it would appear certain that there are sometimes cerebral fevers whose existence is never suspected: at the same time they took advantage of their mistakes as to the appearance of some signs of phlegmasia after death, and led on by their horror of the word gastro-enteritis, they conceived the idea of substituting that of cerebral fever. For some years nothing else was talked about: when you were called to a patient, they would say to you, "come and see a cerebral fever:" the students got into the habit of saying that they or their friends were attacked with cerebral fever—nothing but cerebral fevers were in fashion. Now, at the bottom, what was all

this? Simply patients attacked with gastro-enteritis, accompanied with cerebral symptoms, that is to say, with gastro-enteritis that had not been arrested, and had become sufficiently intense to act upon the brain and induce nervous phenomena therein. This kind of language went on until M. Bretonneau's work on dothinentery appeared. It then became allowable to speak of the digestive canal, provided the name given to its inflammation by the physiological physicians was abjured, and that of dothinentery placed in its stead. Subsequently, it being perceived that there was great affinity between dothinentery and typhus, these two expressions were taken as equivalents, and they arranged the matter so as to aim at destroying the whole physiological doctrine of the gastro-enteritis, which they made to converge towards this common rendezvous. In this manner they got out of the predicament, and were enabled to refer to the digestive canal: they allowed it to be the chief focus of the febrile phenomena, without, however, confessing that it was inflamed—a happy subterfuge which gave them breathing time. Mine be it to combat with these assertions, and to shew you their falsehood: I will only attack doctrines, for I suppose the authors who treated of this question acted with the *bond fide* intention of advancing science: but as, on my side, the common interest of humanity commands me to prove that they, on the contrary, keep it back, I shall speak what I think of their dothinentery.

Those who make use of this term have in view to withdraw all the symptoms of gastro-enteritis from the phlegmasia of the villo-mucous membrane of the digestive canal, in order to attribute them, not to the inflammation, but to the isolated affection of the mucous follicles of that canal: this has been the great master-stroke of the inventive minds of these our days. They have insulted the rising medical generation by supposing it to be blind or insincere enough not to recognise the inflammation as indiscriminately resident in the entire mucous substance of the digestive canal, in its nervous papillæ and sanguineous capillaries as well as in its follicles. They have attempted to represent these follicles, which

are only minute folds of the mucous membrane, in which are small cysts that secrete mucosities, as ampullæ intended for absorption, an assertion of which they bring no proof, and which, on the contrary, is anything but fact. They maintain that in their dothinentery these follicles alone are affected, and that they are sufficiently influential over the system to excite violent fevers, to affect the brain, to soften the heart, to produce ataxic and adynamic phenomena: they maintain that no gastritis has existed, no encephalitis accompanying gastro-enteritis, no pulmonary congestion, no peripneumony with hepatization, that should not be placed to the account of these follicles, which are thus made the great culprits of the system. Now, to get at the importance they have assigned to them, they have collected in the hospitals a certain number of typhoid gastro-enterites, ending, for the most part, in death, and they shewed patches of follicles in a state of swelling, turgescence, suppuration, purulent exudation, softening or induration, according to the more or less advanced degree of the disease. But, as they were far from constantly exhibiting a scarlet redness, and as these speculators knew not how to appreciate inflammation in its different periods, as it was essential at any price to do away with the idea of inflammation, and as the word of command was to concede nothing on this score, they considered them authorized, by the cases in which this redness was not present, to reject inflammation in toto, careless of the impregnable objections that might be made against such a decision.

One more difficulty remained—how to make out this isolated affection of the follicles as something important enough to disturb the system, and so frequently cause death. This was not very easy to do; yet they thought to attain it by having recourse to calculations and abstractions. They say, in typhus there are so many disorders of this kind, and so many of that other; there be some that are invariable, and some that are not: those of the follicles were considered invariable, and they therefore made the disease and its results dependent on them. They also managed to conclude that typhus only exists when these follicles are diseased, a conclusion that rests on strained ratiocination, on false numerical combinations and distorted facts: I do not believe that it is because they observed them badly, but it was my place to put them in their real light before you.

If I have made no mention of the supposed petechial and miliary fevers that still occupy the Italians, it is because Pinel has already disposed of them—they are now forgotten. The efforts made to bring them again into credit have been fruitless: in vain has it been attempted to make typhus of them—they have been acknowledged to consist of a subcutaneous eruption of small trans-

parent bubos consequent on excessive transpiration, favoured by a warm climate, and which may appear in a number of diseases, having, as an essential characteristic, an accompanying mode of visceral inflammation.

I might also have mentioned the nervous fevers of the Germans, which is nothing but an ataxic or adynamic gastro-enteritis, which they, and Marcus in particular, have thought proper to regard only with reference to the cerebral or spinal irritation; but I prefer to dwell upon an affection that some people would bring into power among us, under the name of dothinentery or typhoid fever. It is, however, a mere hybrid, and in the system of those who maintain its existence, it is impossible to say whether they would make an inflammation of some other condition of it: they fancy there is an air of importance and superiority in thus applying doubts to the most evident questions.

The Numerical Method, as applied to Dothinentery or Typhus.—In order to establish this dothinentery a numerical method has been had recourse to, which I shall proceed to examine, without reference to individuals. This method is borrowed from authors of statistics, and the attempt made to apply it to medical questions. So great is the imitative tendency in man, that no sooner does a new idea arise than people hasten to make essay of it, and multiply its applications. Persons that do not think deeply, at first imagine they have found the philosopher's stone: better sense, however, in time again takes precedence, and the method is appreciated. The method that we are now speaking of is in itself good, but the proper use of it should be known; for, ill applied, it becomes of no value, or even hurtful: it may easily deceive inattentive persons; it requires particular organic dispositions for calculation that do not exist in all men, as phrenological observations prove; those who have not such dispositions, and to whom calculations are irksome, hasten to the result. So much for medical questions. In statistical questions greater rigour has been used, and more positive results arrived at; the method has been found excellent for determining the averages of births and deaths, for shewing whether one disease is more or less fatal than another, &c.: these are simple questions, to which calculation is readily applicable. But I suppose that instead of one element the question has ten; the application of the method should be ten times made—if twenty, twenty times—otherwise the result will be illusory. And remark first of all that this result, as obtained by the arithmetical physicians, does not include the causes of diseases, numerous as they are, containing as they do pathological elements as important as the symptoms and anatomical lesions, and each of them requiring a particular calculation.

Yet this method has always been employed, and by it I too have proceeded—

only, there are two ways of using it, without figures, or with figures. In the former, a certain number of facts, stored in the memory, are compared, and the consequences deduced without laying stress on the calculations; this is the manner in which all founders of systems have proceeded. Look at Sydenham and the classical writers of the last century; they give you the result of the comparison of a great number of facts without using figures, and tell you that such a cause produces more diseases than such other, that such a symptom is most frequently observed, such treatment most frequently the best, &c. This mode of proceeding has been adopted by all the men who have given an impulse to science. Then came the calculators. The figure ought to have confirmed what genius had discovered; for, I opine, it is generally genius, and not the figure, that makes the discovery. Men endowed with the power of perceiving relations are led on by the abundance of facts, and arrive at deductions previous to having employed the slow method of calculation; yet they may be deceived, and it is necessary that these men who advance the sciences, and appear from time to time in the course of ages, should be subjected to the criticism of calculators. If they fall before it, they are spurious geniuses. But to be judges of them, certain rules should be followed—the judges themselves should possess some genius, above all, integrity, and should apply their calculation to all the elements of the question.

Pass we to the application that has been made of this method to gastro-enteritis, and let us see what it has produced. It has led to the proposition, that the symptoms of typhus or dothinentery are the consequences of the affection of the intestinal follicles. Mark, of their *affection*; they first said of their *inflammation*, but became afraid of having advanced too far, and therefore afterwards confined themselves to the former term. This affection has been regarded as a specific eruptive disease, of doubtful nature, having a necessary and fatal duration, like small-pox pustules, and a progress that cannot be changed. Now, how has the numerical method arrived at this result?

It has arrived at it by multiplying observations ten, twenty, thirty, eighty times, if necessary, on a class of subjects attacked with dothinentery: but experience proves that another class with other phlegmasiæ may also have the follicles affected.

It has arrived at it by calculating from a species of treatment that is always the same; but I can positively assert that another kind of treatment would have given another result, and that the progress which they have presented as of necessity would have been changed by this treatment; you see what applications of calculation should have been by right made to answer this single objection.

It has arrived at it by giving no account of the regimen followed by the patients: but another regimen, like another treatment, would not have produced a similar number of autopsies, nor similar alterations.

It has arrived at it by keeping out of view the mode of action of external causes, or by making them vague:—whereas I maintain that a good interpretation of those causes would have thrown light on the question, and shewed the part that irritation plays in this disease; but this part has not been given, and they have even abstained from using the word irritation.

It has arrived at it by making no account of anterior irritations—a question of the very first importance to men exposed to the influences that induce the disease, among whom were some already in a latent state of phlegmasiæ. In fact a number of individuals are always to be found in society whose habits, mode of life, regimen, griefs, misery, or excesses, have rendered feeble and valetudinarian, and who go on living with points of latent phlegmasia. These individuals may be said to be victims already devoted; whenever epidemics arrive, they are the first to be carried off; and when you hear speech of deaths occurring in the space of twelve to twenty-four hours, you may be certain it is they that have been seized. The numerical doctrine neglects this important datum, which would materially modify its results, as would the ages, sexes, external causes, regimen, and treatment.

It has arrived at this result by getting rid of all the lesions of typhus other than the affection of the follicles, in order to find that alone invariably. This is false *par excellence*; for, in the first place, the cerebral phenomena are at least as constant: by them the patient dies, and I cannot see why the preference was not given to them; in the next place, these phenomena exist in gastro-enteritis, where we find no altered follicles after death, as well as in those where such are found. It is, therefore, false that this alteration of the follicles is the generative organic phenomenon of adynamy and ataxy.

It has arrived at this result by affirming that the intestinal follicles are not diseased in many acute and chronic affections other than dothinentery, in which however they are affected as well as in what is called dothinentery. In fact, very many individuals who have not exhibited the collection of symptoms to which this new name has been assigned, who have had eruptive phlegmasiæ or peripneumonies, with anterior or simultaneous irritation of these follicles, have presented them in a state of alteration similar to that of dothinentery. Here, then, is another false observation.

It has arrived at this result by making use of cases where redness had dissappeared either in the stomach or the intestines, in

order to bring the inflammatory nature of the disease into doubt. Herein it has given proof of great ignorance: it has shewn its ignorance of the displacements of inflammation, and of the fact that the stomach, after being disorganized, may be made pale by the fluids that pass through it. It has said that inflammation is a secondary and accidental thing, inasmuch as redness is not always met with; that softening was inflammatory when this redness accompanied it, and non-inflammatory when it did not, &c. Pitiful reasons! these are only circumstances of the stage, and the predominance of the inflammation; if this predominance takes place in the lungs or the intestines towards the close of the disease, the small degree of redness that existed in the stomach disappears; for the patient must drink, and the fluid he drinks carries off the sanguineous molecules of the stomach—they never thought of this simple explanation; if, on the contrary, this predominance has been maintained in the stomach, if the patient has been stimulated, if the inflammation has lasted longer, the stomach exhibits more redness or density around the softening. All these circumstances should have been carefully calculated by the partizans of the numerical method—since they love calculation, here is food for them. One might say to them, “apply your method to the different durations of the diseases, to the cases in which the patients have been thirsty, to those where they have drank water, to those where they drank something else, &c. &c.; here is matter enough for volumes; we place you on your own ground, but you must calculate everything.” It is proved that softening of the stomach depends on inflammation, and the numeric doctrine only denies this fact, because it knows not the reasons why that organ loses or preserves its redness. So, also, of that of the intestines.

The numerical doctrine arrives at the conclusion that the follicles are not diseased by inflammation, by not stating the truth as to the actual state of the organs; for, it must be told, it has frequently dared to affirm the absence of inflammation in the mucous membrane, when it was evident there. Moreover, it has not comprehended that to die after a long continued inflammation that has exhausted the powers and decolorized the blood, is to die by inflammation. By a kind of vicious circle, and striking want of good faith, it would that we should find in the individual who has languished and slowly consumed, the same redness as in him who has sunk at the onset of an inflammation.

The numerical doctrine has considered as accessory and inconstant lesions, those of every other viscera than the digestive canal, and has been content to say, that they sometimes exist, and sometimes they do not, without giving any reason for their

existence or non-existence: yet this is a point, the solution of which was fundamental in the construction of the entity, for the first question that you put to yourself is the wherefore of these alterations and their inconstancy. Instead of answering this question, it has examined the state of the organs in different acute diseases, and has entered into a cool calculation, by which conclusions have been arrived at, all of which are most attackable. Thus, as they, the calculators, almost always found a phlegmasia of the stomach in peripneumony, they conclude that gastritis is not an exclusive phenomenon of typhus—as if any physiological physician had ever maintained the contrary. All that we have said is, that inflammation of one organ may induce that of another, and that this phenomenon is complicated in all manners, and is unceasingly tending to propagation. No doubt, in the majority of peripneumonies, there is congestion of the stomach, but as soon as I have combatted the pulmonary inflammation, the gastric congestion disappears; and if, in order to resolve the former, I think it advisable to cause revulsion to the stomach—by tartar emetic for instance—I do so. Prove to me that arsenic is the better remedy in such a case, and I will give it, for I am of no party nor coterie, and I admit all means that are sanctioned by experience. This congestion of the stomach may proceed to an inflammation which will not yield to the treatment best adapted to peripneumony, but requires a specific one to itself. Similar inflammations I am in the daily habit of combatting. But wherefore conclude from this fact, that gastritis is not a symptom of typhus? What is the meaning of this two-horned reasoning? Gastritis may complicate all possible inflammations, and become so predominant as to cause death.

There may also be an enteritis, with predominating pulmonary phlegmasia; the consequence is the same—one must be treated by treating the other, or each of them separately; and we are not to conclude that enteritis does not constitute typhus, because we meet it in company with peripneumony.

There may also be peripneumony with predominating gastritis: here, the answer is the same. The manner in which we study irritation, shields us from the absurd conclusions that are drawn from these coincidences and dependencies which inflammations have with regard to each other. You will one day laugh at the serious air with which some people treat the ridiculous questions that originate in these circumstances; you will not comprehend how it was possible for them not to attain the truths which I laid down at the commencement of this course, on the subject of inflammation in general. You did not, perhaps, then know what I was driving at—you see it now. You must study that phenomenon, and not an

entity wherein there is only one particular thing, and wherein whatever is not that particular thing, is accessory and independent.

Another consequence of these calculations and comparisons, has been the assertion that the follicular patches of the intestines are to be regarded as the leading phenomenon or peculiar characteristic of typhus. But these are met with in other diseases than typhus; in small-pox, measles, peripneumony—in any disease. These patches were found in cholera, and some one announced it to me as a great novelty; but I knew it beforehand, although I had never seen it. Had we not been told that cholera principally attacks intemperate men, and such as live on with gastro-intestinal irritations? This was enough for me to know. All these questions run into each other: one solved, there is ground taken up for solving the others, provided people know how to compare and draw conclusions. "The patches," say they to us, "did not then exist, or were indistinct." A greater number of cases in which they did not exist at all might be found; but as they were moved by the interest of faction, they have put these aside as not smiling on the system they uphold. You may observe that it is not with these calculators as with physiological physicians, to whom all facts are good, and who hold by their method alone. Present a new or extraordinary fact to the latter, and they will tell you how it ought to be studied, to what organ it ought to be referred, with what vital act it is allied. With them the most empirical practice is equally interesting with the most rational; they reject nothing, and it is unjust to attribute the slightest exclusiveness or partiality to them.

The numerical method* entertaining the quixotic aim of proving that in typhus or dothientery the affection of the follicles is everything, and the rest nothing, considers itself bound to maintain that diarrhœa is not owing to an affection of the great intestine; indeed, it is forced to do so, for as the physiological physicians had proved that the diarrhœa is owing to the descent of the irritation below the ileo-cæcal valve, and as there is diarrhœa in dothientery, had that proposition been allowed to remain untouched, its entity would have been trenchanted upon, and the colon must have been considered as the seat, and its inflammation as the cause. It therefore determined to attribute the diarrhœa to the small

intestine; many people, it says, who had this affection, exhibited scarcely any redness of the great intestine: this slight alteration is insufficient to produce diarrhœa. Moreover, it adds, on calculation I observe that in the cases where it is met with, the affection of the follicles has been more frequently evident than it; therefore, it is on this affection that the diarrhœa depends. Now, this conclusion is still the result of the same mode of procedure, which consists in keeping account of the state of all the organs in patients that die in typhus, and saying that the variable or the least marked lesions do not essentially belong to it, and cannot be characteristics of it. For the rest, this mode of procedure affords no notion as to the causes of these lesions, and is reducible to the assertion, that sometimes it is the entity, and at other times something else, that produces them; which is in fact, speaking, yet saying nothing. It is not remarked that every predominant lesion may be accompanied, in an accessory shape, by all manner of secondary lesions, (since inflammation proceeds in all kinds of ways), and that what is advanced about the cadaveric lesions of other organs than the digestive canal compared to those of that canal, may be advanced in the contrary sense, about the lesions of the canal as compared with those of other organs. Lest this should not be clear to you, I will proceed to make it so.

Referring to generalities, let us suppose that there is a phlegmasia of an organ; if it is not arrested other organs become inflamed: this is a fact, and cannot be made into an entity. Let it be a gastritis: if you stay it before there has been any communication, it will have been simply a gastritis; but if you allow it to go on, it may become complicated in various ways: cold acting on the lungs, you will have catarrh or peripneumony: the digestive canal being perforated, you will have peritonitis: mental affections coming into play, you will have cerebral irritation, &c. Let it be pneumonia: there may be secondarily a gastritis, or pleurisy, or cardio-arteritis, or rheumatism; and each of these diseases may in turn predominate and become the primum mobile of the pathological phenomena and anatomical alterations.

Would you go and take them all one after the other as the centre of an entity, and say, in such an affection we found the stomach so many times inflamed; so many times thinned; the spleen so many times swelled, so many times softened; the lungs so often hepatized, or gorged, or crepitant, or tubercular, &c.? This sterile enumeration would neither show you the causes nor the connexion of all these phenomena, and would lead you to the reconstruction of the ancient entities, and to all the trash of the old ontology. How much more simple is our method, when we say that the causes should be studied, the effects followed up, that no disease has an invariable course, that inflam-

* Throughout this lecture, M. Broussais addresses himself to the refutation of the arguments that are the support of this method, avoiding, with Gallic politeness, immediate allusion to its supporters, even *en masse*. Hence the terms "it is forced," "it is determined," and so forth, which, without this explanation, might appear absurd.—J. M. G.

mation extends if not arrested, that it changes posture, &c.

The numerical method has attributed a host of secondary lesions to fever, and has regarded the affection of the follicles as the only anterior lesion. But what can it understand by fever, when they attribute to it sore throats, pulmonary or cerebral congestions, cystites, gastrites, enterites, &c.? Is fever the acceleration of the blood's circulation? but this alone could not produce so many diseases: you daily accelerate the circulation by walking, by stimulants, by violent movements, without inflammation ensuing. Is it the collection of symptoms or organic lesions of dothinentery, as indeed they say it is, in answer to the question, "what is fever?" at the same time that they enumerate both, in order to give an idea of fever? But on the one hand fever is a symptom, and I wish to know how a symptom can produce so many functional and organic lesions as are admitted in dothinentery; and, on the other hand, if fever is only a collection of lesions, I wish to know what produced those lesions. What can be said in reply, except that it is inflammation?

The numerical method pretends to determine the medium duration of diseases, and of dothinentery in particular. But what certainty is there in the duration assigned to them, unless you take account of the causes, the varieties of symptoms, ages, temperaments, predispositions, treatments, &c.? Apply, therefore, your calculation to all the circumstances and all the divisions and subdivisions of each of them; apply it to patients that have been treated in a certain manner, to those treated in a certain other manner, to those that have been purged, to those that have been bled, &c. Here is calculation enough: deal thus with all diseases, and you may make myriads of volumes, and God knows when you will finish. The numerical method is a good one, but people should know how to make use of it.

The numerical method attempts to find the essential symptoms by expunging those that are not met with in the majority of cases. It says, such symptoms are met with ten times, such others six times, others five times, and such others were altogether wanting: therefore, these are necessary and essential, and those are only secondary, and make no part of the disease. It has created factitious entities, and has lost itself in a frightful waste; and had it treated diseases otherwise than it did, results very different from those arrived at would have been obtained. And what have all these proceedings proved? that there is a host of circumstances to which its calculations have not been and never can be applied: that the succession of symptoms established by it is not, as asserted, constant: that the alteration which is given as fundamental is no longer so: that dothinentery has not an

invariable course, and that, in that form, is nothing but a factitious entity, an imaginary being.

The numerical method has rejected the name of gastro-enteritis because, according to it, the stomach and intestines are not always inflamed. If it has not always found the stomach inflamed, you know the reasons of it; I have before stated them, and they apply to the intestines also. As to the follicles, which they maintain are always affected, they never are alone inflamed to disorganization, but they may retain the marks of phlegmasia when the mucous membrane has almost entirely lost them, because their organization is more complicated, and they constitute kinds of minute parenchymata. But this is common to all the mucous membranes; the complicated tissues to which they have communicated phlegmasia, or that have it concurrently with them, retain it longer, and often exhibit more profound alterations. For the rest, I have in vain sought for alterations of the follicles, unaccompanied with that of the intestinal mucous membrane, and in this particular I have my suspicions of the veracity of the numerical method. Although it has minutely calculated all the cadaveric phenomena, it has founded the nervous phenomena on nothing, and has left them in a vague. It has not seen that the brain collects the irritations and becomes disorganized with or without traces of sanguineous congestion: it has said that the cerebral symptoms depend on the follicles—which is an absurdity—and that they should be left just as they were found. More than this: it has even laid at the door of the follicles the incipient phenomena of lassitude, headach, vomiting, &c., which indicate that the irritation is commenced in the upper portion, or that, after beginning in the middle or lower portion, it has ascended to the upper. The two latter cases may perhaps be imagined to tally with the assertion, but to say that when the vomiting is at the onset, they depend on an affection of the follicles, is really too much. The following is scarcely less: there being but slight alteration of the great intestine only three times in eighty without any diarrhoea, it has been concluded that such alteration is not requisite to the production of diarrhoea—instead of saying that this alteration was insufficient to produce it. Pain of the belly, it says, was only wanting in nine out of eighty-four times. This tells against the treatment; for this pain may be got rid of easily in three or four days, and if it lasts longer, it is in consequence of bad treatment.

As regards the gastric symptoms, we have seen that it is ignorant of their value, and makes them subordinate sometimes to the follicles and sometimes to the fever; but again I ask, what is fever? how does it produce symptoms, itself being only a symptom? how prove that it is not the effect of a

lesion? I have tired out the medical world with refutations of these false ideas, and I can scarcely imagine that there is a head so weak as to reproduce them.

In the treatment we use nothing but drugs pitted against the symptoms, and an ignorance in appreciating their effects. It is even said that any medication whatever is indifferent with regard to the progress of the disease—a pitiful falsehood, that proves how entirely the part enacted by irritation has been misunderstood.

But enough of this attempt to do away with gastro-enteritis.

—o—

A Sketch of the Medical and Statistical History of Epidemic Diseases in Ireland, from 1798 to 1835, with the Method of Prevention and Cure, as practised in the Fever Hospital, Cork Street, Dublin. By WILLIAM STOKER, M.D., Hon. Fellow of the King and Queen's College of Physicians in Ireland, &c. &c.

(Continued from page 427.)

IN 1810, the condition of the working classes being much deteriorated, partly by the cheapness of ardent spirits, but chiefly by want of employment, and that of the middle classes from want of trade (see Medical Report for that year), a remarkable revolution in the external character and nature of epidemics took place. Fevers became more typhoid or pestilential than had been before observed. The prominent symptoms were those of debility, marked by feebleness of the pulse and coldness of skin, such as had not been previously observed, and they were accompanied by corresponding alterations in the external characters of the blood, which, instead of being firmly coagulated and sily on the surface, as happened before, at least at the commencement of the disease, was seldom so at any stage of it. This was stated in my report of that year; and also that crises and septenary movements still continued. It appears also in the report of that year, that even then the aggravation of symptoms led to the question of late years so vital—whether or not a new disease, *sui generis*, had been generated here or imported from abroad? The number admitted greatly exceeded that from the same district in the preceding year, and the number of deaths was nearly double, viz. admitted, 1774; died, 154; average mortality, one in 11 & 40-77ths*.

In 1811, there was another decline of disease, seemingly also connected with a corresponding improvement in the condition of the working classes and in trade, and partly, perhaps, with a check to disease given by the Cork-street hospital. The numbers admitted, from the whole city, were 1472,

less by 302 than the preceding year. The deaths amounted to 115, or 1 in 12 & 91-116ths, a smaller average mortality than in the preceding year.

In 1812, the malignant type of distempers which first appeared in 1810, again apparently, under a repetition of similar causes recommenced; and notwithstanding the reduction of the numbers admitted in the preceding year, increased to 2265, additional accommodation being provided at the Cork-street hospital to meet the pressure. There was not, however, an increased average of mortality, the deaths being 166, or 1 in 13 & 107-166ths admissions.

In 1813 the numbers affected by distempers of nearly the same type as that of 1810, further increased; but whether owing to a more appropriate treatment in mixed cases and in distinct forms of typhoid and inflammatory disease, successfully adopted, chiefly according to the indications afforded by morbid actions, and co-existing alterations in the external characters of the blood, already intimated when treating on the pestilence of 1810, or to earlier application for admission, or to both those causes combined, the mortality in the Cork-street hospital was in 1813 less than in the preceding year. The number admitted was 2627, deaths 164, average mortality 1 in 16 & 3-164ths.

In reviewing this lessening average mortality of the prevailing fever since 1810, it should be noticed that a comparative trial was made in that year, of small bleedings in all cases of epidemic fever, on the principles of Drs. Clutterbuck and Broussais, and adopted by Dr. Mills—then one of the physicians to the Cork-street hospital—and of not bleeding except for obvious symptoms of inflammation according to opposite principles maintained by the other physicians of that Institution. The result of this truly important trial was given in tables, which were annexed to a letter first addressed by my colleagues, Drs. Barker, Hagan, and Gamble, and myself, to the Managing Committee, afterwards published in the Edinburgh Medical and Surgical Journal, No. 40, and subsequently appended to my Treatise on Fever, published in London, 1814. These tables are too extensive for insertion in this sketch. The following is a reference to them:—

In col. 1, were the different months of Dr. Mills' attendance. In col. 2, all the patients, male or female, treated by him, together with the event, whether successful or otherwise; and on the same lines in col. 3, a similar statement of all the patients treated by the other physicians during the same months; to save the trouble of calculation, the proportion of deaths to recoveries in each month, among the patients of different sexes, treated by Dr. Mills and the other physicians, was given in col. 4; underneath the total result is given; and thus the reader could, by inspection, determine the merits of

* See Medical Report for the year 1810.
By Richard Gamble, M.D.

the different modes of practice, as it affected the proportional number of deaths during the whole or different periods of Dr. Mills' attendance.

It appeared, as the final result, that amongst the patients treated by blood-letting, the proportion of deaths to recoveries was as one to 11 & 49-55ths, and amongst those treated according to the more ordinary methods, as 1 in 12 & 101-110ths, a proportion differing from the former in no small degree, and justifying the conclusion, that the treatment of fever, by small and repeated general detractions of blood, was either of little efficacy or injurious.

It must add to the weight of the above conclusions to observe, that the data on which they depend had been furnished from the most authentic sources, namely, the diet tables, in which each physician enters daily the patient's diet, and at the same time registers the date of admission and dismissal, the time of remaining in the different wards, along with the final event of each case; and the different parts of the system being so contrived as to check each other, an error in the tables can scarcely exist without detection.

In 1814, the great importance of the above inquiry became still more obvious, and the absurdity of the doctrine of inflammation being the proximate cause of the typhoid epidemic distempers then prevailing, which was attempted to be established chiefly on appearances found after death; hence too, was proved the necessity of treating inflammatory fevers, or those symptomatic of inflammation, in a different manner from typhoid and other diseases symptomatic of debility. The distinguishing characters of each as well as of the morbid actions and changes in the vital fluids became then also more manifest. These circumstances, as stated in the preface, led to my Treatise on Fever, published in London, 1814, and as that was a faithful transcript of facts, I can now refer to it in support of opinions which all my subsequent experience has tended to fortify; that inflammation is not only distinct from, but opposite to either typhoid or any other disease symptomatic of debility, however it may sometimes be combined with, or modify them. Longer, and more experience than falls to the lot of most men, will, I trust, plead my excuse for maintaining my position at a time when I believe it is very necessary for preserving the *juste milieu* between exclusive humoralism on the one hand, and exclusive solidism on the other, which, I believe, more than any other cause, retarded the advance of medical science during the period embraced in this sketch, and even, I am persuaded, perverted it so far from its first design, as on some occasions to become, instead of the most beneficial, the most destructive of human inventions. The number of admissions into the Cork-street Fever

Hospital, in 1814, was 2329, the deaths 143: average mortality, 1 in 16 & 3-164ths admissions. This year's result, too, afforded evidence in favour of the opinion that idiopathic and symptomatic fevers are distinct in their nature, for it was on these principles that the cases in the hospital were then treated, more especially as respected bleeding. As diseases became more pestilential, however, the advantages of still greater caution, more especially as regards arteriotomy than those expressed in my treatise, in 1814, became obvious. (Appendix, Note C.)

Besides the evidence afforded by the experiments above detailed, of the distinctness of inflammatory fever, and typhoid disease, and of the necessity of different modes of treatment, it was fully ascertained, that epidemics at that time preserved more than since of the aguish characters which often designate idiopathic fevers.

The following table, constructed with that view, assists too to confirm the opinions of some of the best medical writers, that there is a tendency in fever to terminate favourably or unfavourably on particular days:—

On Days of Fever.	No. of Cases.
Second	2
Third	16
Fourth	45
Fifth	129
Sixth	117
Seventh	162
Eighth	173
Ninth	212
Tenth	118
Eleventh	117
Twelfth	121
Thirteenth	82
Fourteenth	79
Fifteenth	74
Sixteenth	51
Seventeenth	42
Eighteenth	30
Nineteenth	35
Twentieth	20
Twenty-first	17
Twenty-second	11
Twenty-third	8
Twenty-fourth	0
Twenty-fifth	6
Twenty-sixth	0
Twenty-seventh	0
Twenty-eighth	4
Twenty-ninth	0
Thirtieth	0
Thirty-first	2
Total	1,773.

Those crises had been marked from the day of attack to that of marked decline of the symptoms, or entire cessation of fever (and it may be observed that the greatest number of crises occurred very nearly on the days mentioned by Hippocrates, viz. 3rd, 5th, 7th 9th, 12th, and afterwards on septenary days) these periods were often so very remarkable

in hospitals, that I have frequently seen patients who, at the ordinary mid-day visit, were hot, restless, anxious, and depressed, with hurried breathing, nausea, and quick pulse, on the succeeding morning tranquil, and without complaint, with all the vital functions regular, and the appetite keen. This change was frequently accompanied with some increased evacuation, vicarious discharge, external or glandular tumour or eruption on the skin; it sometimes followed the removal of some local irritation, as that of a lumbricus from the stomach by vomiting, an occurrence I have often noticed in the hospital. Crises were more remarkable in those fevers which terminated before the tenth day, and in fever, uncombined with organic disease, or local inflammation; and this will explain why they were less noticed among the affluent than those generally admitted into hospitals; in the former class, fever being often combined with, and protracted by organic derangement, Dr. Percival stated to me at that time, that he observed septenary critical movement in the continued fevers of those of the upper ranks of life, yet he scarcely ever saw them succeeded by a complete apyrexia. In cases of idiopathic fever, convalescence frequently took place on the night after admission to the hospital (if that was on the 5th, 7th, or 9th, from the attack), or on the next succeeding to it, if on either of the intervening days; in those instances cleanliness, and removal from the action of foul and contagious air alone, giving free exertion to the operations of nature. It may be further observed, with respect to the foregoing table of critical days, that the phenomena which it exhibits as having occurred in this country, corresponded exactly with what Dr. Francis Balfour had noticed in India and the east of Europe, and that he copied it with gratifying expressions of his approval, as additional evidence in favour of his principles, into his treatise on *Sol-lunar Influence*, published at Cupar, in Scotland, 1816.

In 1815, those diurnal movements, which previously gave to idiopathic fevers more or less of a remittent or intermittent form, became less distinguishable, and the distinctness of continued fever into symptomatic and idiopathic, and into inflammatory, and typhoid disease, became still more manifest, so that appropriate treatment for each could be better prescribed. On this account it was, I believe, chiefly, that notwithstanding the numbers admitted greatly exceeded those of any preceding years, yet the mortality in the hospital was greatly diminished. There were other circumstances, however, that year, which I am sure assisted these favourable results, such as opening a new building with much larger wards than those in the old (see my report for that year), so as to increase the number of beds from 80 to 180. Besides there were earlier application and

increased confidence in the means employed. The number of patients admitted this year from the whole of the city within the Circular-road, amounted to 3789, of whom 187 died, consequently, the average mortality was only one in 20 & 47-187ths admissions*. (Appendix, Note D).

The year 1816, though so constantly cold and rainy as to destroy the sown corn and rising crops to a degree that led to famine and pestilence throughout Ireland in the two succeeding years, was itself remarkably free from both. This plenty and healthfulness were observed also over the whole of Europe. The admissions into the Cork-street hospital from the same district as in the preceding year were less by 1086, viz.: admitted 2703, deaths 173; average mortality, one in 15 admissions. The increase of the average mortality from the preceding year, arose chiefly from the admission of patients labouring under phthisis and dropsy, into the wards which would otherwise have been vacant. This frequency of phthisis, when epidemics do not prevail or are prevented, (e.g.) small-pox by vaccination, fully accords, like the alternation of ague and continued fever in the years 1808 and 9, with the opinion long received, that many congenite diseases, which do not arrive at their acme before puberty, have their fatal ravages anticipated by prevailing and malignant epidemics†.

Previously to entering upon a description of the year 1817, when famine and supervening pestilence combined to extend and aggravate the epidemics of Ireland in an extraordinary manner, a brief description of the prevailing forms of diseases immediately before that time may assist to better understanding the frightful increase and aggravation that occurred afterwards. The fever was still the synochus of Dr. Cullen, with the alteration in his definition proposed at the beginning of this section, I mean, by the substitution of pyrexia and phlogosis, occasionally for synocha, and for the cauma of Dr. Good. Dynamic or inflammatory and adynamic or typhoid fevers, were constantly presenting themselves together, but in different degrees in the same patient. Typhus fever seldom preceded, but often supervened on inflammation. Local inflammation was sometimes kindled in the course of typhus, but more frequently after either a favourable or unfavourable crisis. Typhus, too, often supervened on, or rather superseded inflammatory and chronic affections of the brain, the lungs, and liver, other vital organs, to which the labouring classes in this, as in other large cities, are much predisposed. The influence of seasons on these combinations was manifest, and very similar in successive years. The connect-

† See Medical Report for 1816. By Wm. Stoker, M.D.

tion between symptoms, and sudden changes on the weather, was very obvious. In winter, pectoral and hepatic affections, and sometimes bowel complaints from the preceding autumn, rendered continued fevers more difficult of cure. In spring, typhoid symptoms became less, and inflammatory affections more frequent, the lungs being most generally engaged. In some years, early in this century, however, a malignant influenza prevailed, to obliterate that reaction which generally marked the vernal season. On such occasions corresponding changes in the blood to those which occur in typhoid fever, warned physicians of experience to be cautious in the abstraction of blood. (Appendix Note E.)

The same treatment for the "stitches," as they denominated the prevailing distemper on these occasions, especially as regarded blood-letting, was not prescribed as for ordinary inflammation of the lungs. In summer, epidemics became more typhoid, the head being most generally engaged, the same corresponding changes in the blood contraindicating its abstraction; the biliary system, too, was much affected. In autumn, the typhoid type of disease became in general more urgent than in summer, and in some years gave a more pestilential character to prevailing diseases. These effects of season, however, and their malign influence on the epidemic constitution of the air, were aggravated by predisposition from other causes both moral and physical, (e. g.) in 1813, a very fatal epidemic was propagated through Ireland by such combination of causes. Its most alarming symptoms were sudden prostration of strength, discoloration of the skin, and diminished temperature, congestion in, or excessive hemorrhages from the bowels, and alternately with these, coma, sometimes delirium tremens, putrid peripneumony, extensive dark petechiæ with ecchymoses, and bubonic tumours. The broken-down crassamentum, and the dark colour of the blood, drawn or effused, before or after death, corresponded also with these symptoms of pestilence*.

Referring again to my Annual Reports, and my Treatise on Fever, published 1815, for a fuller description of the prevailing medical theories and practice at that time, than would be compatible with the limits of this sketch, it must suffice for the present to state, that a rational empiricism was still very generally adopted, though modified by the eclectic pathology of Boerhaave and Haller, and subsequently by the ingenious theories of Baglivi, Cullen, Darwin, and Brown. Hence, though changes were carefully noted in the quality and quantity of the vital fluids and

morbid actions in the solids, still the hypotheses of accumulation or exhaustion of excitability had their influence. These modified theories, however, were afterwards generally rejected, when signs of previous inflammation were said to be so frequently detected after death, as to justify the opinion that the proximate cause of epidemic and pestilential diseases had been thus discovered, and that the ratio symptomatum, and the ratio medendi might also be explained by that circumstance alone. The post mortem examinations, however, previously published by Dr. Beddoes, and all my own experience afterwards in autopsy of diseased fluids before, and of diseased solids after death, led me to question the ultra-phlegmasiasm which was the result of such partial inquiries. In my Treatise on Fever, moreover, I stated numerous cases to prove that though signs of inflammation were often to be met with, yet that they were not always found, on examination after death, whilst autopsy before death seemed to show that even when signs of inflammation were afterwards found, they were rather adventitious than essential; and so far from being connected with the origin of the disease, they had in some cases supervened even at a late stage of it. In corroboration of the veracity of these statements and of such as I had previously made with the same view in my annual reports from the Cork-street hospital, the records regularly kept at that institution may be also referred to.

The aids which I received on these occasions from some of the most distinguished members of the different departments of medicine were such as deserve my grateful acknowledgments; and though I cannot here state them as fully as I wish, the following instances should not be omitted. Large and general bleeding in typhus and in mixed fevers being recommended by some who entertained the new doctrines, because a few examples were adduced when patients did not die under that practice, Drs. Purcell, Percival, Plunket, and Harvey, who always opposed such practice, met the arguments in favour of it by repeating the aphorism of their preceptor Dr. Cleghorn, when told of patients surviving monstrous doses of poisonous drugs, "that it is sometimes hard to kill a man." On the subject of small bleedings indiscriminately in fevers, Surgeons Richards, Crampton, Colles, Carmichael, and Wilmot, observed that inflammations which produced such morbid actions were not likely to be relieved by the abstraction of two or three ounces of blood; whilst Dr. Kirby, Dr. Macartney, and other anatomists further stated that the appearances found on the bodies of those who died of typhus, were not those of inflammation but the contrary. And Mr. Daniel Moore, an eminent apothecary, was opposed to either large or small bleedings whenever the blood, as in typhus, did not coagulate firmly, and was

* In adapting modes of treatment during this transition of febrile to more pestilential diseases, besides discontinuing arteriotomy, the substitution of leeches circa anum, and blisters to the region of the liver, were decidedly beneficial.

without sisy surface; he said it was contrary to what he saw successfully pursued by his distinguishing contemporaries, Drs. Barry, Hutchison, Quin, Plunket, and Harvey. The ultra phlegmasiasm of 1814, is now, it is true, generally disclaimed by most professors, but so long as any physician of eminence affirms that "fever is one and indivisible," and others lean towards the term "typhitis," for denominating pestilential diseases, and to the significant termination *itis*, thus to express the combinations of malignant distempers that now prevail, so long, the question must be deemed one of vital interest by every conscientious practitioner of medicine.

It may be useful to observe, previous to more practical details, that I adopt the term "idiopathic," according to its general acceptance, to distinguish between fevers not produced by other diseases, and those which are obviously symptomatic. This division is objectionable, perhaps, in a mere systematic arrangement, but often found of much practical utility, by dividing the typhous and contagious diseases from phlegmasiæ, so frequently combined with them in certain seasons, and under unfavourable circumstances predisposing to them.

The benefit derived by patients labouring under idiopathic fever from cleanliness, ventilation, cool regimen, and plentiful dilution was then generally agreed on. Even the knowledge of these important steps in the cure of fever had been the slowly acquired result of scientific research and patient observation, in opposition to long-existing prejudices.

The other remedies then recommended by experience might be arranged according to their value*, viz. purgatives, topical bleeding, antimonial powders, yeast or barm, wine, emetics, cold or tepid affusion, blisters.

Blood-letting had not been adopted as a remedy for typhus, though from the occurrence of cases in which it was indispensable on account of the combination of pulmonic inflammation, there had been frequent opportunities of judging of its efficacy; but such were its effects upon the typhoid symptoms, that the similar urgency of active inflammation could alone justify further experiments with that remedy. If, indeed, the inflammatory diathesis impeded any important function, or threatened the destruction of the organization of a vital part, and thus became the paramount consideration, it was opposed by the only effectual remedy, the proportionate employment of the lancet, but with much greater caution, however, than in cases of pure phlegmasia, for in whatever degree the symptoms of typhus attended, those of debility may be expected. If the pulse in such cases be constantly examined

during the operation, it would be found very differently affected by the same evacuation in inflammation merely. After the abstraction of the first two or three ounces of blood, which generally hurries the circulation, probably from the alarm of the patient, the pulse sometimes quickly becomes small or rebounding, and in either case denotes impending weakness. In typhus, too, the pulse is more affected by the motion of the patient, and I have known cases in which it was excited twenty beats in the minute by sitting up, and in others in which it fell as many by turning from the back on the left side.

The appearance of the blood drawn is also different, for though that taken in the first cup be slightly buffed, it rarely continues so in successive ones; on the contrary, soon after it is drawn, the crassamentum becomes dissolved or broken into fragments, tinging the serum with its colour, sometimes of a very dark brown, and sometimes of a greenish hue. The distinct and opposite consequences of these distinct and opposite states of the circulating mass, are no less remarkable and decisive. Increased vascular action and higher temperature being attendant on buffed blood, whilst weakness and failure of the pulse, and diminished warmth of the surface, and of the breath, as closely waited on dark-coloured and infirm blood. That which was most firm, coagulated, and sisy, being also generally succeeded by tumour and suppuration; but clotted and grumous blood by the speedy destruction of the part, external or internal, or by malignant pestilential tumours. Besides, the morbid appearances of the blood at this time not only indicated such distinctions between idiopathic and symptomatic disease, by its colour and relative degrees of sizziness, but also by the shades of colour, aid was given to distinguish between the separate diseases of the principal viscera in the cavities of the thorax and the abdomen. These facts may be seen more fully detailed in my *Pathological Observations*, and also cases to exemplify, as well as experiments I afterwards instituted to illustrate their application in the diagnoses and treatment of diseases. (See Appendix, Note G).

It is probable that much of the violent opposition among medical authorities on this subject, would have been reconciled if all the circumstances under which blood-letting had been used were attended to; thus it might have been effectual in epidemics produced by sudden changes of the weather in particular situations, such being mostly inflammatory. It seems probable, that the fever partook of that form for which bleeding was recommended by Sydenham, Munro, Huxham, and Pringle, and more lately by Borthwick; for they in general justified its use by the degree of inflammatory disease, designated by morbid action and sisy blood. That, however, it would be found not only inexpedient for the

* See my *Treatise on Fever*. London, 1814.

cure of typhoid fever, when uncombined with inflammation, as then happened more frequently every successive year, but prejudicial, is consonant with the views taken by the ablest writers of the past, and by the most experienced practitioners of this century. The comparative trial of small bleedings, made in 1810, already referred to, was decidedly unfavourable to that practice, and the black sloughing ulcers, which resulted from the puncture of a lancet in the veins, and still more so in the arteries, rendered it still more objectionable*.

In concluding this section on the growth of disease and pestilence during the period it embraces, it may be useful to observe, in connection with contemporary events, that it appears from a carefully constructed table of admissions to, and deaths in the Cork-street Fever Hospital, that the most remarkable increase of admissions was in the years 1806, 1810, and 1815, and that it was in the years 1807, 1808, and 1810, that the average mortality increased most remarkably. That at the conclusion of 1816, however, owing to the diminution of mortality each year, from 1810, under the treatment then adopted, the mortality was reduced nearly to that which took place the first three years after the opening of the institution and before the increased fatality of 1807. But these facts, however important they may be with respect to this section, will be found still more so, when viewed in connection with the details next to be entered on. On both accounts, the following table affords, I think, a suitable link between the former and latter period included in this and the next section:—

Years.	Admitted.	Died.	Mortality.
1804	415	29	1 in 14
1806	1264	103	1 in 12
1810	1774	155	1 in 11
1816	2703	173	1 in 15
Total in 12 years, to 1816 inclusive.	22884	1570	1 in 14.9-15ths.

This table exhibits the numbers admitted, the relative numbers who died, and the average mortality in the years 1804, 1806, 1810, and 1816, and lastly, for the first twelve years from the opening of the Cork-street House of Recovery.

(To be continued.)

* The results of the comparative trials of indiscriminate bleeding in mixed fever, and only when signs of inflammation were manifest, would have been obviously far more decisive, had all the cases of the latter description been separated. Such a separation was attempted by myself; but owing to the difficulty of it, and the pressure of other avocations, it was abandoned.

Reviews.

An Introduction to Hospital Practice in various Complaints; being a Clinical Report of Fever, Gout, Rheumatism, Cholera, Jaundice, Erysipelas, Insanity, &c., and Diseases of the Chest and Heart, with Remarks on their Pathology and Treatment. By C. J. B. Aldis, M.A., M.B., and Inceptor Candidate of the Royal College of Surgeons, London. 8vo. pp. 125. London: Longman and Co. 1835.

THIS volume is a clinical report of medical cases treated in St. George's Hospital, and is very creditable to the author. It often surprises us that reports of the medical practice of our hospitals, infirmaries, and dispensaries are like angels' visits, while surgical ones are blazoned forth every day. This arises from the fact, that the College of Surgeons has much more influence and power in manufacturing young doctors than the once powerful, but now obsolete Board of Physicians; while the Apothecaries' Society is too juvenile to enforce a proper knowledge of practical medicine.

It is really preposterous to reflect, that the surgeons and apothecaries of this country, who are in reality the physicians of the public, should be allowed to assume that privilege without a proper experience in medical diseases. The College of Surgeons never examine, and indeed that body is wholly incompetent in such maladies, while the Apothecaries' Company extends its examinations to all the medical sciences, but especially to materia medica and therapeutics. Few in that quarter are more competent than in the former; and most of both boards know as much about modern pathology as about the hieroglyphics of the ancient Egyptians. But these bodies are however entitled to credit for shrewdness, in exceeding their legal rights, and usurping those of the philosophers of the Physicians' College. It is, however, lamentable to meditate on the inattention paid by physicians of hospitals and dispensaries, and by students, to medical diseases, but most by the latter, who are to learn pathology and sound practice by intuition or inspiration.

In proof of this position, we state that surgeons' wards are crowded, the physicians'

deserted; and by those who are to obtain a livelihood by the practice of medicine, and not of surgery. His Majesty's leiges are the sufferers; but the Medical Reform Act will reverse the present order of things, and it ought to have passed three centuries since.

Dr. Aldis remarks in his preface, that it is only of late that medical clinical reports were recorded in the hospitals; and in this statement he is perfectly correct. Even now such reports are superficial, puerile, and unworthy of the physicians of London in nearly the middle of the nineteenth century.

Dr. Aldis has set an example to other physicians, which we hope to see followed. He has published a concise report of many diseases, and appended remarks on pathology after each class. The cases are, however, given too briefly, and the constitution, habits, &c. of the patients generally overlooked—a fault in most of our clinical reports. The principles and practice recommended in the work are worthy of adoption.

—o—

A Further Inquiry concerning Constitutional Irritation and the Pathology of the Nervous System. By Benjamin Travers, F. R. S. &c., &c. London: Longman and Co. 1835.

THE former work of Mr. Travers, on Constitutional Irritation, excited much criticism, both of a favourable and unfavourable kind. Most men engaged in practice, perceived that it contained a leading idea of great therapeutic importance, and abounded in observations only to be made at the bed-side of the patient. But the nature of that leading idea, in itself delicate and obscure, required for its propagation particular qualities both in the reader and the author. The former had need of comprehensiveness of intellect, and a determination to examine, without reference to minor faults, the practical utility of the principles inculcated; and to the latter were necessary, if he hoped for a general accordance with his sentiments among the profession, much clearness and precision of language, and that power of illustration which is necessary to make theoretic notions plain to men not accustomed

to exercise the power of reasoning further than its primary and obvious steps. If it be true that a want of the first qualities on the part of his reviewers, subjected the work of Mr. Travers to some animadversions which were undeserved, it is not less true, that though not a tame or an inelegant writer, his style is not happily adapted to his subject. His mode of writing is easy and flowing, but with too much redundancy; its great fault, however, is looseness. He sometimes uses identical, or very similar terms to express different ideas, or vice versa: the same conceptions are clothed by him in varied terms of expression. This is a laxity from which none of us can be entirely free, and indeed, upon subjects which cannot be mistaken, it may have something of elegance in it. But whoever writes other than drily and tersely, upon matters which do not address the senses, must write incomprehensibly. Indeed, of some faults of composition our author seems aware, for he says, in the preface of his work, that his "only regret has been, it had not fallen to other hands, in which he is satisfied it might have been so treated as to have risen to the dignity of a discourse on the Philosophy of Surgery." Now, we presume Mr. Travers to have advanced beyond the period when an author employs a deprecatory preface as a graceful appendage, which has no meaning. Taking him then to be in earnest, we also regret that nature and education had not more peculiarly fitted him for his task; but we do not agree with him in regretting that it had not fallen into other hands, because, though more expressive writers might have been found among our contemporaries, we know none in whom the persevering observation, and the originality evinced in his productions, could have been met with.

The "Inquiry" is not a work which can be completely analyzed; it must be read, well considered, and compared with its details of cases and bed-side occurrences, ere its value can be properly estimated. We shall not, therefore, abstract much of it, but shall employ ourselves to unfold and examine the principles upon which it is written, which we are tempted to do upon a more extended scale than usual, because the review in the pages of our respected contemporary, the

Medico-Chirurgical, in our opinion conveys very erroneous impressions on the subject of irritation—impressions not the less erroneous because they are shared by many ardent and intelligent pathologists, with most of the unthinking part of the profession. A fashion has grown up of late to believe scarcely anything can happen in the economy without some visual or tangible change, either chemical or mechanical: or that if any effects do occur which give us no sensible evidence, they are few and unimportant, or from their nature inscrutable, and therefore not legitimate subjects for study, or that their scrutiny can only be made by advancing our physical methods of investigation to a higher degree. Now, to these opinions we are utterly opposed. We affirm as a fact, that many *actions* of the organs of the body are found to go wrong without there being any perceptible change in the structure. That where changes of structure occur, they do not in many instances explain all the disease; that any advance in physical science is not hastily to be looked for, but that men have now and have always had faculties to observe the *laws* of the unknown powers which are presumed to exist in the animal economy; and although we cannot explain their nature we can prove by experiment that they are under our control. If by bark a man be cured of ague, is not that a fact as positive and as useful to be known as that in the same disease the spleen is engorged; yet I cannot explain the essence of ague. From observing it in various degrees and circumstances, I establish some of its laws; namely, that it occurs in wet places, at particular seasons, is often attended with internal engorgements, &c. A man has a blow on the testicle, and it makes him sick; to be sick is an act of the stomach; the stomach, therefore, and the testicle suffer together. They sympathize then; but other parts sympathize also, and in various ways. We cannot find out how this sympathy is established, but we can observe in what particulars the sympathies vary, what increases them, whether any thing can restrain them. Thus we classify the phenomena, and ascertain the laws of sympathy, with the same certainty though not to the same extent as the laws of motion. Now it is not uncommon in

diseased states to observe very strange effects of this kind take place between remote parts; but as these are not always attended with suffering or pain, a word was required capable of comprising all the disturbances of action that may occur in structures distant from the part first affected. The word selected is constitutional irritation; it may not be a good one; but that is a matter of taste. It is in general use, and the ideas attached to it are becoming every day more clear and definite. It is generally understood to mean a series of effects the causes of which are not known, but to the knowledge of the laws of which a great approximation has been made: and it is often restricted to those cases where the communication between the diseased part and the rest of the economy appears to be made through the medium of the nervous system only. Mr. Travers embraces many other subjects in his Inquiry, but that arises from his particular opinions; for he considers even the purulent deposits which sometimes occur in viscera remote from a wounded part, to be the result of long-continued irritation rather than of absorption.

The commonest forms of constitutional irritation are hectic fever, consequent on suppuration, and the sympathetic fever which follows injuries; of the latter Mr. Abernethy has given a very good account in his lectures; but every one must have observed that the sympathetic fever varies so much in its symptoms and effects as to require a much more extended account of it than has yet been given. Mr. Travers enters not far into this particular subject, though he mentions many facts and cases that bear upon it; but his attention seems to have been chiefly directed to those instances where formidable or fatal effects have supervened on injury, in consequence of the previous condition of the patient, and where the mode of connexion between the two causes was obscure. But perhaps here he should speak for himself, which he does with much force.

“The term irritation, in a pathological sense, is by some protested against as of hypothetical existence, like the Archæus of old; let practical men substitute another term equally significant and intelligible, for the derangement of the presiding nervous agency of a part or the system, and the symptoms thereto belonging. They are not

less marked than those of inflammation and fever, neither of which approach to substitutes, for in numberless instances neither are present. Nor will contractility, sensibility, erythism, do one whit better in point of accuracy, nor excess, or defect, or perversion of nutrition; or innervation, which last comes nearest to the definition, be more eligible. It is a monstrous evil in science to multiply even synonymous terms: the term irritation was not of my choice, but in constant, though I grant imprecise, use; yet I know of none equally unexceptionable to convey the sense which custom has rendered almost universal, and in my judgment, reason and experience confirm.

"But the signs of irritation, it is said, are but morbid sympathies, and the expression of them, those of inflammation and fever. If local irritation be ever so strictly local, it is still the derangement of that local sympathy which puts the nerves and vessels and other constituents of the affected texture in consent, although the derangement may not be such as to excite inflammation, or in the remotest degree to affect the constitution; such a sympathy is nevertheless indispensable to the phenomenon of local irritation; and to that of constitutional irritation à fortiori it is directly instrumental. In the first case it may be so inconsiderable as not to be recognized as an object for medical interference, in the second it is always palpable to observation; so that sympathy is bound up with its existence. But sympathy is a healthy phenomenon, and disturbed or morbid sympathy could not be an admissible synonyme for irritation, because it is, as I have before said, not a primary condition. It must have material to act upon; an irritant is essential to constitute irritation. The irritant in relation to the part or system is morbid; the sympathy only becomes morbid when it appears as an instrument or sign of irritation.

"If irritation and inflammation are co-relative terms for the same state, how happens it that the former is so often present without the latter? and if the symptoms of constitutional irritation are those of idiopathic fever, how is it that they vary in so many cases, one from the other? If they are capable of being confounded, not I alone err, but better informed and abler men than myself are in error. The fact is undeniable that the one often merges in the other, and that different febrile conditions supervene upon that of irritation; that the sympathetic fevers of inflammation and mortification are synochus and typhus fevers, and fairly warrant the inference, that similar conditions of body to those present in injuries and external inflammations are present in idiopathic fever; that perhaps sympathetic cannot always be distinguished from idiopathic; some have thought never: but unless it be fair to say that because the pulse of an hysterical girl or of a nervous dyspeptic beats a hundred and twenty in a

minute on the visit of the physician, ergo, they are the subjects of fever, I maintain the distinctness of the constitutional state which I have described as a result of local injury, from fever under any modification. They mistake me who suppose, that the symptoms which I have had occasion to exhibit in the progress of many cases, have been other than symptoms of fever, in my view more than in theirs; but that in many, the symptoms have been either for a time, or altogether unaltered to fever, and, therefore, improperly designated by the term 'irritative fever,' and that a considerable proportion of cases falling under the observation of surgeons is of this description, I re-assert, without fear of contradiction from those who exercise discrimination and are without prejudice. Inflammation and fever in acute cases come to the relief of irritation, local and constitutional, which may be said to terminate in them: on the other hand, irritation may predominate to the exclusion, or at least in the absence, of fever, for months together, and ultimately destroy, (unless healthy secretions, rest, and appetite, are legitimate symptoms of fever), as it may destroy before inflammation and fever have had time to form."

Now this we consider good sense; and we are not to be driven from the lessons of observation and experience, backed by an accordance of sentiment on the part of such men as Hunter, Cooper, and Abernethy, not to mention older writers, because morbid anatomy has done much, and because some pathologists fancy that to dissect the body, and profess to chop logic, are sufficient to form a sound practitioner; but on this topic also our author expresses himself so well, that we must make another quotation.

"It is familiar to observation, that the greatest benefits to science as to knowledge in general, admit of being converted into positive evils by exclusive study and abstract speculation. To illustrate my meaning—if the study of diseased actions had gone hand in hand with that of diseased structures, and the wards had contributed their fair proportion with the museum, it is impossible that such a doctrine could ever have been advanced.

"The effect of morbid anatomy holding the first and almost the only place in the mind of the medical inquirer, is to substitute effect for cause, the laws of physics for the laws of life, to confound the cause of death with the cause of disease, and in short to obscure by attempts at simplification. I venerate that study for its power of confirming or correcting the opinions of the cautious and intelligent student of living nature; of shedding light where darkness reigned supreme; developing and enabling us to connect and compare the characters of morbid changes with the phenomena of disease

during life, and thus to establish inferences, and gradually to arrive at a knowledge of the principles and laws which regulate morbid actions. And there can be no doubt that science is indebted to pathological anatomy for great advances in our time, subjected to the correction of minds well tutored and long disciplined at the bed-side: but this must be both the initiative and the moderator of our post mortem researches, or the museum becomes a thing apart, a mere collection of curiosities, quite as capable of perverting, as of guiding aright the mind of the beholder.

“When I entered the profession at the commencement of the present century, this department of pathology was comparatively barren, and beginning only to be cultivated: the example of Baillie was held in high esteem, but the education of physicians had not, with almost this exception, embraced the details of structure, and was very deficient in morbid anatomy. The reaction about that period commencing, as in the example of Farre, has since that time become general, and so increasing, as already in some branches to have reached a high point of cultivation—witness the labours of Abercrombie and Bright. In France and Germany, these labours have been prosecuted with great zeal and success. Of what they will effect for the extension of scientific pathology and the improvement of practical medicine, we may take as earnest what has been already done by Laennec and others. In surgery, which has necessarily held a closer alliance with anatomy from an earlier date, the advance has been most unequivocally illustrated, within the period of which I have spoken, by the history of ophthalmology, the diseases of blood-vessels, of joints, &c.

“But we begin at the wrong end if we lose sight of the principle which should guide these researches—if, unlike the illustrious Morgagni and his school, we overlook or do not specially cherish the connexion between the symptoms and the seats and causes of disease; and a very doubtful service would be rendered to science, if the analysis and classification of the various changes met with in dead bodies were to be employed as instruments for the synthetical arrangement and elucidation of the vital phenomena—in fact, for the natural history of disease.”

We conclude this notice of the first part of Mr. Travers' work, recommending our professional brethren to study it and examine whether its principles accord with what they witness in their practice. The problems he places before us are of the first importance, and may be conveniently summed up as follows. Is there a condition where no visible alterations of texture occur, and where nevertheless the functions are sus-

pendent or disturbed? Where alterations of texture occur, are we always to consider them as the cause of disturbed function? may not such alterations be consequences of the unknown condition termed irritation? Shall we reject the examination of this question because it is difficult, and throw overboard all previous observation, and begin the study of disease afresh by the aid of the knife and scissors, the glass and the chemist's apparatus; or shall we not rather pursue the two methods at the same time? This applies to local disorder—but the same questions apply to the effects of local injury on all the general functions. Can these be impaired by agencies that cannot be recognized by the senses?—and can the laws of these agencies be traced to such an extent as to increase our therapeutical means? Lastly, has success attended our present endeavours to establish the laws of irritation? for example, is it true, as Mr. Travers thinks, that there is such a thing as *reflected* irritation, *i. e.* that when a broken leg has caused irritation in the constitution, the disorder at large re-operates, so as to cause more irritation than usual in the leg? We trust many of our readers will be induced to follow up this Inquiry in the true spirit of the author who commenced it. We are sure they will not be deterred by the clamour of those who cry out that these are metaphysical speculations. Metaphysics are cognizant only with mental phenomena. If the endeavour to discover the laws of unknown agencies be metaphysical, then astronomy is metaphysics, and Mr. Faraday, when he pursues his beautiful researches into the laws exhibited by the unknown powers, which have been called magnetic and electric influence, is not a chemist, but a metaphysician. The study of irritation is not a matter of curiosity; it is part of the business of life, and though we never can arrive at the same degree of proof as may be obtained with reference to the laws of the agents that govern the motions of dead matter, there is little doubt that we may obtain, by cautious deductions from accumulated facts, so much as will enable us to effect much practical good.

We shall review hereafter the second part of Mr. Travers' book, the subject being a fuller development of his views as relates to the Nervous System.

Observations on the Climate, Soil, and Productions of British Guiana, and on the Advantages of Emigration to, and Colonizing the Interior of that Country: together with incidental Remarks on the Diseases, their Treatment and Prevention; founded on a long experience within the Tropics. By John Hancock, M.D. Fellow of the Medico-Botanical Society of London, and of the Philosophical Society of British Guiana; &c. &c. 8vo. London: Fraser. 1835.

It appears by the preface of this essay, that the author has travelled more than any other individual in South America; and he now gives an account of his observations on a delightful part of that great territory. We shall, however, confine our extracts to his description of the "climate and diseases of the country, with hints respecting their prevention and treatment." But we shall first allow him to introduce himself to our readers.

"The author of the following pages deems it necessary briefly to advert to the grounds on which they are offered to the public. He sojourned from the year 1804 to 1828, inclusive, in South America, and chiefly in British Guiana, where he followed his professional pursuits: and with the view of acquiring some knowledge of the botany of a country most rich in medicinal plants, and of some peculiar practices followed with great success by the inland tribes, in the cure of diseases, he frequently visited the Interior by the rivers Essequibo, Demerara, Pomeroon, Orinoco, &c. On one occasion he travelled more than a thousand miles amongst the rivers, forests, and savannahs (or two thousand going and returning); and he presumes that no one has ever traversed this extensive country to a greater aggregate distance than himself;—not even excepting the wanderings of his esteemed friends Waterton and Hillhouse, or even of the illustrious Baron de Humboldt. Not wishing the matter, however, to rest on his own testimony, he has adduced the evidence of travellers who have visited the interior parts of Guiana, which will be deemed, it is hoped, sufficiently corroborative of what he has stated from his own observation.

"If the author's attention was especially directed to the divers medicinal substances, of barks, roots, gums, balsams, &c.—and which he certainly considered as the most important objects—still, it will not be supposed he could regard with indifference the climate, soil, and varied productions of a country so rich and so favoured by nature as is the country known, we might say only by the name of British Guiana."

We have had many opportunities of hear-
VOL. VIII.

ing a vast deal of diversified information on American botany from the author, at the Medico-Botanical Society, and can bear our testimony in favour of the accuracy of many of his former statements. We make this remark, as the following extracts may perhaps be questioned by some of our readers.

"*Climate and Diseases of the Country, with hints respecting their Prevention and Treatment.*—Guiana is the most favourably situated of any part of America, or the world, perhaps, with respect to the winds and sea-breezes. It lies in the main track of the equinoctial currents; whilst hurricanes, so terrific and destructive amongst the West India islands, are unknown here, and the equinoctial gales are extremely steady and uniform throughout Guiana. At Angostura, three hundred miles inland, they commence not an hour later than on the sea-coast.

"An opinion is very prevalent, that the heat of climate renders Europeans unable to labour, or encounter much fatigue in these countries. This is a great mistake; for, on the contrary, it is a fact that those who take most exercise enjoy the best health, provided they live temperately. It is the excessive use of strong liquors that proves deleterious to Europeans in hot climates, and which, together with the heat, renders them incompetent to sustain much fatigue, until they become accustomed to it. It is alleged, most erroneously, that strong liquors are necessary to counteract the debility arising from the heat. Except in great moderation, they have the contrary effect, and have ever been the chief cause of the mortality which formerly prevailed, and must ever prove dangerous to the habitual debauchee. The writer, although not the most temperate, can aver, that during an experience of twenty-five years in the warmer parts of South America, he ever enjoyed the best health when he used most exercise. In every part of the world, exercise and temperance are the greatest safeguards of health; but indolence is even more pernicious in hot climates than elsewhere.

"The sackooru and casseri form the most wholesome, nutritive, and delicious drinks (made chiefly from mixtures of cassada, maize, and sweet potatoes slightly fermented). This kind of beverage might be substituted for malt and spirituous liquors with incalculable advantage. Those who use this sort of drink, owing to its substantial and restorative properties, as we ourselves experienced, lose the desire for strong liquors. This fact, which we had previously heard reported, was confirmed amongst the Macoosies, who make constant use of such beverage: they as constantly showed a disgust for spirituous liquors, whilst the Arowaks, Warrows, and those of the coast, had an insatiable desire for them."

Dr. Hancock considers the climate of

Guiana possesses great efficacy in scrofula and phthisis, not as a prophylactic, but as a curative of these disorders, of which he has known various instances. We cannot understand how phthisis, when really present, is to be cured by any climate, or by the murderous irritants of St. John Long, or even by the peculiar method of the renowned author of "*Consumption Curable.*" The climate, however, is by no means so salubrious in other diseases, and seems to favour certain epidemics.

"Instability of climate contributes more, perhaps, than any other cause to the production of epidemic diseases. The fatal Asiatic cholera, for instance, which has pervaded almost every part of the habitable globe, excepting Guiana, arose in that part of Asia which is subject to great changes of temperature—at one time to the hot winds from sandy deserts, or the tropical seas, at another, to the chilling blasts from the *Gauts*, or from the Himalaya mountains, the highest in the world, and covered with eternal snows. In further illustration of the subject, let us contrast the steady climate of Guiana with that of Canada, where enormous changes are often experienced, and consider that the population of Quebec was last year decimated by spasmodic cholera; it is stated in the *Times* of March 6th, that *one-tenth* of the inhabitants had fallen victims to this fatal scourge.

"The yellow-fever, as before observed, has many years since totally disappeared on the coast of Guiana. In 1804 it prevailed with great mortality, chiefly amongst the sailors, who, in a state of intoxication, not unfrequently slept on the ground or on deck: they were mostly on the following day attacked with depression, dry skin, and the symptoms termed yellow fever, and in those days we actually knew of no means of averting the consequences."

Our author next gives some directions to those who visit tropical climates, which deserve attentive perusal.

"From what I have observed in the islands, especially in Martinique and Grenada, I have reason to consider their climate as far less healthy than that of Guiana. Adynamical and malignant fevers are still very fatal amongst the islands. These fevers, however, may be easily arrested at the onset;—a fact, which, strange to say, is little known, and only practised imperfectly by some few Creoles and native inhabitants: it consists in procuring a perspiration, with as little delay as possible after the fever is found to be approaching, by the use of vapour-baths and fomentations, warm sudorific drinks and enemata*; not waiting for depletion or pur-

gatives, but employing them secondarily as required.

"The common or European practice is to administer calomel and purgatives, antimony, &c.; occasionally to bleed, and apply blisters; but such measures are seldom or never known to arrest the disease. The method by sweating appears, indeed, by far the most rational, when we consider that these disorders are brought on chiefly by colds and suppressed perspiration, after heats, atmospheric vicissitudes, and intoxication: the pores of the skin becoming closed, the blood is driven inwardly upon the viscera, and becomes partially stagnant. The natural method, then, is most obviously as promptly as possible to open the obstructed pores, to drive the blood to the surface, and to promote the secretions by which the vital fluid is depurated, and on which all the functions of life most immediately depend. This should be speedily attended to before fatal lesions or inflammation become fixed on the vitals. When these indications are acted on at the commencement, they prove as efficacious as they are simple and obvious.

"It is melancholy to observe, however, that the few precious moments are suffered to elapse, very often waiting for the medical adviser, the medicaments to be prepared, or some useless affair to be attended to, whilst the principal and essential point is not thought of. By the Spaniards, too, a trifling preliminary course of antiphlogistics are employed, (*para refrescarse*). This course, however, I consider as less hurtful than that of giving strong purgatives at the beginning; for by the latter, the natural effort or elimination by the skin is counteracted—as purgatives tend to impede the secretions by the skin, and thus to retain any irritative acrimony: hence we may see good reasons (though not now recognised) why Hippocrates and the wisest of the ancients forbade the use of cathartics at the beginning of fevers or inflammations—which are one and identical, differing only in degree and the nature of the parts primarily affected. It should be observed, too, that a dry skin is a constant symptom attendant on the commencement of all the pernicious fevers and dysenteries in the tropics, and doubtless in every climate; whilst the malignant fevers, like cholera, are not unfrequently ushered in with looseness of the bowels: this should afford a hint to the followers of the cathartic plan. The same means in effect are resorted to with equal success against the dangerous fevers, dysenteries, &c. by the aborigines of North America, that of *vapour-baths*, along with the copious use of alexipharmic tisanes, or infusions of sudorific herbs; and this is the proper way of arresting typhus and all

very plentiful draughts of hot punch, a very powerful sudorific; and thus preserve themselves and their comrades on the invasion of yellow-fever.

* I have known old sailors use a method of their own with great success, that of taking

malignant fevers and dysenteries*. This supposes that we take the fever at the onset, as ever should be done if possible; and the same, followed up at later periods, together with bleeding and evacuations, and the use of stimulant frictions, as the case may require.

"The transpiration is copious in hot countries indeed, it forms the best index to the state of health; and those who know this, are enabled to guard against the more common cause of disease in hot countries, suppressed perspiration†. Unfortunately, however, very few are aware of this fact, and are fearful of using exercise, in the heat of the day especially, and they allow the main-spring of health to flag, the secretions to be suppressed; they become pale and debilitated, and obnoxious to fever. They resort to purgatives—salts, jalap, and calomel. The latter is found the more useful, (and that in repeated small doses), because it tends to restore the secretions, but is feeble and insufficient, unless assisted in its action by sudorific baths and diluting drinks. The true remedial means are generally disregarded—the cathartic system being mostly mistaken for it.

"By the Dutch physicians in the colonies, diseases were mostly ascribed to the bile and *slime*. In Europe we have the more elegant (and euphonious designation, *affections of the gastric and chylipoietic organs*, both, however, implying the same aperitive indications, directed against the supposed offending humours, scybali, &c., in the alimentary canal.

"The necessity of preserving the perspiration is more evident in warm climates

than in cold; for, in the latter, the insensible perspiration is usually sufficient for the preservation of health: but even here it has not escaped the notice of the wisest physicians, that the cutaneous discharge is the most immediately essential to life, and to the due regulation of the healthy functions: in short, we are taught by daily observation in every country, that by far the greater number of all our ailments arise from colds and suppressed perspiration; and it appears to me very surprising that a matter of such vital importance should be so lightly regarded*.

"I have long been of opinion that the exemption from phthisis on the coast of Guiana is partly owing to the gaseous emanations from the soil; but I have reason to believe that the main cause is referable to the free perspiration experienced here, together with the almost total absence of those chilling blasts which are common in other tropical regions. And the means which are found most efficient in the cure of this distemper confirm me in this opinion; that is, by the use of diaphoretic, alterative remedies, such especially as the composition of sarsa, bark of guaiacum, waik-root, &c., together with small doses of mercury, antimony, opium, and the use of vapour-baths—means which most steadily promote transpiration, urine, and all the secretions, which eliminate the causes of disease from the habit and purify the blood. Divers instances of the cure of siphilis cachexies (foul disorders), and even confirmed consumption, at Angostura and the missions, seem to me fully to justify this conclusion (see *Med. Bot. Trans.*; and the *Lancet*, 1829, and 1831-2; *Med. and Surg. Journal*, vol. iii. and v.)

"On this point I may further remark, that numberless disorders may be, at their commencement especially, most speedily removed by the means here indicated; and the *rationale*, or reasons for which, will appear sufficiently evident to those who are aware that most of our ailments, in every climate, arise from colds and suppressed perspiration, together or coincident with a morbid state of the fluids.

"When matter from extensive ulceration and abscess (as in the lungs) has not a free discharge, it becomes absorbed into the mass of circulating fluids, and produces an irritative fever, termed hectic. By repose, and warmth of the bed at night, the patient sweats, by which the fever abates. The sweating is an effort of nature to relieve the system of

* To this end nature offers us a multitude of plants in every country: amongst the most valuable here are sage, balm, hyssop, menthæ, agrimony; and they are most efficient when combined or infused together, and drunk warm in bed. Rheumatism, as well as dysentery, typhus, &c., are thus readily conquered.

† Many mariners have learnt this by long experience: I have just conversed with one who is very intelligent and worthy of confidence, (Mr. R. Featherstone of Wiveliscombe), who has made sixteen voyages to the West Indies and Demerara, twelve in the capacity of carpenter, and four as chief mate. He drinks with moderation, uses much exercise, and perspires very freely in the warm climates: although of a full habit, he has never been attacked with fever within the tropics, but enjoys the best health, and observes, that he usually grows stouter whilst there, and especially at Demerara. This I have noticed, because it tends to exemplify and confirm my own views and experience. Mr. Featherstone is now about to sail for America, and on his return will be ready to answer any further interrogatories. But many old and experienced masters of vessels will be found to bear similar testimony,

* The vapour-bath affords one of the most effectual means of opening the pores of the skin and readily averting the evils which most commonly assail us. Many ingenious contrivances for this purpose have been offered to the public, and no family ought to be without one of them; but, to persons on ship-board, or those going out to hot, to cold, or any other climate, they are truly the most essential and invaluable safeguards.

the offending humour; which is evident from this, that if we collect the clammy transudation, we find it to possess most of the properties of pus. This view of the subject, however, is disregarded; and so perverse is our pathology, that, instead of assisting, practitioners seek to suppress the salutary discharge, whilst, in general, they appear to entertain no idea of the means of altering the habit, healing the ulcers, and supporting the strength and vital powers. The means above noticed, have been found most efficient in healing ulcers in all parts of the body, internal or external.

"Views like the foregoing, however, which are chiefly built on the experience of ages, have long since been exploded as antiquated, and with the explosion, common sense has been driven from the field: no pathology is now recognised besides the unmeaning and senseless mummery about *irritation, sympathy, brain affection, thoracic affection, abdominal affection, increased action, disposition to inflame, &c.*, as though the different parts of the body were endowed with volition, and, without assignable cause, with the power of taking on any mischievous action at will."

Such are the opinions of our author, and we leave the reader to estimate them. We must however remark, that those who intend to visit Guiana, medical or civil, ought to peruse this pamphlet. It is both instructive and interesting to the general and medical reader.

Practical Anatomy of the Nerves and Blood-vessels supplying the Head, Neck, and Chest; intended as a Guide for the use of Students in the Dissection of these Structures. By Edward Cock, Demonstrator of Anatomy at Guy's Hospital. London: A. Schloss. 1835.

THE author of this little work is of opinion that it is impossible to trace the blood-vessels and nerves by following the arrangement necessarily adopted in works on descriptive anatomy; because every description commences with the original trunks; "and as they are all deeply buried beneath the surface, they are consequently the last parts to be laid bare by the knife of the dissector." He therefore begins his descriptions with the most superficial branches of vessels and nerves, and proceeds to their trunks. This method may be practised with great advantage, as well as the usual one. The little work before us is well calculated to assist the anatomical student. It is a good companion at the dissecting table, and will be very useful to those for whom it is intended.

Compendium of the Ligaments; illustrated by Woodcuts, with the Articular Cartilages, interarticular or moveable Fibro-cartilages, synovial Membranes, and Bursa Mucosa of the Joints; the Mode of Union, and the Bones entering into the formation of each; and an Outline of the Dislocations, Fractures, Physiology, and Pathology. By A. McNab, Junr., Member of the Royal College of Surgeons. London: Henry Renshaw.

THIS is a most useful compendium for students. It contains every thing its title sets forth, and places the diseases to which it refers in a scientific view. It gives the anatomy, pathology, and treatment of dislocations and fractures in a clear and concise manner, and is an instructive work to students and junior practitioners. We are great advocates of works of this kind, as they save those commencing the study of medicine a vast deal of expense, and they often contain as much as some of the largest works on the same subject. But when students have arrived at their second or third session, they ought to procure the latest editions of the standard systematic works on the different sciences.

—o—

An Introduction to the Study of Practical Medicine; being an Outline of the leading Facts and Principles of the Science, as taught in a Course of Lectures delivered in the Marischal College of Aberdeen. By John Macrobin, M.D., Junior Professor of Medicine. Part I. 8vo. pp. 226. London: Higley. 1835.

THE author of this work confines himself in this part to the pathology and treatment of congestions, inflammations, hæmorrhages, dropsies, and fevers, and these diseases he describes with great accuracy. He details the ancient and modern opinions, and has executed the task he has undertaken with much ability. We need scarcely observe that a work on the practice of medicine cannot be reviewed to the satisfaction of our readers or to the author, and both must be content with the expression of our opinion of its merits or demerits. Dr. Macrobin is entitled to praise for the arrangement he has adopted, and we think, if the remainder of the work be equally well elucidated, it will be a valuable manual of the practice of medicine.

An Experimental Guide to Chemistry. By E. Davy, M.R.C.S. 12mo. London. 1835.

THIS is a very useful manual, and admirably adapted to impress the elementary facts of chemistry on the mind of the beginner. Its plan is to render everything obvious to the senses, by deducing each principle from some simple and striking experiment. The work, though intended only for the tyro, bears evident traces of the hand of a scientific and experienced chemist, who is capable of illustrating the study on a much ampler scale. We hope Mr. Davy will follow up this small but useful essay with one adapted to more advanced students.

—o—

The London Surgical Pocket Book, Alphabetically arranged from the Lectures and Works of the late Mr. Abernethy, Sir Astley Cooper, Mr. Lawrence, &c. &c.: with a Pharmacopœia and Glossary of Terms. London: Sherwood and Co.

THIS work is well executed, and supplies the place of the Surgeons' Vade-mecum. It is one of those useful and comprehensive manuals now so popular. Every student and junior practitioner ought to possess it. The compiler has laid the best national and foreign works under contribution, and has compressed a vast deal of information into a very small space. The work only requires to be known to be greatly encouraged.

DUPUYTREN'S CLINIC.

Sarcocele.

A MAN about thirty years of age had suffered for a long time with a hard, smooth, voluminous tumour in the left side of the scrotum. He felt in it occasional lancinating pains; and towards the summit of the tumour, it was thought a slight fluctuation could be perceived. The affection had obstinately resisted every remedy. The spermatic cord appeared healthy, and no swelling of the inguinal glands could be detected. The weight of the tumour, its size, the character of the pains, the slightly altered colour of the patient, all induced the surgeon to believe that he had to do with a true sarcocele. Nevertheless, the fluctuation which had been thought to exist, and more particularly the unfortunate examples of hydrocele, with cartilaginous degeneration of the tunica vaginalis, in which the mistake had not been discovered till after the extirpation of the testicle, have for a

long time made it a rule with M. Dupuytren, in all operations for sarcocele, to have recourse to a method which effectually places him beyond the reach of such an error. This method consists in first making an incision in the skin, extending from the external abdominal ring to the base of the scrotum. This incision is equally necessary in the case of sarcocele, and in that of cartilaginous hydrocele, in order to uncover the testicle enveloped in the tunica vaginalis. The tumour being thus laid bare, an explorative puncture is made in a central point, and often in various other places, through the tunica vaginalis. If this puncture gives issue to a liquid, and thus makes known a hydrocele, a portion of the cartilaginous tunica vaginalis is excised; the wound is filled with lint, and the testicle is preserved. If on the other hand, (as happened in the instance before us), the puncture gives exit only to blood, or to no liquid at all, we are assured that the tumour is a sarcocele, and proceed to its extirpation. A remarkable case of cartilaginous hydrocele occurred at the Hôtel Dieu, which M. Dupuytren himself believed to be a sarcocele, and in which he would inevitably have fallen into the error of extirpating the testicle, if he had not had recourse to this explorative method.

This method was adopted on the present occasion. After having tied the external pudic artery, and made the explorative puncture, M. Dupuytren seized and drew forward the scrotum with his left hand; and with a few strokes of the bistoury, the tumour was disengaged. The spermatic cord was then dissected out, and held with a tenaculum while the vessels were tied, and was then divided. The wound was dressed an hour after the operation.

The examination of the testicle revealed a substance which was fibrous in some places, cencephaloid in others, interspersed with what appeared to be scrofulous tubercles. We say *appeared*; for we believe if M. Dupuytren had touched the parts which he took for tubercles, he would have recognized a substance analogous to the yellow tissue, of which he has himself given so exact a description. The parts in question were resistant, elastic, very yellow, and not pulaceous, as tubercles are. The tumour was formed at the expense of the testicle itself, which had acquired perhaps twenty times its natural volume. The tunica albuginea was adherent in various points; and was traversed by a great number of voluminous vessels.

Amputation of the Breast.

Case 1.—A woman aged thirty-eight years, the mother of six children, all of which she has suckled, had an ulcerated cancerous tumour of the left breast, occupying the whole of the mammary gland. There were lancinating pains in it, with considerable emaciation, and a swelling of some of the

glands of the axilla, regarded by M. Dupuytren as symptomatic. Two semi-elliptic incisions uncovered the tumour; and their external angle was prolonged to the enlarged axillary glands. The mammary gland having been dissected out, there was perceived under the lips of the wound, a series of little tumours. They were removed along with a strip of cellular tissue, which had been left attached to the mammary gland: and at length the inflamed glands in the axilla were drawn out, still attached to the mammary tumour, by means of the chain of little tumours already mentioned. The diseased axillary glands extended to the length of two inches, beyond which a ligature was placed, to guard against a flow of blood from the neighbouring vessels. A stroke of the bistoury divided this chain; one half being taken away with the tumour, and the other being attached to the ligature, with which they will come away. A great number of vessels of considerable size gave out blood, and were tied. In amputations of the breast in women who have suckled several children, the vessels are much larger than in females who have never given milk. The patient was removed to bed; and the wound was not dressed till the expiration of an hour.

On examining the tumour, the mammary gland was found to have degenerated in various points into a fibrous matter; and in others, invaded and hollowed out by the carcinomatous ulcer. The glands taken from the axilla yielded, on being cut, a whitish matter; which on being collected on the blade of the knife, assumed a milky character.

Case 2.—A woman, forty-five years of age, with a delicate constitution, thin, and of a nervous temperament, had in the left breast a scirrhus tumour, moveable, ulcerated in the centre in the situation of the nipple, and fungous. The tumour appeared to have commenced in the gland, and to have invaded all the surrounding cellular tissue, giving rise to lancinating pains. After her entrance into the hospital, the patient experienced a kind of nervous excitement, which made her ardently desire the operation, and gave her a sort of factitious courage. This excitement is often the forerunner of nervous delirium, and may sometimes produce unfortunate consequences, in the most simple and skilfully performed operations.

The patient was placed in a chair, with the arms and body enveloped in a towel. The operator standing behind the chair, in order not to obstruct the view of his proceedings, laid bare the tumour by two semicircular incisions, which inclosed the whole of the mammary gland. The tumour was then dissected out, from the outer side (the axilla) towards the inner (the sternum), and was detached entire. A portion of the great pectoral muscle was removed, because the cellular tissue connected with it was affected.

Only four ligatures were applied, no other artery pouring out blood. Nevertheless the wound was not dressed for an hour, in order to avoid secondary hæmorrhage.

The dissection was made from the axilla towards the sternum, because no gland was observed to be enlarged in the first of these regions. This proceeding, which M. Dupuytren has adopted for more than twenty years, has the advantage of occasioning less pain to the patient; for the first strokes of the bistoury divide the nervous trunks which are distributed to the mamma and the neighbouring parts. But it is not proper in those cases in which there are inflamed axillary glands; for then, if the dissection be commenced on that side, we cut the bands which unite those glands to the mamma; and thus lose the power of drawing them out, and facilitating their removal.

The tissue of the mammary gland was found on examination to be (as had been predicted) of a scirrhus nature. In various parts it was softened. The mischief had commenced in the centre, and had extended in the form of rays towards the circumference. The incisions were made in the sound parts.

Case 3.—M. Dupuytren extirpated a tumour, of the size of a large filbert, situated in the cellular tissue above the left mamma. The patient was thirty years of age. The operation was very simple; one incision sufficient to lay bare the tumour, which was then seized with the forceps and drawn outwards. A few strokes of the bistoury detached it. We notice this case as a proof of accurate diagnosis. Before the operation M. Dupuytren announced, that the tumour was of a fibrous nature, and consisted of two lobes; and every one might have convinced himself of the correctness of this opinion. It is to the precision of his knowledge of the pathological anatomy, that this professor frequently owes the accuracy of his diagnosis.

Within a month two other amputations of the breast were practised at the Hôtel Dieu, and both with success.

Excision of the Tonsils.

A young man, between twenty and thirty years of age, thin and lank, had been subject to repeated attacks of inflammation of the throat, in consequence of which the tonsils were enlarged to such a degree, as to interfere with deglutition, respiration, and articulation. They were seized, one after the other, with Museux's forceps, and excised with a bistoury guarded with linen till within about an inch of the point. Very little blood escaped. The tissue of the bodies removed was dense and resistant.

The operation was very simple; the patient was seated on a chair, with the arms and body enveloped in a towel. No instrument was employed to keep the mouth open. No accident followed the operation.

Tracheotomy.

A young woman, eighteen years of age, of a weak constitution, and with irregu-

lar menstruation, had suffered for a long time with a tumour in the right side of the neck, beneath the angle of the jaw. It was hard, and of a large size, projecting at least as much internally as to the exterior, rendering respiration and deglutition difficult, and causing lancinating pains to the patient. When she first came to the Hôtel Dieu, the nature of the pains, the peculiar character of the tumour, and the commencing deterioration of the health of the patient, induced M. Dupuytren to believe that the affection was of a cancerous nature. Its situation and depth rendered its extirpation difficult, if not impossible. Some palliatives were administered, and the young woman left the hospital. Four months afterwards she returned much worse. The tumour had acquired double its former volume, and a kind of indistinct fluctuation, or rather softening, was perceived towards its apex. The disease was pronounced, with still greater certainty than at first, to be cancerous and incurable.

The patient had become considerably emaciated; her complexion was greatly altered, and respiration and deglutition were now very difficult. Her state, for two months, grew worse and worse, until suffocation appeared at times so imminent, that M. Dupuytren recommended that recourse should be had to tracheotomy if a fit of a more violent and menacing nature should occur. "The patient," he observed, "is every instant exposed to perish from suffocation. By opening the trachea, the respiration will be rendered more free; and this unfortunate patient, who would have died at an earlier period in fearful agonies, will obtain a month longer of life, and probably a less cruel death."

A frightful suffocative fit having come on the day afterwards, tracheotomy was immediately performed by a dresser. The inferior part of the thyroid membrane, and two or three rings of the trachea were divided, and a gum-elastic canula was introduced into the wound. The respiration was re-established, and the patient was instantly relieved. She went through the month of life which M. Dupuytren had allotted her, in a tolerably calm manner. By means of a sound passed into the œsophagus, several drinks and some liquid food were administered. For a day or two she appeared better; but she quickly relapsed. The diarrhœa became more abundant; a violent cough came on; and in its paroxysms, she brought up a great quantity of serous pus, of a very unhealthy nature. From the dullness on percussion of the right side of the chest, M. Dupuytren considered that this matter came from a cavity in the right lung, towards its upper part, and in the neighbourhood of the bronchial tubes. The day before her death, a whitish exudation, forming a kind of false membrane, not organized, and but slightly adherent, covered the tongue, and the interior of the mouth. The same kind of ex-

udation was observed in the case of another patient, who died a few days before, from diffused phlegmonous inflammation of the arm.

On examination after death, the body was found to be in a state of extreme emaciation. The tumour when divided presented a cerebriiform appearance. A whitish milky fluid, a characteristic sign of carcinomatous degeneration, exuded, and could be taken up on the blade of the scalpel. The chest having been opened, the left lung appeared slightly gorged with blood. Some old cellular adhesions existed on the left side. The right lung was in a state of grey hepatization. A vast purulent cavity was formed in its inferior border, extending to the diaphragm*. It was empty; and had evidently furnished the pus which M. Dupuytren thought had come from the superior part of the lung. Some parts of the lung, less inflamed and engorged, floated when placed in water; the rest fell to the bottom. False membranes, recent and not yet organized, were found on this side of the chest.

To the Editor of the London Medical and Surgical Journal.

SIR—Will you have the goodness to grant insertion of the accompanying letter in your Journal of next Saturday, and oblige, Sir, your very obedient Servant,

W. KINGDON.

2, New Bank Buildings,
Oct. 26, 1835.

—

TO THE MEDICAL PROFESSION.

GENTLEMEN—Having been of late treated with injustice by the majority of the Council of the College of Surgeons, and having been taught that he who tacitly submits to injustice becomes an instrument to his own degradation, I take this, I believe the most proper method, to protest against the measure of exclusion that has been practised towards me. Thinking that such a body would not willingly treat any one with injustice, I suspected there must have been, unknown to me, some disparaging report abroad, and therefore addressed the President and Council to inquire if, to the belief of any of them, such report existed. After some time I received an answer avoiding the question, and thus in effect admitting that if they allowed me an unsullied reputation, they damnified their own conduct. On the same showing, however, their conduct was calculated to damnify my fair fame, more

* The purulent collection here spoken of had probably taken place, not in the substance of the lung, but between the layers of the pleura. According to the best pathologists, an abscess in the lung from pneumonia is a very rare occurrence.

valued and estimated by me, as more essential than life itself to the well-doing of myself and family.

Without power to question this conduct, shielded as it is by charter, granted we may presume by a gracious sovereign, for the benefit and not the oppression of his subjects, I still have the power, possessed by every English gentleman, to see that my reputation do not suffer by the selfish or partial conduct of others; and it is for this reason that I now address my professional brethren. After more than twenty years of public and private practice as a surgeon in London, I must be known to some of you, and I address you to entreat that if any of you know, or think you know, any thing disparaging to my character, you will have the goodness to inform me, and thus confer the greatest favour it is possible for man to confer on man; for I am conscious that any such disparagement need only be made known to be proved as resting on misapprehension or founded on falsehood.

Having avoided all ineligibility to a seat at the Council of my College, the exclusion would seem to imply that I have by some act, either professional or otherwise, rendered myself unfit for election.

Unless erroneous information respecting me, given to the Parliamentary Committee by the then President of the College (which he afterwards made all endeavours to correct, that gentlemanly feelings could prompt), has been deemed a sufficient cause to throw me out of my fair professional course, or unless my not having an interest in common with surgeons of hospitals, or a mind easily led to surrender its own views, and see things as others wish, be deemed a sufficient cause—and neither of these can be supposed to influence the minds of honourable men—I must remain under the stigma of exclusion for my own demerit, did I not make this appeal to my professional brethren, so as to make known to them that on the majority of the council rests the responsibility of having used their power unjustly. Such conduct needs only to be canvassed for the reprobation of the right-thinking, and fall on those who practise it; and I have felt it my duty to offer my character for the strictest investigation, in order that the majority of the Council may have the benefit, if any thing can be found against it, as an excuse for their unprofessional and unjust conduct. It is the conduct of such men, that drives the quiet and the peace-lovers to desire and enforce change. It is the conduct of such men that renders futile the best efforts of the honourable and the able to place the affairs of our country on a footing of fairness and stability.

I am Gentlemen, very faithfully yours,
2, New Bank Buildings, W. KINGDON.
Oct. 26, 1835.

The London Medical

AND

Surgical Journal.

Saturday, November 7th, 1835.

THE OLIGARCHY OF LINCOLN'S INN. ELIGIBLES AND INELIGIBLES.

IN a letter which appeared in last week's *Lancet*, and *Lizard*, but which arrived too late for insertion in our journal, Mr. W. Kingdon complains of having been passed over in the list of the "eligible" to the oligarchy of Lincoln's-Inn-Fields. Mr. Kingdon is an experienced and excellent surgeon, and a most respectable man, and as such he has a right to be considered eligible to any post of honour in the profession; but it is to us matter of simple astonishment how Mr. Kingdon can regard a seat among the oligarchs as a thing to be coveted. We solemnly declare that if we were practitioners of surgery, and were elected by the council of the London College of Surgeons, we should, without a moment's hesitation, decline that pretended honour, and real disgrace. Our answer would be "we never desire to sit in that council till we are called to it by the voice of a majority of the commonalty." The parable of the sour grapes cannot here be applied to us, since we are physicians, and have nothing to expect from the College.

We did indeed, when green and unsuspecting youths, possess ourselves of its diploma, of which circumstance we are heartily ashamed. We could divide, and go to buffets with ourselves, for having given two-and-twenty pounds sterling in exchange for the privilege of appending to our name M.R.C.S.L.—the which, being properly expanded, stands thus; M-cre, R-aw, C-ringing, S-tupid, L-ubbers—as we ingenuously confess we at that time were, for allowing ourselves to be taken in by such open and notorious rogues.

Mr. Kingdon has evidently formed a most erroneous estimate of the cha-

racter of the twenty-one. "Thinking," says he, "that such a body would not willingly treat any one with injustice, I suspected there must have been, unknown to me, some disparaging report abroad." Injustice! We wish the council were guilty of nothing worse than that; if so, they would merely be like other unprincipled men who have their own interests to serve: but they are obnoxious to much heavier charges. We say nothing of their thefts and breaches of trust, on which the history of the profession for the last thirty years has formed a running commentary, but we would direct attention to their Neronic tyranny and cruelty. Have they not aided and abetted the conspiracy of those wicked women, the odious hags of Blackfriars, to bedaub the profession with jalap, and to render it impossible for nine-tenths of its members to subsist, otherwise than by choking the public with the same unpalatable material? Have they not, thereupon, with the coolest and most deliberate malice, jibed at the deplorable condition of their brethren—exerted their influence with the public charities to exclude from the office of surgeon every body engaged in the practice of pharmacy—and declared for their part that they could by no means admit retail tradesmen into their honourable body? Have they not, in one word, done everything in their power to mar the interests and wound the feelings of the general practitioners of England? They have! This is more than injustice, it is fierce atrocious inhumanity! So much for the injustice of the oligarchs; but Mr. Kingdon suspected that there must have been some disparaging report abroad concerning him; his suspicions were just—he has the reputation of being an honest man—which is precisely the worst of all possible recommendations to the favour of the twenty-one. Let Mr. Kingdon and all other members of the profession rest assured that the men of Lincoln's Inn have only two

principles of election; *fellow-feeling* towards knaves, and *fear* of those who, from whatever cause, have risen to a dangerous eminence. If they see a man whom they believe to be altogether such as themselves, a man who is likely to go all lengths with them in oppressing, degrading, and insulting the commonalty, him will they joyfully elect; if they see a man whose powerful opposition, whether from good or bad motives, threatens to bring the edifice of their iniquity about their ears, him will they invite with the treacherous fawning of a well dissembled hatred: if they see a man whose distinguished talents and upright character give him a strong hold on the public esteem, him will they endeavour to conciliate, that their own dusky reputation may look bright in the sunshine of his deserved popularity—how else are such men as Sir C. Bell and Mr. Green, to be found among them? Our only wonder is, how individuals so respectable, can condescend to such society; let us hope they do so with a view of improving it if possible.

Mr. Kingdon may console himself with the reflection that there are scores of surgeons in London in the same predicament with himself, nay, the greater part of them in a worse, since Mr. Kingdon is only pronounced *individually* ineligible, while every surgeon in general practice is declared not only individually, but *generically* ineligible.

We hope that the exclusion which has so galled Mr. Kingdon, will have the effect of opening his eyes to the character of those whose confraternity he desired; we hope that he will add his highly respectable name to the list of avowed and active medical reformers—in which case we shall merely have to congratulate him heartily on his escape from the perils of evil communication.

And oh! ye men of Lincoln's Inn! our wise charming shall not be lost upon ye, deaf adders though ye be.

We will ring the changes in your ears unceasingly, till surgeons in general practice are made as eligible to the council as any others—till the profession are admitted to the unheard-of privilege of administering their own affairs with their own hands.

The chief objection urged by the oligarchs against admitting general practitioners to the council, is really most facetiously impudent; provoked as we are at it, we never can help laughing when it is mentioned. A general practitioner, say the senators, is a tradesman; he may become bankrupt—and then what becomes of the dignity of the council of which he is a member? Excellent! Do not the council know, and does not everybody know, that although surgery has long been raised to the rank of a profession in the eyes of the public, it still remains, in all its legal relations, a *trade*. Any one of the high and mighty men of Lincoln's Inn can, if he pleases, send in his bill as a tradesman, and enforce its payment; and any one of them may become a bankrupt just as readily as any apothecary in England. But we may have misunderstood them mayhap; they only mean to say that although they are tradesmen, they are in no danger of falling into embarrassed circumstances as long as they have the keeping of the College funds! We believe them; but for all that, they may be, and they are, bankrupts in the worst sense of the term—bankrupts in reputation. We advise them then at once to declare their moral insolvency; to render up everything—the building and library of the college to the members to whom they belong, and the museum to the nation whose trust has been betrayed: the twenty-one may then go freely forth like poor but honest men, with nothing left but their character—that they may very well be allowed to keep, for nobody will covet it.

ELECTION OF MEDICAL OFFICERS IN THE ROYAL HOSPITALS.

OUR readers will have perceived that we have looked with considerable interest on the late election of resident surgeon of Christ's Hospital. As the time for that election approached, we felt more and more confident that the governors would really and truly select the best fitted candidate, but we have been wofully disappointed. Against the gentleman who (we know to his own surprise and astonishment) has been elected to this office, we have, as we stated last week, nothing to record, except, that it is utterly impossible that for years, let him labour as he may, *he can be* so competent as the individual, whose indisputable talents, whose lengthened experience and reputation, brought him originally into the service of the hospital, at the solicitation of a special committee of the governors, who went to the ballot against him, and who obtained what would, under any other circumstances, appear almost a disgraceful minority of votes.

We do not here desire to advocate the cause of Mr. Plumbe, because we know full well that he can do it for himself; but we take the occasion as one on which we hope to sound the trumpet of alarm with effect amongst our professional brethren over the whole country.

By this act and deed of the governors of one of the first royal hospitals, they have boldly proclaimed that neither the advantages of peculiar fitness, of established reputation and experience, will avail anything. *They will have none but scions of their own stock; and competent or incompetent as these may be, it is quite clear to us, that opposition to them is vain and useless;* for the future, any attempt to contend with them, be the candidate whom he may, must most assuredly lay his account for at least a useless expenditure of time, and if he is fool enough, of money also.

Now, let us descend a little to particulars, by way of illustration. Christ's Hospital has for time immemorial been supplied, as regards medical officers, from the maternal fount of St. Bartholomew. An event occurs—a special committee of governors is appointed. Scores and scores of years have passed over the heads of these reverend governors, and yet no neglect detected, no abuse discovered;

nearly one fourth of the boys labouring under contagious disease in the mean time, and deprived of their education. Can it be a matter of surprise, that the governor who obtained that committee, and who of course became its chairman, should name it a committee to inquire into the efficiency of the medical establishment? It *was* so named, and the committee proceeded to their work. What did they do? They sought the first authorities on the class of diseases which had so impeded the vital objects of the charity—namely, education. They sought the counsel of gentlemen who had for years had medical charge of the largest public establishments for children in England, and they found these gentlemen unanimous in condemning the diet of Christ's Hospital; but they found their *own medical officers* assuring them that vegetables were not necessary to the health of the children—that dry bread contained vegetable matter enough for all the purposes of health of the children!! Laughing, as we do, at the absurdity of this position, we cannot help pitying its advocates, since the governors at large, without any other impulse we believe, than that given by Mr. Plumbe's denunciation of the diet "divested of vegetable matter in any form whatever (except bread)," as the primary and predisposing cause of almost all those diseases which infested the institution—directed in all manners and forms, a most liberal supply of vegetables.

Well, these measures were adopted, much to the annoyance, as it appears, of those who declared the absence of necessity for them. Nevertheless, the boys appear to have been exceedingly well satisfied, and most decidedly to have improved in their health.

It seems that we have before us an example of the truth of the old adage, that great effects arise from little things, for out of the investigation and the inquiries of the special committee alluded to, has arisen, 1st, the resignation of the physician in London, leading, it is perfectly true, to the appointment of a surgeon who held five different offices before; 2nd, to the resignation of the respected general practitioner at Hertford; 3rd, (and we have good authority for the statement), to the threatened resignation of the consulting surgeon in London; 4th, to the *abdication* of the treasurer, (and the term has not been

misapplied, for he has been as much a king at Christ's, as King Harrison has been at Guy's); 5th, the departure of the venerable apothecary in London.

Now, we will ask, if there were not something rotten in the state of Denmark, *could* all these things happen in the space of one short year?

However, we will leave that for the honest part of the governors of Christ's Hospital to consider: our business is with our professional brethren; we would really appeal to them, and we would say, why stand aloof and see these public appointments quietly bestowed on those who have no pretensions, except such as nepotism gives them—*why do the mass* of general practitioners succumb quietly to this system of tyranny over the mind? What do we see in the case before us? For time immemorial, Christ's Hospital has been supplied with medical officers from the adjoining sister institution, St. Bartholomew: the rule has never been broken within the memory of the present generation till now. Why is it broken now? We are able to solve the mystery. The people of St. Bartholomew's had three of their school in the field; those of St. Thomas' and Guy's, only one. Still the league was preserved intact and entire; they ran the race amongst themselves: no interloper, no pretender, on the loftier grounds of experience and acquirement, was to be listened to. The governors of Christ's Hospital *dared* not, in the face of the world, take from St. Bartholomew's a confidential medical attendant, with the fact before their eyes, that the teachers of that school had done, not good, but mischief, for years; but they did dare, despite the sacredness of their charge, to reject, perhaps, the only man who could have been of service to them in England, so far as regards this horrible pest of the institution, ringworm, and who was, moreover, recommended to them by more than ordinary experience in the diseases of children generally.

Now, our readers will say, what is the secret here? we will tell them. It is not that Mr. Plumbe's talents are doubted—it is not that any apprehensions are entertained by these *parents depute*, and guardians of Christ's Hospital children; it is not that they, the governors, believe that all *has really been done* which medical science affords the

means of: quite the contrary; Mr. Plumbe, it seems, having had the exceeding ill luck of being applied to by the special committee, as the fountain head of the best information they could get, is to be blamed because that special committee had, and professed no other object, than the correction of abuses. Mr. Plumbe too, if we are correctly informed, has sustained, willingly on his part we have no doubt, the stigma of a reformer in medical science, and that is enough to create enemies to him in all and every of the royal hospitals. What has happened in Mr. Plumbe's case as a surgeon, will most assuredly happen in the case of any physician who may think proper to become a candidate for office in any of the said royal institutions. Superior qualifications go for nothing with these gentlemen governors, possibly because they do not know how to estimate them, but more probably, because they look to their office and its solemn duties as mere means of serving their friends.

—o—

Hospital Reports.

NORTH LONDON HOSPITAL.

Cases of Erysipelas—Use of Nitrate of Silver.

GEORGE INNES, aged 31 (admitted Oct. 3rd, under Dr. Elliotson), a stable-man, of healthy appearance, but intemperate habits; he generally drinks gin and ale mixed. On Monday last he got very wet, and on Thursday, when he went out of doors, he felt chilly and weak: he then went home and took some brandy and water: next morning he found his face swelled and inflamed. He consulted a surgeon, who gave him some opening medicine, and ordered him to bathe his face all day with cold water. These means produced no relief. The greater part of the right cheek, a smaller part of the left, and the eyelids of both sides, are now affected with erysipelatous inflammation. It has extended also slightly to the forehead, and there is a little vesication on the nose. Complaints of smarting in the forehead and eyelids, but has not much pain elsewhere. No pain within the head, but he complains of giddiness; has not slept for two nights, in consequence, as he thinks, of pain in the eyelids. Great thirst; tongue rather white in the centre; no sickness or pain in the epigastrium. Bowels purged for the last five or six days without medicine; has had retching in the morning daily for the last six months; skin hot; pulse 92, soft; body tremulous, and has been so since last Monday.

Applicetur sol. argent. nitr. saturata faciei.

Oct. 4th. Feels much better; the pain of the application was severe for several hours, but since it ceased he has had no pain whatever. Passed a very good night. Pulse 80; tongue cleaner; talks rather wildly; forgets the time he has been in the hospital—thinks he has been in three or four days, until reminded of his error, when he remembers correctly.

5th. Erysipelas better; face much less swelled; pulse 80, soft; but he talks very incoherently. Complains of some giddiness, which he says he has long suffered under. Body rather tremulous; does not perspire.

Morph. mur. gr. ss. Extr. colocyuth, gr. xss.

6th. Talks very incoherently; body tremulous; squinting, and contraction of the pupils. Erysipelas better; pulse full and rapid, but soft; bowels confined.

Ol. croton, gut. jss.

7th. Still talks very rapidly; the squinting continues; bowels have been freely opened; was very restless all night. He appeared, on the whole, to be rather more tranquil to-day. Tongue dry and chapped.

8th. Much better to-day; is quite rational, and expresses regret for his former violence. Bowels open; pulse 72, moderate; tongue moist.

From this date he continued rapidly to improve, and was discharged cured, Oct. 20.

James Hetherington, aged 46, admitted Sept. 18th, under the same physician as the last case. On Monday last, felt a slight languor, to which he paid no attention; on the following day his memory became impaired, and his mind confused, so that he was unable to attend to his business. Frequent shiverings came on, and were succeeded by transient flushes of heat. He lost his appetite: the sight of food, or mention of it was disagreeable to him, and he felt a parching thirst. His bowels became relaxed, and the urine scanty and high-coloured. On Wednesday morning a redness and burning pain appeared in the nose, and spread rapidly over the face; the former symptoms then subsided, but the dislike to food, and diarrhoea remained. Yesterday he had slight headach. The present symptoms are, redness of the face, forehead, and upper and back part of the neck, disappearing on pressure, and instantly returning when pressure is removed; considerable tumefaction of the cheeks and eyelids, so that the eyes are half closed: burning heat over all these parts; the middle of each cheek is whitish, apparently owing to small vesicles: great thirst; slight headach; no appetite; tongue white and furred; tremor of the hands and general weakness; bowels relaxed; pulse 120, soft.

Applicetur sol. argenti nitratis saturata faciei.

Sept. 19. No longer feels any of the ori-

ginal burning pain, or even that caused by the caustic application, which at first was very severe. Bowels open once since his admission; thirst much diminished; pulse 90, soft; some excoriations on the cheeks and neck, from the solution Ung. zinci partibus excoriatis.

21. As there was some soreness and redness over the scalp, Mr. Taylor ordered the head to be shaved, and sol. arg. nitr. to be applied to it. The soreness in the face is now gone, except that caused by the application of the caustic. He talked wildly yesterday and to-day, and dressed himself three times to go out. He mutters incoherently about his business, and the money he loses by his illness. Thirst greater than at last report; tongue white; tremor of the hands; pulse 110, soft.

22. More quiet; no burning pain; some soreness from the caustic. Tongue white; thirst diminished; appetite a little better; bowels regular; pulse 85, soft.

24. The swelling in the head is much reduced—the cuticle is peeling off. Tongue nearly clean; no thirst; appetite returning; bowels open.

26. The cuticle covered with the nitr. arg. is fast coming away, and he feels quite well. Appetite pretty good; tongue moist; bowels open; pulse 84, soft.

Discharged cured October 3.

Joseph Morris, aged 53, (admitted Sept. 11th, under Dr. Elliotson), a man of intemperate habits. Had been working in a draught of air, and caught a severe cold. The parotid glands became hard and painful. On the 6th inst. his upper lip became red and painful, and the redness subsequently extended over the face, accompanied with a burning pain; small vesicles also appeared, which broke, and discharged a little fluid: he applied to a medical man, who, after bleeding him to lbj., advised him to go to an hospital. The inflammation now extends all over the face and forehead. Mr. Taylor applied a solution of nitr. arg. (gr. x. to ʒj aq.) to the affected parts, but they only darkened the skin. The tongue is furred, pulse 100, great thirst, no appetite; bowels opened by medicine.

Applicetur sol. nitr. arg. saturatæ partibus affectis.

Sept. 13. The face is now quite black from the effects of the nitr. argenti; pulse 95; face in a burning heat all night.

14. Face less painful; pulse 78, small and weak; bowels opened by medicine; tongue dry and furred.

15. Feels much better and less weak; tongue dry and furred; thirst continues; pulse 85.

17. Thirst much diminished; feels stronger, and the appetite is returning.

Discharged cured, Sept. 29th.

Matilda Scotlock, aged 27, admitted Oct. 2nd, under Dr. Elliotson. She caught cold from having had her feet wet, and was attacked with cold shiverings, which lasted the greater part of a day; the next morning she observed that her forehead was swollen, and felt tender; she had also headache. The next day the swelling and tenderness had extended down each side of her face accompanied with a dingy redness of the skin, and a strong sensation of heat; the entire scalp has now become affected, as also her ears, which are very painful, and discharge some serum: several bullæ have formed on the left cheek; the headache now is very slight. Previous to her admission she took some medicine, which acted very much on her bowels; she had also a lotion to apply to the parts affected, but she used it only once, on account of the severe pain and sensation of heat which it caused: her bowels are open; tongue white; appetite bad; pulse 80, and small. Abradatur capitis pillitium.

Applicetur sol. argenti nitr. saturata partibus affectis.

Oct. 6. The swelling and redness has not extended beyond the parts to which the lotion has been applied: she feels much better; the pain and heat in the affected parts have greatly diminished.

10. She washed off the lotion; the redness and swelling have declined, and she feels no pain or heat in the parts which were affected; her general health is good.

13. Her face is fast returning to its natural appearance, and her general health good.—Diætâ media.

17. All traces of her complaint have disappeared, and her face is now restored to its natural state.

Discharged cured, Oct. 20th.

—o—

Practical Observations on Midwifery. By William F. Montgomery, M.D., M.R.I. Professor of Midwifery to the King's College of Physicians in Ireland and Physician Accoucheur to Sir Patrick Dun's Hospital.

On some peculiar Forms of Relaxation of Uterine Tissue.—It is perhaps scarcely necessary to premise, that when the uterus expelled the product of conception at the period of its growth, a process of active contraction immediately commences, by which, assisted by absorption, the structure of the organ is gradually condensed and rendered compact, and its volume is speedily reduced to its original dimensions. Under such healthy and favourable exercise of the natural functions the blood-vessels which enter into and permeate in every direction the uterine structure, and which have been hitherto in a state of enlargement necessary for nutrition of the ovum, are effectually compressed, and their orifices internally sealed.

up, so that no injurious loss of blood takes place either at the time of delivery or subsequently. But unfortunately matters do not always proceed thus favourably, the uterus being liable, under certain circumstances, to fall into a state of atony and relaxation, which is occasionally productive of the most deplorable results,

Now there are two conditions of this accident peculiarly formidable: 1. As it occurs immediately after delivery. 2. At periods more remote from the time of child-birth, as after several hours or days. These two forms of the accident are, I believe, now so generally understood, and have been so accurately described by authors, that I do not propose here to offer any observations upon them, as the reader will find elsewhere a very full and satisfactory account of the subject, particularly in the treatises of Ramsbotham* and Ingleby†, to which, therefore, I beg to refer him. But there is another variety of uterine relaxation, of whose existence I have fully satisfied myself in many instances, though it has not, as far as I am aware, been described, or even noticed by any writer; the peculiarity of it being, that it continues in a chronic form, occurring most frequently after early abortions, sometimes after delivery at the full time, when there has been profuse hæmorrhage, and sometimes as the result of protracted or undue lactation. With regard to that form of it which follows early abortion, I should observe that it is not necessarily connected with any loss of blood during the miscarriage, as the cases to be detailed will show; but about the time that the patient is beginning to resume her ordinary occupations, and by taking more exercise, increases the rapidity and force of the circulation, she is unexpectedly seized with hæmorrhagic and leucorrhœal discharges, considerable in quantity, and of course quickly inducing great debility, and exciting painful and alarming apprehensions of the existence of some lurking malady. In general the patient experiences but little pain, most frequently none; but she feels an internal fullness, which appears to her to interfere with her passing water; she has a dull aching feel in the small of the back, and is constantly annoyed by a sensation of relaxation in the whole contents of the pelvis. If an examination is made, the vagina is found unusually unresisting and relaxed, and the os uteri gaping wide open, with its lips tumid, thickened, and projecting, but at the same time soft and flabby; the cervix is dilated, so that the natural tapering form of that part is gone, and the body of the uterus itself is felt enlarged and doughy when pressed by the point of the finger, which however does not give any pain whatever, the organ appearing

indeed quite insensible. This condition of the uterus may persist for many weeks, sometimes for months, being attended by various degrees of constitutional disturbance, as the discharges to which it gives rise may be so profuse as to endanger life, while at other times they are but slight, or appear only occasionally, and at length attract attention more by their long continuance, than from any great severity in the symptoms by which they are attended. The possibility of conception is by no means excluded during a moderate degree of this state of the uterus; indeed, on the contrary, my experience would lead me to say that it is very apt to occur under such circumstances; but if the tone of the uterus is not completely restored before the recurrence of pregnancy, abortion will almost inevitably happen, as in Cases III. and IV. This, as well as other points in this general description of the affection, will probably be best elucidated in the details of a few cases, which I shall endeavour to give as briefly as possible.

CASE I.—In July, 1830, I was called to see a lady at the north side of the city, who had just miscarried in the second month of gestation, with profuse hæmorrhage, by which she was much exhausted; the ovum had come away entire, and was about the size of a walnut, and I learned from her that she had miscarried twice already within the preceding six months; on this occasion she seemed to recover well, and was able to leave her bed in less than a week. I established a tonic system of treatment both in medicine and diet, but at the end of a month her strength had not returned, and she had never ceased to have vaginal discharges since the time of the abortion. Apprehensive that some portion of the decidua might be retained in the os uteri, I examined that part, and found it just in the state it had been a month before, gaping open, soft, relaxed, and flabby. I now strongly recommended her to go out of town, and take a house on the sea-shore for the purpose of bathing, leaving her husband behind. This was done; she continued to take small quantities of quinine and gentian with aromatic sulphuric acid, and bathed every day in the open sea until November, when she returned home completely re-established in health, and immediately afterwards conceived. She passed through her pregnancy without any tendency to abortion; and on the 6th of the following August* gave birth to a fine healthy child, which, by my advice, she attempted to nurse, and for the first time succeeded perfectly. She had previously had five children, and has had two since, which she also nursed, and is now in

* Ramsbotham's Practical Observations on Midwifery, Part 1. p. 186.

† Ingleby on Uterine Hæmorrhage, Chap. 22, 23, and 24.

* This lady told me on the 10th of December, that her confinement would take place on the 5th of August; she had a few pains on the 4th, and again on the 5th, and was delivered on the 6th.

better health than she had enjoyed for some years.

CASE II.—On the 29th of January, 1832, Mrs. V. sent for me in consequence of being, as she thought, threatened with abortion in the third month, having had a similar accident at the same period of gestation in the preceding June. She had now a good deal of fever about her, with some red and glairy discharge from the vagina, but no pain. On examination the os and cervix uteri were found in a natural and healthy state, and gave no indication of an impending abortion, which, however, took place on the night of the 30th, without either pain or hæmorrhage. While she was passing water she was conscious of something solid passing from her, but did not know she had miscarried until she saw the fœtus in the morning; it was of the third month, very much decomposed and altered in form, in consequence of which she became impressed with a very whimsical notion: she had been some time before greatly startled by a hatching hen which flew up into her face, and she now quite gravely asked me if I did not think what she had been delivered of was very like a chicken. She appeared to recover well, and at the end of a week was able to go about as usual. On the 29th of March, just two months after the miscarriage, she sent for me, and informed me that from the time of the abortion she had never been entirely free from vaginal discharge, which was occasionally accompanied with pains resembling slight after-pains; she was also annoyed with vesical irritation and dysuria, and was now much alarmed from an apprehension that she was labouring under gravel, or was threatened with cancer. On examination I found the uterus almost exactly in the state I had felt it two months before, after abortion had taken place; the os uteri gaping open to the size of a shilling, with its margins soft, relaxed, and puffy, but totally without tenderness on pressure. She was ordered the same tonics as in the former case, and to use free ablution to the lower part of the trunk with cold salt water, which was to be exchanged for the open sea bath as soon as the weather should permit. Under this treatment her health was perfectly re-established in about six weeks, during which time she lived *absque marito*. She conceived again towards the end of May, and was delivered on the 27th of February, 1833.

CASE III.—May 12, 1834, I was urgently requested to see a lady, sister to the patient, Case I., and mother of six or seven children, her family having become greatly alarmed for her safety, in consequence of profuse hæmorrhagic discharges. On seeing her I ascertained that a little more than three weeks previously she had miscarried early in the third month, with very little pain or hæmorrhage; she had apparently recovered well, so that at the end of a fortnight she went to church, but while there she felt

greatly fatigued, and was seized suddenly with a smart uterine hæmorrhage, in consequence of which she nearly fainted, and it was found necessary to have her conveyed home. She was visited by her medical attendant next day, who established a rigorous system of low diet, and water for drink, with full doses of laudanum, and the constant application of cloths wet with vinegar and water; in addition to which a bag of chalk, moistened with vinegar was introduced into the vagina. Under this plan, which had been pursued without intermission for a week, matters became much worse, and when I first saw the lady she was lying on a sofa in her bed-room, unable to move, and almost without pulse, the countenance blanched and ghastly, the whole body chilled, and shivering with cold, from being constantly soured in wet, and the mind depressed to the lowest degree of despair. On examination I found excessive relaxation of the vagina, the os uteri so open that it would readily have admitted the points of three fingers, its lips tumid, but soft and puffy; the body of the organ enlarged and doughy. I recommended the immediate removal of the wet cloths, and the application of dry and warm ones in their place, and a jar of warm water applied to the feet; a scruple of ergot of rye to be given infused in warm wine, the diet to be exchanged at once for jelly, good broths, chicken, and claret; tonics as in the former cases, and removal into the country as soon as it can be accomplished with safety. Under this system the lady was soon much better (as I was informed, for I saw her only once at that time), but she remained in town, and conceived again about the end of June, and again miscarried on the 15th of August, when I attended her; there was no hæmorrhage of any consequence, but the uterus was still evidently in a relaxed condition, which however I obviated by rest in the horizontal position for several days, allowing a generous diet, and administering tonics early. I also prevailed on her to leave town, and go to the sea-side, her husband remaining at home. She continued in the country till the beginning of winter, by which time she had completely recovered her health and strength. Soon after her return she conceived again, and on the 9th of the present month, September, was safely delivered of a daughter.

(To be concluded in our next.)

—o—

TRANSPPOSITION OF THE THORACIC AND ABDOMINAL ORGANS.

M. BALLY has recorded a singular case of this kind in a man, aged 25 years, who was under his care at La Pitié, for disease of the ileum. The most remarkable fact referrible to it is, that the man never experienced any inconvenience from the transposition of his organs during his life. This case is perhaps unique.

MEDICAL BOTANY.

PLATE VIII.—ATROPA BELLADONNA.

(DEADLY Nightshade.)

Off.—The leaf and root.

The deadly nightshade is a herbaceous perennial plant, which is indigenous both in mountainous and woody situations, and sometimes cultivated in gardens. The whole plant is poisonous, especially the root; and the berries, which ripen in September, from their beautiful appearance, like black cherries, have sometimes proved fatal to children. The symptoms excited are, dryness of the mouth, trembling of the tongue, very distressing thirst, difficulty of swallowing, fruitless efforts to vomit, and great anxiety about the præcordia. Extravagant delirium then comes on, followed by sopor. The pupil remains dilated, and is not sensible even to the stimulus of light. The face becomes tumid, and of a dark red colour. The jaws are sometimes locked. Symptoms of irritation are rare, and never severe, but the narcotic symptoms last for several days. Fatal cases are uncommon. The body in such cases soon putrifies, swells, and becomes marked with livid spots; blood flows from the nose, mouth, and ears, and the stench is insufferable. On dissection the blood is found to be fluid, the intestines are inflated and inflamed, or eroded and gangrenous. The best method of cure is to excite vomiting as soon as possible, by emetics, and tickling the fauces; to evacuate the bowels by purgatives and glysters; and to give largely, vinegar, honey, milk, and oil. In some children who recovered by this treatment, the delirium was succeeded by a profound sopor, accompanied with subsultus tendinum; the face and hands became pale and cold, and the pulse small, hard, and quick. Their recovery was slow, and the blindness continued for a considerable time, but at last went off.

Medical Use.—This virulent poison, under proper management, may become an excellent remedy. Besides its narcotic power, it promotes all the excretions; but its exhibition requires the greatest caution; for it is apt, when continued for any length of time, even in small doses, to cause dryness and tension of the throat and neighbouring parts, vertigo, dimness of sight, and even temporary blindness. When any of these symptoms occur, its use must be suspended for some time, and afterwards resumed in smaller doses.

SOLIDIFICATION OF CARBONIC ACID GAS.

M. THILORIER has transmitted a letter to the Académie des Sciences, in which he declares that he has reduced carbonic acid gas to a state of solidification, and proposed to liquefy it before the Academy.

STATISTICS OF THE HOSPITALS OF PARIS.

In 1833, individuals were admitted 65,938
In the infirmaries and asylums . 12,757
In foundling hospitals 21,351
In the orphan asylums 1,539
Into other institutions 72,746

The sojourn of the patients in the hospitals was as follows:—At the Cochin and Hôtel Dieu 19 days, at Charité and Pitié 21, at Necker 23, St. Anthony 27, Beaujon 29, Maternity 17, Maison de Sante 24, St. Louis 37, Enfants-malades 41, Veneréal 48; on an average 23.51.

The foundling infants in 1833, were 4,803; in 1832, 4,982; in 1831, 5,667.

HONOUR CONFERRED ON M. GAMA.

THE king of Sweden has conferred the honour of Knight of the Order of Wasa on M. Gama, surgeon in chief of Val de Grâce. The French surgeon had extracted a ball from the neck of his Majesty, when Prince de Ponto Corvo.

PROVOKED ABORTION IN RETROVERSION OF THE UTERUS.

M. ROUX informed the Académie de Médecine on the 18th of October last, that the surgeon-in-chief of the hospital at Amsterdam had shewn a woman four months pregnant, who suffered from retroversion of the uterus. The uterine neck compressed the bladder, and caused complete retention of urine, while the fundus of the organ was distinctly felt in the sacrum. Every means failed, and the symptoms became alarming. The surgeon introduced a piece of sponge into the cervix uteri, which, in the course of the day, induced abortion, and all the symptoms assumed a favourable aspect.

NATURALIZATION OF HAHNEMANN IN PARIS.

THE French government has authorized Dr. Hahnemann to practise in Paris, but it appears that the admiration of his Parisian disciples has diminished since he has become their rival. The learned Doctor has failed to be considered a prophet in his own country; and his disciples in London are now seldom heard of, even among the nobility, their patrons, and supporters.

THE PARIS AND LONDON PHARMACOPEIAS.

THE commission appointed in Paris to revise the pharmacopœia are the ablest professors, among whom are MM. Orfila, Andral, junior; Richard, Bussy, Caventon, Robiquet, Pelletier, Souberan, and Royer Collard. The London College has appointed a committee, and transferred the chemical part to a lecturer on chemistry who is not a physician. A comparison between both works cannot fail to be interesting to our readers.

M. BROUSSAIS'

*Course of General Pathology and Therapeutics;
translated and revised*

By JAMES MANBY GULLY, M.D.

LECTURE XXII.

*Prognosis of Gastro-Enteritis.—History of the
Origin of the Broussaisian Ideas of Fever.*

A FEW words remain to be said on the subject of fevers. Whenever the phenomena of a febrile state proceed from one determinate point, they cannot certainly be regarded as effects of a general affection of the fluids, or as essential fevers. The only affections that would have any right to retain this title are those from the irritation or absorption of a poison—be it virus or miasm—such as small pox, measles, or plague, and, in some cases, yellow fever, typhus, &c. But you must recollect what I stated in my preliminaries. Whatever the poison may be that has been introduced into the body, the disease cannot consist in an affection of the fluids. So long as they alone are affected, you have no signs of it. He who does not suffer from, or whose health is not deranged by the absorption of a virus, absorbs it as well as he who does suffer from it. You go into a ward of small-pox patients where you are imbued with the miasms, but you do not fall sick: whilst your companion does fall sick if he be predisposed. You may say that the blood in your vessels has not suffered from these miasms, whereas that of your friend has been thereby altered. But no analysis proves this difference; and as regards him or you who is attacked, you will always find that the disease takes a start from some one point or organ, as in common gastro-enteritis; so that the absorbed virus, in this case, does not produce a general disease, and the laws that bear upon the reputedly non-poisonous inflammations are also here observed. If you tell me of experiments in which a poison, such as sanies, is introduced into the body of an animal, by injection into the vessels, by inoculation,

or by swallowing, I make a similar answer; the affection is not general, and there is always one primarily disturbed organ: the animal vomits, has mucous and bilious dejections, abdominal pains, in short, a gastro-enteritis. He is not uniformly and generally affected; all that you can say is that the blood has been the vehicle of the morbid cause.

This explanation made me return to the history of gastro-enteritis and enter upon the prognosis. Its gravity depends on several points, on the individual predisposition, on the age, on the degree of irritability, &c. Let us examine these various points.

On the score of predisposition, when gastro-enteritis breaks out in an individual already affected with chronic gastritis which he bore about him—and there are many in this case—it is necessarily more serious than in others not so affected. It will be more obstinate, and will not yield to the abortive measures which succeed in twenty others beside him. You should therefore make yourself acquainted with his previous mode of life, whether he has been intemperate, whether he has had several attacks of gastritis that were not completely cured, and especially whether he had not already begun to decay. In such a case, you must expect great difficulties: the least that can happen is the prolongation of the disease. If the patient has previously been affected in the middle and lower portion of the digestive canal, as evidenced by colics, meteorismus, and diarrhoea, you must expect a terrible disease; experience proves that, with similar antecedents, the phlegmasia is already considerably advanced at the time of the outbreak of the acute stage. Unfortunately we have more frequent opportunities of verifying this fact in our military hospitals than elsewhere, because soldiers, more familiarized as they are to the idea of death, and too much given to imagine that they will remain infirm and valetudinarian, and that such a state of life is not worth preserving, readily commit suicide. Only yesterday, at Val-de-Grâce, a case of this kind occurred: the patient killed himself. He had had symptoms of bronchitis,

which we had got rid of, and symptoms of gastro-enteritis that were already considerably reduced, together with some cerebral phenomena. We found in his body the phlegmasia that was being obliterated in the recently inflamed points, and that had produced induration, and threatening or already commenced disorganization in those where it had existed for a longer time. If the patients with this predisposition are aged, you have more to fear, because they bear phlegmasiæ worse than young subjects. To make a vividly acute disease in old men, a considerable quantity of stimulus must have been administered: they often have far advanced disorganizations even before the explosion of the disease. Do not, however, imagine that all men, young or old, who have these chronic gastrites preceding acute gastro-enteritis, die, or are even beyond a radical cure. On the contrary, it not unfrequently happens that they are cured at once and by the same remedies of their old and their recent disease, and are better than they were previous to the latter. Persons having gastro-duodenitis with turgid liver, are more especially instances of this: and the ancients who observed this, though less frequently than modern physiologists do, inasmuch as their treatment was inferior to ours, said that fever overcame obstacles and resolved obstructions. Boerrhaave, Sydenham, Hoffmann, Van Swieten, and others, held this opinion, and even went so far as to excite the fever when it was not sufficiently strong.

As regards age, acute gastro-enteritis is less frequent in old than in young persons, and the chronic kind more common. It has been said that dothinentery is never met with beyond the fortieth year: but such is not the case. True, that disease is less frequent in advanced age than at other periods, but this is owing to the weaker affectibility of the glandular, secretory, and follicular systems at that age. Yet if you go to the Salpêtrière, you will meet with a tolerably large number of adynamic fevers among the old men. Somebody has written a work on the dothinentery of young people, commissionaires, and water-carriers: let him write another one on that of old men, and he will see whether the disease is not common with them and young men, and whether their follicles do not become diseased. They certainly will not be so as frequently, for the simple reason, that old men commonly carry about with them old phlegmasiæ of the stomach, duodenum, and liver, and that when gastro-enteritis seizes on them, it predominates in those parts, makes rapid progress, acts upon the brain, and kills them before it has had time to reach the lower part of the digestive canal.

In children gastro-enteritis is serious. At that age, as well as in old age, it is characterized by the facility and rapidity of cerebral congestions: hence it was that Pinel

took his model of his cerebral fever from children and old persons. This peculiarity does not exclude the possibility of the same phenomena in young and adult individuals, only they are more rare in the latter. After a few days, and often a few hours, of gastro-enteritis, children quickly fall into a state of cerebral congestion, their diseases are rapid in progress, and the danger comes less from the digestive canal than the head. In old persons it more especially comes from the digestive canal, and in adults from both sources.

According to the seasons your prognosis will differ. The gastro-enteritis of the winter, of the close of autumn, and the beginning of spring, of the variable seasons in short, are more serious, because they are very frequently complicated with bronchitis and pulmonary congestions. Laennec judiciously remarks that catarrh almost always accompanies intense fever: this is easily explained: the current of the blood cannot be accelerated without the transmission of a greater mass of blood through the lungs, and at the same time an increase of the bronchial secretions. This augmentation is more or less marked, according to the constitution of individuals: fat, plethoric persons, with voluminous hearts, and habitually constricted respiration, will never have a gastro-enteritis of any intensity, without a copious catarrhal secretion: then, dry and nervous individuals are less subject to it. In the middle of summer, and in hot latitudes, this bronchitis is sometimes dry; in winter they are mucous and catarrhal to the greatest degree, and almost anything will cause a pulmonary congestion to ensue. If both diseases have co-existed from the onset, this conversion of catarrh into peripneumony occurs towards the close, and gives rise to the black induration, of which a bastard peripneumony has been made, and which some have more especially attributed to the stasis of the blood; but if you examine both sides of the lungs, you will find the induration neither equal nor uniform in them.

Aneurismatic disposition of the heart, which leads to these complications and thereby renders gastro-enteritis more serious, is met with in very many men, who originally have a heart of a size disproportionate with their stature, and is seen more in cities than in the country and mountains where the voluntary muscles are more developed. In cool and uncertain climates, where strong passions as well as catarrhs are rife, a twentieth part of the population is often affected with this hypertrophy of the heart. In fine, whether this disposition be innate or acquired, those having it have the catarrhal symptoms more decidedly, and are more subject to difficult breathing and peripneumony than others.

Regard must be paid to the manner in which the disease commenced and has been

treated. If it has been neglected, badly managed, or exasperated, it will of necessity be more serious. In the garrison of Paris we diminish the intensity of gastro-enteritis by issuing orders of the day by which patients are obliged to be brought to us in a stage of the disease that is more tractable, and in this manner we prove the efficacy of our means, and the power of our art.

Regard must be paid to the moral state and characteristics. Individuals whose life is a series of sorrows and vexations, or who have overworked the head, when once the fire is lighted up in the system, are liable to have it propagated to the organ that happens to be the most inflammable, and this, in them, is the brain. The pusillanimous have more serious symptoms, both from the gastro-enteritis and from the phlegmasia, that may be superadded. In this matter there are two divisions of patients, the timid and the courageous. The latter are able to recover from worse conditions than the former: I wish to verify this fact by phrenology, or, if you like it better, verify phrenology by this fact, and I observed that the cerebral organ, or region of the head corresponding to courage, was more developed in the men who exhibited the most resolution and coolness in their diseases.

Regard must be paid to the intensity of the circulatory and nervous phenomena: the more rapid the circulation the more serious the disease. Those subjects, however, must be excepted, in whom the rapidity of circulation is naturally greater. They are certainly more inflammatory, and have more violent gastro-enteritis; but the danger is not so assuredly measured by the pulse in them as in others: at least it is certain that persons with a feeble heart and slow pulse are more easily cured. Generally speaking, the frequency of the pulse should be the measure of the intensity and extent of the disease. As to the nervous symptoms, they may be observed from the onset: the patients lose courage, and have the presentiment of a serious disorder, repugnance to engage in serious affairs, and tendency to stupor when not in pain: these symptoms announce an affection of the nervous system, consequent on gastro-enteritis, and this is easily proved by applying a few leeches over the epigastrium, for after such application they disappear. They are not, however, always so easily dissipated, but exhibit great intensity in two principal circumstances: in that where the brain, being predisposed to inflammation, encephalitis becomes predominant, constituting the ataxic form: and in that where the disorganizing inflammation of the mucous membrane of the digestive canal threatens, or is already going on, constituting the adynamic form. This disorganization once consummated, the cerebral functions are irrecoverably lost—nothing can re-establish them: in vain you multiply your bleedings, se-

tons, moxas, &c., the patient dies. There is no exception to this rule; and a consequence of it is, that the adynamic state and the stupor are exclusively owing to the inflammation and alterations of the digestive mucous membrane. In fact, take a febrile disease that is not produced by gastro-enteritis, a primary peripneumony for instance, and you see it not. If this peripneumony be complicated with gastritis you will have ataxic symptoms, without those of stupor and insensibility: if it be at the same time complicated with enteritis, you will have the latter alternating with the former, and accompanied or not with tumefaction of the intestinal mucous follicles. More than this; if after a certain time the stomach recovers and the inflammation becomes more concentrated in the lower region until disorganization ensues, the patient may survive fifteen, twenty, or thirty days without stupor or delirium, without the stupid look that characterizes the disease, in short, with adynamic and ataxic symptoms. In the chronic state the same is observed when that state goes on to disorganization of the mucous membrane. Thus in both cases you have in the obstinacy of the nervous phenomena the proof that a serious inroad has been made in the mucous membrane of the digestive canal; nor is it necessary that the patient should vomit, that he should have pain of the epigastrium, hiccough, sensibility of the belly, &c.; all these symptoms may be altogether wanting, or have disappeared after existing. The stomach, thinned and exhausted, no longer re-acts and allows torrents of fluid to pass through it; while if, on the contrary, it recovers itself, you see the stupor disappear, the eyes become moist, the complexion clear, &c. Not that some slight febrile movements may still appear: but you have no more stupor or adynamic intoxication, or they are only slight and temporary. Such, then, are the nervous and circulatory symptoms that give the measure of the irritation and extent of the inflammation in a more certain manner than some others of which I have still to speak.

Pain on pressure shews that the disease is violent; but we must not think to measure the intensity by this sign: for if it exists in some individuals, it is wanting in many others: nothing is less trustworthy: the stomach and intestines may be in a frightful state of disorganization without any pain being exhibited. Indeed, the intestines are rarely painful in persons that have been submitted to a negative regimen and mild drinks: their sensibility is scarcely ever exalted but in those who have been stimulated.

Meteorismus is always a disastrous sign, and a proof that the small intestines are involved in the disease. The addition of "diarrhoea announces that the lower portion of the digestive canal is affected. When it

supervenes at the commencement of the disease it is not dangerous: at the end it is considerably so, particularly if it persists for two or three days: it is a proof of disorganization in the ileo-cæcal region.

The symptoms of danger are moreover always in proportion with the multiplicity of the seats of inflammation. If with the signs of gastro-enteritis you have those of cystitis, carditis, with unyielding arteries and cardiac palpitations, they constitute very untoward symptoms. An irregular and intermittent pulse is a dangerous sign.

The ataxy and adynamy of the early days of the disease are of slight consequence, especially when they can be attributed to congestion of the digestive mucous membrane; but they become more and more so after eight or ten days, unless they are owing to some imprudence that may be easily obviated; a spoonful of wine, or even of soup, is sufficient to renew them, as well as the diarrhœa and the increased pulse.

The early appearance of eschars indicate a deep lesion of the digestive organs. Attacks of erysipelas are advantageous if they diminish the fever, dangerous if they augment it. Parotid swelling is no sign of malignity, and is not dangerous, except by leading to cerebral congestions; they are of less import the earlier in the disease they appear, because at that period the subject is more fresh, and is a better object for antiphlogistic treatment.

Proceeding to the signs of a favourable prognosis, we find that when the nervous phenomena yield to antiphlogistics, and do not continue longer than two or three days, it is a good omen; when the pulse, from being contracted, fills out and remains so, you may have very good hope; when the stupor, sordes, subsultus, and low delirium cease, and at the same time the appetite re-appears, it is fortunate. But be not too confident, and do not pronounce the patient to be past all danger, for there may possibly may be a circumscribed but serious disorganization in the small intestines, which causing perforation, may end in a fatal peritonitis. Avoid, therefore, any positive prognosis or sweeping declaration: you can only hope. To be certain of success the frequency of the pulse must also diminish: for it sometimes keeps up notwithstanding the return of appetite, the re-establishment of the natural facial expression, the renewed moisture of the eyes, the clean, moist tongue, &c. As long as it continues you can answer for nothing; the smallest excess, the slightest error, may renew the disease, cause it to reach the upper portion, attack the nervous system, perforate the intestine, or proceed to the lungs: be therefore ever on your guard. When the frequency of the pulse begins to diminish the patient gradually recovers, provided he takes proper care: when it falls from five to ten beats in

twenty-four hours, he may, on the same condition, be considered out of all harm.

When patients sink in relapse we commonly find ulcers entirely or partially cicatrized, others with shrunk edges, others in which they are rugous, hard, and elevated, and others, again, that have perforated the intestinal coats and given origin to peritoneal inflammation—which, however, may exist without such perforation.

The fæces will recover of themselves, and when it so happens it is a favourable circumstance; there may be one or two loose motions, but if they subsequently become figured, convalescence is certain.

Treatment of Gastro-enteritis.—First of all, the disease should be taken from its onset, and it should be borne in mind that every gastro-intestinal irritation may become a gastro-enteritis at any age, though the disease has existed several times before. With this idea uppermost, you will have in view the distinction of the phlegmasia of the digestive canal, commencing with gastric disturbance, and announced by foul mouth, headach, lassitude of the limbs, nausea, shivering and heat, variable sensibility of the stomach, &c. These symptoms, which may be the prodroma of gastro-enteritis if not prevented from running through its stages, may also not bear that reference to it if it be arrested. Only imagine the position of a man who collects observations; he takes a certain number of them, ten, or fifty, or eighty, that have not been arrested at the onset: he relates the symptoms of the onset, and tells you these are the prodroma, and he then describes the disease itself; as if it were not always the same subject, varying only in aspect and form, just as an adult is only a child in a state of full development. Of these eighty prodroma, sixty at least might have been cured, and would only have been the first degree of arrested gastro-enteritis, had they been treated at an early period. This is the question stated. I think that long ago I cleared it of all the sophisms by which some desired it should be obscured. Those who have attentively observed these prodroma, have viewed them as I have done, whenever they called in the aid of their conscience as well as of their reason—I say of their conscience, for this is necessary in medicine, and unfortunately proves that all men are not sufficiently provided with it. It is a fundamental faculty that needs considerable cultivation.

In what are called its prodroma then, gastro-enteritis must be arrested, and the most efficacious means of this end, consists in local bleedings, leeches or cupping, over the epigastrium, demulcent poultices, abstinence, and mild drinks. This treatment most assuredly puts a stop to three fourths of acute gastro-enteritis. Yet some are cured by a different treatment, by an emetic for instance. This emetic, which I suppose to be tartarized antimony, excites the sto-

mach, and provokes copious evacuations. Now, all evacuations are debilitating and even antiphlogistic, when the diseased has not been too much stimulated in producing them. But the digestive canal, and the stomach particularly, is a highly sympathising organ, which communicates its irritation to the secretory organs, and gets rid of it by abundant secretions of bile, of pancreatic fluid and mucosities, and at the same time, by the diluents with which the administration of emetics is accompanied; so that their phlogosing action may be compensated and neutralized by these evacuations and dilutions; and so true is this, that when the emetic is not followed by copious evacuation, it irritates, even in the peripneumony in which it is given, and when the stomach is not at all very slightly affected. Besides, it must be remarked, that in some persons the secretory organs respond more readily than in others to the stimulus of tartar-emetic. If you hit upon one of such persons, it is very possible that, after a bleeding, an emetic puts a stop to the gastro-enteritis. But because this happens occasionally, you must by no means conclude that it is a certain remedy: so far is it from being so, that in the great majority of cases—about seven eighths—the disease, after being diminished for a few hours, is renewed in intensity. When I was in the habit of treating according to the *Nosographie philosophique*, that is, with tartar-emetic, I almost invariably found nervous pneumonia supervene the following day. So accustomed were my colleagues and myself to this, that when we saw a patient with incipient gastro-enteritis, being treated with an emetic, we said, “that man has a gastric disturbance to day, and to-morrow he will be in a state of adynamy;” it scarcely ever failed to be the case, and then the disease went on rapidly, in consequence of which I abandoned this kind of treatment. For a long time I did not apply leeches, because I had no precise idea of phlegmasia and its peculiar actions, that is to say, its tendency to extension in the digestive canal, and to propagation in the system at large: at that time I thought of little else but bilious or gastric fever. However, by giving up emetics and keeping to emollients, I diminished the number of adynamic fevers, which are now called typhoid or dothinentery. When patients in this condition were brought to me, I no longer dared to give them bark, camphor, snake-root, &c.; and confined myself to acid, slightly vinous beverage; and I cured a good number with this *limonade*. At length, as the inspection of bodies always discovered to me inflammations in the digestive canal, doubts arose in my mind, and I said to myself, “these inflammations are affirmed to be the effect of the disease, and no attention is to be paid to them—suppose I reverse the proposition!”

I was in this state of perplexity when I

was left, in Spain, with a great number of patients, without resources, and without medicines, having nothing but vinegar and water. I gave these in mixture to my patients, some of whom, that had ataxic symptoms, were better next day, and improved daily: it cured several of them. A revolution then took place in my ideas, such as is perhaps now going on in yours, and I felt that the time for a revision of what I had learned was arrived. This I undertook in 1814, on my return to France, when I found myself, as it were, forced to commence lecturing, in order the better to arrange the truths which as yet I had only a confused conviction of. I began by asking myself, and many of my then pupils, the majority of whom are still living, whether the supposed essential fevers might not be phlegmasia, and ought not to be treated as such. We began the reform of the treatment. We observed that many gastro-enterites, after having at first gone on well, suddenly became worse; we wished to ascertain the cause of this, and by renewed attention, we at length discovered that the patients had procured either some wine or soup, or boiled meat, &c. I caused these patients to be placed in a ward where they could hold no communion from without, and had them strictly watched. This threw fresh daylight on our views: we ascertained that the least thing was sufficient to reproduce a declining gastro-enteritis, and that the lightest aliment, or the smallest dose of a stimulating medicine, caused the return of the ataxic symptoms. Our theory was then established.

I am not the only one that effected this revolution in science. I was encouraged and seconded by my fellow labourers, of that period, who are now eminent physicians. It was not without difficulty and efforts, of which you can form no idea, that I tore myself from my former notions. Those who would bring you into the same state of embarrassment have themselves never been in it, or are so organized as to live tranquilly in error.

From this date then, the method of treating gastro-enteritis was definitively fixed in the following manner, and is the method that I follow to this day.

—o—

A Sketch of the Medical and Statistical History of Epidemic Diseases in Ireland, from 1798 to 1835, with the Method of Prevention and Cure, as practised in the Fever Hospital, Cork Street, Dublin. By William Stoker, M.D., Hon. Fellow of the King and Queen's College of Physicians in Ireland, &c. &c.

(Continued from page 460.)

[The following paragraph was accidentally omitted last week.

The first fever hospital in Dublin was opened in Cork-street, 1803, and it was free

to the five adjoining parishes. In this year 415 patients were admitted, and of these 29 died; mortality 1 in 15. In 1805, 1024 were admitted, and the deaths were 67; about 1 in 15. In 1806, 1261 admitted, deaths 103; 1 in 12. In 1807, 1100 admitted, deaths 92; 1 in 11. In 1808, 1071 admitted, deaths 94; 1 in 11. In 1809, 1051 admitted, deaths 83; 1 in 12].

Period from 1817 to 1834.—Increase of disease and famine, simultaneous, and equally prevalent over Ireland in 1817, 1818, and 1819.—Type till 1822, the same as in the preceding years of the 19th; and from the history left by others, as in the corresponding years of the 18th century. The cases being, until 1822, febrile—sometimes symptomatic of inflammation, at others proved by morbid changes, in both fluids and solids, before and after death, to be wholly functional or idiopathic.—In 1823, 1824, and 1825, pestilence followed the loss of trade and the destitution of the poor.—Still more remarkably in 1830, 31, 2, 3, 4, and 5, an epidemic constitution of the air contributed to its malignity.—Then not only the evident distinction between symptomatic and idiopathic fever, and between fever and typhus was further exemplified; but the violent transition of typhus to epidemic cholera was first observed. On all these occasions corresponding changes in the external characters of the vital fluid, identified the prevailing distempers with the pest of the blood, as described in sacred history.

THE commencement of the period embraced in the second section, was as much distinguished by sudden and rapid growth of febrile disease, as that of the first was by its rise. Besides the miseries of famine, which succeeded the failure or destruction of crops in 1816, were simultaneous and commensurate with the sudden increase of fever in 1817 and 1818. But the growth of disease was not nearly so rapid in the metropolis as in the other parts of Ireland, where famine was not so effectually opposed by a liberal supply of food, fuel, and other necessities of life. These coincidences must have afforded valuable instruction to those entrusted with devising preventive measures, had not the preconceived opinions of the *ultra-contagionists* fatally misled them*. The same prejudice, however, still, unfortunately continued, notwithstanding that in each successive year since, other concurring and more evident causes occurred, such as heat and cold not alternating as before with summer and winter; the unprecedented privations of the working classes, and total loss of trade. The latter too became more and more manifest as the chief concurring

causes; whilst the separate agency of contagion, according to any laws laid down by its own advocates, became more difficult to be identified. Certainly it never was proved wholly independent of other more evident causes*.

Famine being, in the year 1817, for the reasons assigned, less productive of disease in Dublin than in the rest of Ireland, no additional fever hospitals were erected there. The admissions, therefore, into the primitive one, still afforded, as suggested in some of my annual reports, a tolerably accurate scale for measuring the increase of disease in this city. Moreover it likewise assisted in showing the relative mortality compared with 1816, the preceding year. These facts may be seen in the annexed table.

Years.	Admitted.	Died.	Average mortality.
1816	2703	173	1 in 15
1817	3682	231	1 in 16

These results, if duly examined and compared with the previous statements from the annals of the Cork-street hospital, are quite conclusive as to the superiority of supplying the poor with the necessities of life, which was adopted in Dublin, during the first three quarters of 1817. Surely such facts are well deserving of the attentive consideration of political economists. It appears, moreover, that though this increase of disease in Dublin, in 1817, compared with other parts of the kingdom, or with 1816, which was a remarkably healthful year throughout Europe, was slight, yet compared with 1815, when the previously tardy advance of disease was opposed by the complex apparatus provided for checking contagion, there was an actual diminution. There was, therefore, a much greater number of patients in the Irish metropolis in 1815, when the most extensive apparatus ever provided against contagion, was in full operation, than in 1817. But it was contemplated, in the latter years, only by the advocates of these measures, that a new and specific contagion had been imported, although great superiority of the means employed in the first three quarters of 1817 over the anti-contagious apparatus, and over the principles of its adoption, was rendered still more manifest. The very great importance of the illustration afforded by the relative increase of disease in Dublin, and in other parts of Ireland, from 1815 to 1817, under opposite modes of practice, will plead for dwelling so long on it. The subject demands much more space than can be given to it on the present occasion. A retrospect, however, of these events in 1817 and 18, may be found in the reports for 1820, 21, 23, and 28, and

* Medical Reports for the years 1817, 18, 19, 20, 23, and 28.

* See Dr. Haygarth's Letter to Dr. Percival, in 1800, and Dr. Stokes' Essay on Contagion, 1819.

are epitomized in the following table, which includes the years from 1817 to 1828.

Years.	Admissions.	Deaths.	Average mortality
1817	3682	231	1 in 15*
1818	7608	258	1 in 30†
1819	3873	224	1 in 17‡
1820	2974	203	1 in 14§
1821	2973	246	1 in 12
1822	2307	137	1 in 16¶
Total from 1803	46361	2869	1 in 16**
1823	2668	241	1 in 11††
1824	4599	327	1 in 12‡‡
1825	3878	381	1 in 10§§
Total 3 years	11145	949	1 in 11
1826	10882	386	1 in 28¶¶
1827	6544	344	1 in 19***
1828	2964	193	1 in 15†††

The average mortality in 1817, became somewhat less than in the preceding year. In both, however, the same principles and practice were pursued, and in the same forms of disease as in 1810, when the first remarkable evidence of a tendency towards

* Famine stayed in the city by supply of food; raged in other parts of Ireland.

† Many other fever hospitals established in Dublin, and received vast numbers. Actual mortality dreadful.

‡ These admissions into the Cork Street hospital, and deaths, no longer measure the increase of disease in Dublin.

§ Contagion, famine, malaria (vide report 1820, 21), manifest relative agency.

|| Diseases more typhoid. See report for 1820, 21.

¶ Decline of disease generally over Ireland, as happened in 1816, before increase of 1817.

** Compare the mortality of this with that of the pest of the blood, in successive years it prevailed.

†† Pest of the blood, supervened on influenza. See 2nd part Pat. Obs.

‡‡ All diseases, medical and surgical, affected by the pestilence. See Med. Rep.

§§ Besides the peculiar characteristics of the blood, dropsy and spurious phthisis followed cases of the pestilence.

||| The pest of the blood, epizootic and epidemic. Its symptoms, asphyxia, sudden death, coldness, ecchymoses.

¶¶ The mortality from the pestilence of 1823 was truly awful this year, though the average mortality in hospitals was very small, from the numbers in want of trade crowding them, in famine, not disease.

*** The same observations applicable to 1826 and 27.

††† See report for 1828; the decline of numbers, but increased mortality from the pest of 1823, sudden deaths, phthisis, and dropsy frequent.

pestilence in the prevailing epidemic, was exhibited remarkably in the morbid appearances of the blood, and by corresponding functional derangement. Then, too, in some cases, coagulated and sizzly blood distinguished the increased action of inflammation; and in other cases broken down, dark-coloured blood, as constantly denoted typhoid debility in whatever stage it was observed. (See Medical Reports for 1820 and 21).

In 1818, famine-fever uniting with the pestilential disease, which was the comparatively slow growth of preceding years, the number of the sick in Dublin was frightfully increased, and though other large institutions were erected in the different quarters of Dublin, so that 2,000 beds were provided for sick poor in fever or famine, still 7,608 applicants were received into the Cork-street hospital alone. By far the largest proportion of these, however, were cases of famine rather than of pestilential fever, and demanded judicious administration of food and other necessities at home, rather than of medicines after admission into the hospital. This fact is important in its application, both with a view to medical and political economy. As a further illustration, in connection with it, it should be stated that under appropriate treatment of the different classes of cases of disease and misery, there were but 258 deaths among the 7,608 received into the Cork-street Fever Hospital, or 1 in 30. The question of an imported contagion was also a subject of anxious discussion in 1817 and 18, as may be seen in the annual reports. The description of the epidemics of the preceding nineteen years equally applies to this period.

In the succeeding four years, 1818 to 22 inclusive (see the Reports from the Cork-street hospital for that period), the relative effects of destitution, contagion, and in a less degree malaria, were distinguishable; but, as appears in the preceding table, neither the average numbers admitted, nor the average mortality, exceeded that of the seven preceding years.

It was during the course of this famine-fever, which prevailed in many parts of Europe, from the same causes, that the new views of its pathology were promulgated, first, I believe, by the French Necrotomists, and afterwards adopted by those of Great Britain and Ireland, namely, that it was produced from beginning to end, by morbid changes in the nervous, but more particularly in the ganglionic system. And having already stated the opinions of other eminent anatomists, in opposition to the assertion of signs of inflammation being always detected in the vascular system of the bodies of those dying of typhus, I was enabled, on equal authority, to disprove the more recent doctrines formed on changes in the organization of the nervous system. Moreover, on reading some extracts by M.

Orfila, from a work then recently published by Dr. Kerner, of Weinsburgh, it appeared that the symptoms before, and the appearances found after death, in an extensive district in Germany, were similar to those of the prevailing disease, and were produced by an unwholesome article of acrid food, which all so afflicted had eaten. Hence it was to be fairly inferred that the same morbid changes were incidentally connected with the acrid contents of the stomach in the famine-fever*. The very decisive testimony of Dr. Kirby and Dr. Macartney, on the appearances they found in examining the bodies of the dead, in the malignant fevers, is also stated in the reports for 1820, 21. Also meteoric tables, which show, by comparison with corresponding ones, the connection between the changes in the weather and the growth of disease. To those meteoric tables and tables of disease, I am the more desirous to refer, because their interest will be found greatly enhanced if examined in juxtaposition with Dr. Henry Cope's *Demonstratio Medico-Practica*, in which learned work similar observations were made in the corresponding period of the 18th century†, when he was State physician in Ireland, and still more so if compared with Dr. Fielding's paper on meteorology and influenza, read at the meeting of the British Association in Cambridge. (Appendix. Note F.)

The epidemic of 1823 (see my report from the fever hospital, and the first part of my Pathological Observations, both published that year), underwent a more extraordinary revolution than any I previously witnessed. Its new characters were diminished temperature, loss of vital power, with corresponding asphyxia, dark petechiæ and ecchymoses with jaundiced interstices, extremities blue, severe vomiting, and mucous diarrhœa—the discharge varying from orange-coloured and green to black, sometimes colourless, as in *lienteria*. Fatal terminations sudden, often preceded by metastases. Paralysis and dropsy also frequently succeeded to, or attended on, protracted cases. These aggravated characteristics were still more manifestly connected than in the epidemics of 1810, 17, and 18, with corresponding changes in the external characters of the blood, drawn in the course of disease, or found gorging the large blood-vessels after death, and corroborated the opinion I had previously expressed, of the blood being the chief seat of typhoid or adynamic, as well as of pestilential diseases. I had,

however, never before witnessed, except in a few sporadic cases, nor seen described by the writers of the 18th century, characteristics so formidable, nor morbid changes in the blood corresponding with them in the same degree. The malignity of the epidemic constitution of the air was otherwise very remarkable at this time (see table), and, as may be seen in the medical journals of that day, it interfered with the recovery of patients after surgical operations, both in this and the sister kingdoms. Besides slight punctures received while dissecting in the anatomical theatres, were often succeeded by suddenly fatal attacks of typhus disease. That the malignant influence of the air was not only epidemic but epizootic, was proved also by its symptoms, such as dark petechiæ in all parts of horses uncovered by lair (the tongue, nostrils, &c.), by glandular tumours, both internally and externally on the same animals; by hepatization of the lungs and vascular congestion; dark and clotted blood, and corresponding changes in that drawn or effused in the course of the disease. Numerous cases of this sort were presented to me by the eminent veterinary surgeon, Mr. Watts*. Through his kindness I witnessed

* That the practice of physic may be even much more improved by comparative pathology than the knowledge of the human system by comparative anatomy, can hardly be questioned by any one, knowing how boundless the field of inquiry is in the one case compared with the other. But independently of this, the greater simplicity of the organs of other animals, and of the diseases of these organs, than in man, greatly aid the physician in detecting (if there be any) the traces of similar diseases after death. In the cases and dissections of the horses referred to in the text, the advantages of examining them very shortly after death, essentially promoted my leading objects, namely, to detect, as far as possible, the transition of disease from the morbid fluids to the morbid solids, and *vice versa*. These symptoms of the epidemic, such as loss of pulse and warmth, coldness of breath, skin dark, and clotted blood, ecchymoses, sphacelus, unnatural motions and sounds of the heart, *bruit de soufflet*, in the thorax were all common to the human patient and the sick horse; so were hepatization of the lungs, infarction of the liver; engorgement of the heart, with dark coloured blood, and also of the large blood-vessels in every part of the body, with the same. Besides these appearances, common to all animals after death, of the then prevailing disease, there was copious effusion internally, of lymph, partly coagulable, but rarely any adhesive inflammation. In now republishing this note, on my report for 1823, I may also observe, that in the spring of 1833, when a fatal influenza was both epidemic and epizootic in Great Britain and Ireland, Mr.

* "Nouvelles observations sur les empoisonnemens mortel qui arrivent si souvent dans le Wurtemberg, par l'usage des Boudans fumes," Par le D^r Kerner Tubingue, 1820, 12 nom.

† *Demonstratio Medico-Practica Prognosticorum Hippocratis, &c. &c.* Ab Henrico Cope, Medico Regio ad st. tum in Hiberniâ.

the course of the disease, and the appearances found on dissection in a much shorter time after death than could have been attempted in the human subject. It was likewise in 1823 that I examined the temperature of the patients in the malignant typhus that then prevailed, and the results were, that even the *calor parum auctus*, of Cullen, was not then applicable to the prevailing distemper, as in many cases the thermometer stood much below 96°. So that fever and pyrexia were then as unsuitable denominations for the existing epidemic in Ireland, as cholera and typhus for that which afterwards committed such ravages in Europe in 1830, 31, 32, 33, 34, and 35. In the same year, also, I was fortunate in proving, by experiments, that the buffy coat on the blood, drawn either in inflammatory or dropsical complaints, did not depend, as previously supposed, in slow coagulation and the subsidence of the red particles, but probably on functional derangement of the chemical affinities subtending to vital power, which my experiments in 1807 indicated in the organs of sanguification. If compatible with the space that could be here given to it, it could be shown that great advantages, both in theory and practice, are derivable from the results of the foregoing observations, but reference, on that part of the subject, to my Pathological Observations, published in 1823, 28, and 30, must for the present suffice. (See 1st, 2nd, and 3rd part of my Pathological Observations).

2,668 patients were admitted into the Cork-street hospital that year, and 241 died, the average mortality being 1 in 11, though from the opening of the hospital to the conclusion of the preceding year, it was but 1 in 16.

The numbers admitted into the Cork-street hospital during the three succeeding years, viz., from 1823 to 1825 inclusive (though then other large fever hospitals were established in every quarter of Dublin), were 11,145, of whom 945 died, showing a mortality of 1 in 11. Thus the virulence of the epidemic constitution of the air that year was exhibited.

The same symptoms continued with as fatal consequences in 1826, and 1827, as in the preceding three years, but owing to the admission of many not labouring under positive disease, the average mortality in the hospitals was less, viz. 17,426 were admitted into the Cork street hospital, of whom 726 died. To those who witnessed the fever of 1826 and 1827, it is hardly necessary to state, that coldness of the sur-

face and of the breath, asphyxia, blue or purple colour of the extremities and frequent fatal terminations, accompanied by purging and vomiting, were then also often to be met with. So much so, indeed, that Baron Larrey, who visited the Cork-street hospital at that time, has since stated, in his Treatise on Cholera, 1830, how much the disease he then saw in Ireland, resembled malignant cholera.

The year 1828 was distinguished by a diminution, both in the number of admissions and of deaths in the fever hospital; but this temporary decline cannot have resulted from a favourable change in the epidemic constitution of the air, for the cases still, in many instances, presented the same symptoms of malignancy, and the blood still exhibited the same pitchy and clotted appearances, whether drawn during disease, or examined in the large vessels after death, as may be seen in the report for that year. Indeed, in all the cases in that report, both those who laboured under exanthematous and other fevers, *tic-doloureux* and dropsy, and the cases of some horses whose dissection is also given there, the morbid influence of the prevailing condition of the atmosphere, was strikingly apparent*. To illustrate the nature of the fever of 1828, and the mode of treatment employed, I shall take the liberty of submitting the following abridgment of a few cases I noted at that time, and published in the Annual Report of that year:

John Baker, aged 64, of a broken-down constitution, was attacked on the 10th of December, 1828, and admitted into the hospital on the 13th of the same month. His countenance was then sunk, his eyes anxious and hollow, his voice almost inaudible; the skin was generally cold and clammy, and of a livid hue, particularly on the extremities; constant diarrhœa, general spasms, no coma, or delirium. On getting some warm wine, which he drank with avidity, and warmth being applied to his limbs, the pulse became perceptible. Camphorated mixture, with the aromatic spirit of ammonia was then prescribed; and turpentine enemata, with frictions of turpentine, were directed. Under these remedies, with the addition of turpentine in draughts, and a blister to the neck, he improved for some days; but on the morning of the 19th December, after walking to the fire without assistance, he suddenly expired. After death, the skin resumed its purple motley appearance. Dissection was not permitted by the managers.

James Crotty, after eight days' illness, was admitted on the 23rd December, 1828, apparently moribund: his head was drawn back, and the trachea protruded by spasm;

George Watts, jun., kindly gave me, for the Surgical Society, a report of cases and dissections of horses, (both here and in England), in which the symptoms, preternatural alterations of the blood, and post mortem appearances, corresponded minutely with what Mr. Watts, sen., and I had together witnessed in the epidemics of 1823 and 27.

* See report for the year 1828, by William Stoker, M. D., particularly from the 79th to 109th page, and from 143rd to 161st inclusive.

temperature under the tongue 90 degs. Nearly the same remedies were employed as in the last case, and with the same temporary benefit, but general spasms set in, and he soon afterwards expired. The purple colour of the body continued.

Mrs. Edwards, aged 38, was admitted 6th December, 1828, in the last month of gestation. Skin cold and clammy, extremities purple, eyes sunk, features collapsed, voice scarcely audible. Besides particular attention to the state of pregnancy, a similar practice as in the preceding cases was adopted, but the powers of life gradually declined and the motion of the fœtus in utero diminished until death of both took place on the 9th of the same month. On *post mortem* examination, beside evidences of much chronic disease in the cranial and thoracic viscera, the vessels on the surface of the brain were darkly tinged. The lungs were hepatized, and of the same purple appearance as the extremities. These latter results of diseased action were most probably of no long standing, and seemed the immediate cause of death*.

The general and very decided check to the growth of disease, which has been already stated to have occurred in 1828, I always attributed to the filip then given to our *sickly retail trade*; and gladly quoted it as evidence of the buoyancy of this country, when relieved from a concurring cause of its aggravated calamities. Moreover, discord, at once the parent and child of such calamities, ceased during the transient period of prosperity. With respect to medical measures, my subsequent experience of their efficacy further warranted me in recommending those I had employed in the aggravated form of the epidemic, in the year 1823, and which I believe were in both cases essentially the same.

In the year 1829, the same prostration of strength, diminution of animal heat, suspension of the vital powers, and other symptoms of malignancy prevailed as in the year 1828. The average mortality for the same reasons was nearly the same as in the preceding year, namely, 234 deaths and 2,839 recoveries, or 1 in 21. In the report of that year too it may be perceived that several cases then detailed of typhus, dysentery, hepatitis, and rheumatism, were accompanied by some of the symptoms above alluded to. These cases seem to me to have suggested to the author of that report, the term cholera, in a preceding page.†

Having repeatedly announced, from the beginning of the year 1830, that the epi-

demic had, in a large proportion of cases, both in hospital and private practice, assumed characteristics of malignant diarrhœa, resembling those diseases described on the Continent, and in the East of Europe, and therefore demanding particular attention, I have drawn up the following table of admissions and deaths for each month during 1830, 31, 32; and for the first two months of 1833, with a view to that question. I have ever avowed that opinion, and I feel it my bounden duty, however misconceived or misrepresented, still to maintain that rigorous investigation on that subject is necessary for public security:—

Months.	1830		1831	
	Cases.	Deaths.	Cases.	Deaths.
January	355	42	454	38
February	287	23	393	31
March	309	20	332	30

Total each year. }	3168	231½		
Average.	1 in 13.			

From the above table it appears that the mortality of 1830 and 1831 was nearly the same as in 1823; and that the mortality of 1832, excepting in the first quarter, when it was 1 in 8, and in the other three only 1 in 14; but in the month of June when cholera was most malignant, and therefore more strictly excluded, the mortality was only 1 to 22. This relative diminution in 1832, arose from the fact, that in the months of November and December, 1831, and January, February, March, and April, 1832, cases of the prevailing epidemic, not being yet acknowledged as such, were admitted indiscriminately (the mortality of those months was therefore increased); but during the remainder of the year 1832, when the

* A particular description of this examination by Surgeon Trant, by whom I was assisted, is given at the 153rd page of my report.

† See Medical Report from the Fever Hospital and House of Recovery, Cork-street, for the year 1829. By John O'Brien, M. D., &c., &c.

epidemic was most malignant, severe cases were excluded from the wards of the hospital, and sent to the establishments for the reception of cholera patients. The mortality during the latter months of 1832, was therefore less than in the corresponding months of any year since the Cork-street hospital was opened, according to the first resolution of the trustees "for the relief of the destitute poor afflicted with fever, and to check the progress of contagion, as well as acquire and diffuse medical knowledge." (See my comparative view of cholera, Jan. 1832).

Having thus adverted generally to this mischievous anomaly, I shall proceed *seriatim* with each of the three years in question. And first with respect to 1830, it may be seen in the 3rd part of my Pathology* then published, that besides adverting previously to the decisive evidence of Mr. Searle, in the East, in his publication on epidemic cholera, and to that of Dr. Stevens in the West Indies, in his observations on cholera and typhus, in favour of the pathology of the blood I had advocated, it was also stated "that there was then another form of the pestilence, namely, *Cholera*, which was more fatal than the rest."

The following are abridgments from that publication, of two cases in which the intellects were perfect, and both by their symptoms and *post mortem* appearances, tended to prove a direct connexion between asphyxia, coldness, blueness of the skin, sudden death, and morbid changes in the condition of the blood. In both cases, it may be perceived that the epidemic supervened on other diseases, which predisposed to the attack.

John Martin, a butcher, aged 42, was admitted 24th January, 1830, having laboured for eight days under symptoms of pneumonia, which were relieved by copious bleedings, leeches, and blisters, &c. The blood first drawn, I learned was neither firmly coagulated, nor much buffed, but that the last was pitch-coloured and clotted. At the time of his admission no pulse could be felt even in the iliac and carotid arteries, and but an indistinct fluttering at the heart itself. The skin was icy cold, moist, and livid; and the extremities, nose, lips, and tongue were quite purple, as were also those parts to which blisters had been applied. He walked up stairs without help, and his mental faculties were complete to the last moment. Upon stethoscoping his thorax, that peculiar *bruit de soufflet* which, in the cases of horses in 1828, already referred to, indicated hepatization of the lungs was distinctly audible. Warmth and cordials were vigorously employed, but general

spasms set in, and death followed in twelve hours from admission. On inspecting the body next day, it was generally purple, as was usual at that time, not only in the Cork-street, but in the Edinburgh hospital, according to Drs. Alison and Graham's lectures, which I at that time quoted in support of my Pathology of the prevailing epidemic.

Second case.—Mr. T. W., aged 20. This gentleman had long laboured under caries of the dorsal vertebræ, together with pectoral affections, which had become very urgent in February 1830, accompanied with hæmorrhagic fever and dropsy. He came to town for medical advice, and by the antiphlogistic regimen and small bleedings, was relieved, the blood being buffed, and for some days his strength and appetite continued to improve. Unfortunately, however, he was indulged, unknown to me, by his attendants, with too much food, and the affection of the chest became suddenly alarming. Bleeding and blistering were again resorted to, but not with so good an effect as at first. The blood drawn, became a dark-coloured clot, the lips, tongue, and extremities purple; the countenance livid; the voice failed; the pulse became suddenly feeble, and entirely ceased six hours before death, which was about a fortnight after his arrival in Dublin, and about twelve hours after his relapse*. On dissection, the face, neck, and chest were of a livid hue, the tongue, lips, and interior of the mouth quite purple: hypertrophy of the heart, without disease of the valves: the large vessels were filled with dark blood; numerous tubercles in the upper portion of the right lung; the whole of the left lung was emphysematous, and adherent at its inferior margin by a fistulous communication with the 7th and 8th dorsal vertebræ, both of which were in a state of caries. The abdominal viscera were sound except the pancreas, which was enlarged and tuberculated.

In addition to these specimens of the epidemic of 1830, I can only refer for a more complete description of it to the 3rd part of my Pathological Observations, and to Dr. Grattan's Report of the Fever Hospital and House of Recovery, Cork-street, both published that year. In the former of those publications I recommended the root of dandelion, prepared as coffee, both as a preventive, and a remedy in the severe forms of cholera, and obstinate diarrhœa, which then presented themselves in hospital

* It has been objected by those opposed to the investigation, that I sought such cases, as these in the text and not those of cholera. But I never said they were; I am now sure, however, by comparing them with the cases which those objectors have published as examples of the malignant epidemic of 1832, 3, and 4, and those of 1830, they were essentially the same.

* Pathological Observations, part 3rd, 1830. By William Stoker, M.D., page 11 and 101. At the 109th page the above case of Martin is fully detailed under the head of "Pneumonia Typhoidea."

and private practice, and also preparations of achillœa millefolium or milfoil in those hydropic and rheumatic affections with which they frequently alternated*. Very extensive trial of these vegetable substances, both as substitutes for more costly, and sometimes less safe articles of the *Materia Medica*, as well as favourable reports subsequently by some of my medical brethren, led to my first recommendation of them. I repeated it from finding them well suited for preventing and curing diseases more general amongst the Irish poor than those of other countries (e.g.) epidemic cholera, and diarrhœa, and also for other diseases, which I observed frequently to alternate, since they have become more pestilential; I mean dropsy, spurious phthisis, and rheumatic pemphigus. This peculiarity of the diseases of the poor in Ireland (as will appear more manifest under the subject of statistics) arises, I believe, chiefly from scarcity and insufficiency of food, particularly from the unwholesomeness of the potato, the staple food of the peasantry, when that article, as annually happens, is in a state either of decay or immaturity. An antidote, therefore, to such a national calamity, which might, at the same time be an agreeable substitute for ardent spirits, itself a very general exciting cause of such diseases, must be deemed a *desideratum* of great moment in medical as well as political economy. In Dr. Grattan's report of 1830, it is stated that it appears to him that the forms of the epidemic which then presented themselves "passed by such imperceptible gradations into each other, as to be considered but varieties of the same disease.†"

(To be continued.)

Reviews.

A Statistical Inquiry into the present state of the Medical Charities in Ireland, with Suggestions for a Medical Poor Law, by which they may be rendered much more extensively efficient. By Denis Phelan, Surgeon to the County Tipperary Gaol, and to the House of Industry and Lunatic Asylum, Clonmel, &c. 8vo. pp. 324. Dublin: Hodges and Smith. London: Longman and Co. 1835.

(Continued from p. 435.)

THE author proceeds to enumerate the acts relating to the Meath Hospital, or county of Dublin Infirmary, and these deserve especial attention. They shew the baneful influence

of private interest in obtaining local acts of parliament as regard Irish affairs. Thus the physicians and surgeons of the Meath Hospital, are empowered, by law, to elect their successors and contemporaries, and consequently they will prefer their relations and friends. Religious bigotry, where great liberality is professed, has more than once excluded able officers from this hospital. Happy country! blessed with such just and beneficial laws. Even an apprentice to one of the surgeons, who paid a larger fee, was excluded from election, because he was a Roman Catholic! though his master was of the same persuasion, and was the first to raise the fame of the hospital. On another occasion, one of the pillars of the temple paid 200*l.* for his site. We could tell something more of the medical staff of the Meath Hospital: but we shall refrain. Surely the exposure of abuses of this sort, must convince legislators of the necessity of repealing acts of this kind. It is for this reason that we estimate the work before us so highly, and so important to our brethren in Ireland: and, therefore, notice it so fully. But to proceed:

"County of Dublin Infirmary, or Meath Hospital.

"By the 13 and 14 Geo. III. the Meath Hospital, in Dublin, was made the county of Dublin Infirmary. And, in consideration of the existing medical officers having proposed to appropriate the 100*l.* a year, to which the hospital would be entitled from the treasury, to the use of the charity, the act made good the appointment of those officers without any further qualification or examination, and, moreover, conferred on them a very valuable and lucrative privilege, viz., that of "electing a physician or surgeon, in the room of any physician or surgeon who from time to time, by deaths, removal, or otherwise, shall make a vacancy in said hospital." This principle of electing the physicians and surgeons of this hospital, by those already appointed, is, as before observed, a valuable and lucrative privilege, but whether in the present day it is one which will meet the sanction of the legislature remains to be seen, particularly as the medical officers of this hospital have engrafted on it a regulation, by which they elect none as surgeons to the hospital, unless such as have been the apprentices of some of the attending surgeons; a custom which is loudly complained of by the profession in Dublin, and which is stated to be injurious to the interests of the institution, as indeed all exclusive professional privileges are invariably found to be.

* Pathological Observations, part 3, on inflammatory, typhoid, and symptomatic diseases, &c. Dublin, 1830.

† Report of the Cork-street Hospital for 1830. By R. Grattan, M. D.

"The 15 and 16 Geo. III., made donors of 10*l.* life-governors, and subscribers of one guinea annually, governors for such year."

Our author next gives us an account of the laws relating to fever hospitals, by which it appears, that the members of the Dublin College of Surgeons, who are not physicians, are the only officers of such institutions. Here again is private or rather corporate influence at work, for the Dublin Surgeons, imitating the example of the London, to whom we did justice in last week's leading article, have allowed themselves, like their brethren in Pall Mall, to be stultified by their rivals. The truth is, that until the Catholic emancipation and reform bills were passed, a faction had every thing its own way in Ireland. Surgeons were allowed to act as physicians to fever hospitals, a system that would not be tolerated in England or Scotland. But let us hear Mr. Phelan on the subject.

"Act relating to Fever Hospitals."

"A few fever hospitals were established in some of the larger cities in Ireland, under special acts of the parliament of this kingdom. But until 1807, there was no general act to enable grand juries to present for such institutions in counties at large. The 47 Geo. III., c. 44, provides "that whenever any fever hospital has been, or shall be, established in any county, county of a city, or county of a town in Ireland," it is lawful for the grand jury to present a sum of 100*l.* at each assizes; and the 54 Geo. III. enables these bodies to grant 250*l.* for the support of such hospital. Useful, however, as these provisions were, the annually increasing progress of the most malignant epidemic fevers ever known in Ireland, soon made it necessary to grant enlarged powers. Accordingly, the 58 Geo. III. creates a corporation in each county in Ireland, consisting of respectable and influential persons, who are authorized "to build, or hire houses, to be called fever hospitals, for the relief of the poor being ill of fevers," in any place in which funds have been raised for a fever hospital, or for a dispensary connected with one; and the grand jury is empowered to present every year any sum not exceeding the amount of such subscriptions for the support of such fever hospital. But in places where no fever hospital has been erected, or in which such institutions exist, but require to be repaired or enlarged, grand juries are authorized to present any sum which may be necessary, "to erect, establish, hire, repair, and fit up, one fever hospital in any county, county of a city, or county of a town, in which no such fever hospital had been previously established." And that the full amount of such monies as it might be necessary to levy, for

the establishing of these charities, should not influence grand juries, or the corporations entrusted with their establishment, or prevent them from exerting themselves in forwarding such hospitals, the act wisely provides, that the Lord Lieutenant may, *at once*, advance such sums as may be necessary, which are to be repaid by six years' instalments by the county.

"Under this act, the inhabitants of any parish or district are authorized to appoint a board of health, whenever fever or any dangerous epidemic is proved to exist, and government to lend them money, to be, however, repaid by such county, to meet the necessary expenses of checking the progress of such disease, and curing the sick poor. The seventh clause deserves to be given at length, "that, whenever it shall be made to appear, by statement on oath, to the grand jury of any county, city, or town, that there has actually been received from private subscriptions or donations, any sums of money for the purpose of erecting or hiring any house, to be applied to the reception of fever patients, and either attached to any local dispensary or not, and upon a certificate by one or more physicians, that there is a necessity for providing accommodation for such patients, it shall and may be lawful for such grand jury to present in any such county, city, or town, any sum not exceeding double the amount so raised by donation or subscription, and actually received by such treasurer, to be applied by the subscribers in erecting, or hiring, and fitting up such house for poor fever patients, and it shall and may be lawful *also*, for such grand jury to present any such further sum as shall appear necessary to them for the support of houses for the reception of fever patients, whether established before or after the passing of this act, not exceeding double the amount of subscriptions and donations received by the treasurer, and verified on oath." Annual subscribers of one guinea have the power of voting, and are a part of the corporation.

"In passing the 59 Geo. III., the legislature appear to have apprehended the objections and inconveniences, which I shall hereafter shew, apply to the board of health, and, accordingly, provision is made for the appointment of officers of health, whose authority is considerable; but there is this great difference, that the funds expended by the latter must be raised off the parish, and levied by vestry; a provision attended with advantages and disadvantages, and by no means as useful as it was expected to be.

"An act of the 11 Geo. IV., extends, or explains, that of the 58 Geo. III., so that no difficulty should be thrown in the way of obtaining presentments for houses of recovery, for double the amount of that subscribed in counties of cities and of towns.

"The 4 and 5 of William IV., or M. O'Brien's act, enables the governors of fever hospitals to rent or purchase houses or land,

for the purpose of establishing such charities on sure tenures, which before was sometimes difficult: and it makes the payment of subscriptions one year at least before 'the election of any medical officers or any other persons employed in the management of a fever hospital,' imperative, to entitle subscribers to vote at such elections."

Here is an excellent act against bribery and vote-making at elections for fever hospitals; and it is confirmed by the recent law respecting dispensaries, which, strange to say, is not in force in England.

"Acts relating to Dispensaries."

"The 58 Geo. III. is one of the most valuable, if not actually the most, ever passed for the support of Irish medical charities. It authorizes grand juries to present sums equal in amount to those sworn to as having been received by the treasurers of these institutions. Subscribers or donors of one guinea are annual governors, and if the dispensary be connected with a fever hospital, they are governors of both, and until 1833, could vote immediately on payment of their subscriptions; but the 3 and 4 Will. IV., and the grand jury bill of that year, makes it necessary that subscriptions shall be paid one year before any elections of physicians or surgeons; the only exception to this provision being in favour of the original contributors.

"A clause of the 3 and 4 Will. IV., empowers grand juries to withhold presentments in case of bribery at the elections of physicians, or surgeons of infirmaries, fever hospitals, or dispensaries, giving them the power of examining on oath any medical officers 'so elected, or any other person or persons in said county, touching the said election,' and if it appear that any bribe has been given directly or indirectly to influence votes, the grand jury is authorized and required not only to withhold the presentments, but such physician or surgeon is deemed incapable of receiving any money from such county for the management of any of these institutions.

"The Irish grand jury bill of 1833, makes it necessary to lay all the accounts for infirmaries, fever hospitals, and dispensaries, before the magistrates and rate payers, at special sessions, without whose approval the subsequent grand jury cannot grant presentments.

The law ought to be in force in England and Scotland, for nothing can equal or exceed the abuses in hospitals, dispensaries, and public charities in the former. It is notorious that private interest and money secure elections in this metropolis; and that merit has not the slightest chance of success. We now come to the laws respecting lunatic asylums.

"Acts respecting Lunatic Asylums."

"Previous to the year 1821, the state of the lunatic poor of Ireland was miserable in an extreme degree, the chief provision made for their support or treatment being an asylum in Dublin, and one in Cork, both pretty large, and not so badly conducted as some smaller ones in a few other places. The 46 Geo. III. enabled grand juries to present 100*l.* a year for the support of any asylum connected with a house of industry, and a subsequent act increased the sum to 300*l.* a year. Few counties, however, had, or have houses of industry, and still fewer lunatic asylums connected with them. But the 1 and 2 Geo. VI. makes ample provision for every lunatic pauper in Ireland. It authorizes the Lord Lieutenant to direct any number of asylums for the lunatic poor, to be erected and established in different districts, consisting either of two or more counties, or of one county or town only. Each asylum built for two or more counties to contain room for not less than 100, or more than 150 lunatics; and such as are for a single county, or city, or town, to hold at least fifty, or as many more as the Lord Lieutenant deems necessary. The different grand juries are obliged to present such funds as may be required to build and furnish such asylums, and to repay them by such instalments as the Lord Lieutenant directs, who advances the entire from the consolidated fund. He is also empowered to appoint a board of local directors or governors for every and each asylum, when built, and a general board of control and correspondence, and for the superintending and directing the establishment, direction, and regulation of such asylums; this general board to consist of not more than eight persons, who must act without salary, fee, or reward. The Lord Lieutenant and privy council are authorized 'to make, frame, and establish, or upon the recommendation and suggestion of such commissioners for general control and correspondence, to adopt and authorize any rules and regulations for the good conduct and management of such asylums in general, or of any asylum in particular.' When the Lord Lieutenant issues a proclamation for the building of an asylum, the general commissioners are empowered to take a lease of any lands or premises they may please, or to get such valued by a sheriff's jury, (a power which is also vested in the governors of infirmaries in the renting or purchasing of lands or premises for these institutions). The asylum, when furnished, is then handed over to the local governors, to whom the grand juries are obliged to supply funds for the support of such asylum; and by whom a yearly statement of the expenditure, number of patients admitted, discharged, and died, is transmitted to the commissioners of imprest accounts. All criminals tried and acquitted on the ground of insanity, and such as are found insane at the time of their

indictment, may be detained and confined in these asylums, under the order of the courts and the directions of the Lord Lieutenant.

“By the 6 Geo. IV. the Lord Lieutenant is authorized to advance any sums not exceeding 40,000*l.* a year, to be issued out of the consolidated fund, for the support of such establishments; but the grand juries of the respective counties are obliged to make presentments for the repayment of such advances: and an act of the seventh of the same reign, gives the Lord Lieutenant and privy council the power of ‘changing or altering any asylums that have been built, and of erecting and establishing new or additional asylums in lieu of, or in addition to, any asylum or asylums erected under said act.’ But in such cases the expense must still fall on the district for which the asylum is established. When two or more counties are united in a district, the proportion of the expenditure to be paid by each, is ascertained by the Lord Lieutenant and privy council, and if the grand juries refuse to present this proportion, the going judge of assize is authorized to grant such presentment.

“The only other act relating to medical charities which I think it necessary to advert to, is the 1 and 2 Geo. IV., or Mr. Spring Rice’s. It is entitled, ‘an act to make a better provision for the *superintendence* of charitable institutions in Ireland, maintained in the whole, or in part, by grand jury presentments, and for the more effectual audit of the same.’ Its provisions are, that grand juries are empowered to appoint a board of superintendence in each county, to be composed of no less than eight, or more than twelve persons, one half of whom, at the least, shall be justices of the peace for the county for which they are appointed, with power to any three of them to ‘visit and inspect each and every charitable institution’ in such county receiving grand jury aid, and to ‘inquire into and examine the management and discipline thereof, and into the mode in which the several laws, rules, and directions, for the regulation of such charitable establishments are carried into effect, and into the accounts of receipts and expenditure, the attendance given by the several officers and attendants, and to audit and examine the accounts and vouchers of such establishments; and such board to make a report upon each such establishment to the grand jury at each assizes, copies of such reports to be annually printed, with the lists of presentments made at such assizes.’”

These laws are infinitely superior to those relating to the insane in this part of the kingdom. Look to the abuses at Hanwell Asylum, Middlesex, the very sink of iniquity. The last section, relating to acts of legislature on public charities, does not apply to England, which has the blessing of Poor

Laws, that empower every unprincipled scoundrel to seduce and destroy female virtue and honour with impunity. Well may men declare, “the New Poor Law is capital for them”—“the great boon to the female part of the population.” What ignorance on the part of those who enacted it, whose depraved and selfish licentiousness, and ignorance of physiology or the history of human nature, led them to inflict the most unjust and irrational penalties on the weaker sex to the exemption of their own. Is there any one who has closely observed human nature and the world, who will not admit, that men are infinitely more licentious than women, that males of all the mamiferæ are more violent in their amours than females? If this is the fact, and no physiologist can deny it, why pass this iniquitous law, that enables the most depraved and the most gregarious to escape with impunity? We have no hesitation in pronouncing it demoralizing, unnatural, and unjust; and that the common sense of the public will cause it to be speedily repealed. If men are so profligate and abandoned as to be gregarious in their amours, women have an equal right according to the laws of nature, for she does not sanction different privileges to the sexes. She ordains that one sex has the same rights as the other; and it is vain for stupid legislators, and enemies to population, to decree the contrary. But we must conclude for the present with the following extract.

“Acts relating to Houses of Industry.”

“At least one third of the inmates of our work-houses are incurable lunatics, idiots, diseased prostitutes, and persons affected with various chronic and incurable complaints. These institutions being, therefore, in a great measure, medical charities, a brief account of the laws by which they are established and supported, may not be here unnecessary.

“The 11 and 12 Geo. III. repeals an Irish act passed in the reign of Hen. VIII., and another in that of Ch. I., intending to check vagrancy, by badging the poor, and erecting houses of correction, ‘for the suppression of rogues, vagabonds, and sturdy beggars,’ and creates a corporation in every county, county of a city, and county of a town, in Ireland, for the purpose of ‘giving countenance and assistance to those poor who are found disabled by old age and infirmities, to earn their living, and to restrain and punish those who may be able to support themselves by labour

and industry, and yet may choose to live in idleness by begging.'

"It also empowers such corporations to grant badges to the helpless poor, who have resided a year within their districts, which license them to beg in such districts for limited periods; and when possessed of funds, it requires them to build 'hospitals or work-houses, to be divided into four parts:

"1st. For poor helpless men deemed worthy of admission.

"2nd. For poor helpless women.

"3rd. For the reception of men committed as vagabonds or beggars.

"4th. For such idle, strolling, or disorderly women, as shall be committed and found able for labour.'

"This act provides, that 'the grand juries at every spring assizes, may present in counties of cities and towns, any sum from 100*l.* to 200*l.*, and in counties at large, from 200*l.* to 400*l.*, for their respective poor.' The act of 1784 empowers the judge of assize to direct the grand jury to present 100*l.* if he thinks necessary, in addition to the funds provided for by the act of 1772. By the act of 1806, the grand juries at the summer assizes may present such additional sums as shall amount to 400*l.* at least, or at most, 500*l.* in cities and towns, and in counties at large, from 400*l.* to 700*l.* the judge being satisfied that such additional sums are necessary, and the funds well expended. And the act of 1818 provides, that 'the grand jury of every county, county of a city, or county of a town, may present any sum, not exceeding 500*l.* in the year, over and above, and exclusive of any sums which they were by law empowered to present for any houses of industry under the former acts, to be applied towards the support of their respective houses of industry.'

"The act of 1787 empowers the grand jury of a county, in which there is no house of industry, to present, at any spring assizes, the sum allowed by the 11 and 12 Geo. III., for the house of industry of an adjoining county, into which the poor of the former should be received, until one could be built for itself. It also 'authorizes the grand juries to present such sums as should appear to them necessary, for providing and supporting wards for such idiots or insane persons, as should be recommended by two or more magistrates, certifying, that such persons were idiots or insane, and destitute of any means of support,' and 'such sums to be accounted for by the surgeons of the county infirmaries.'

"The governors of houses of industry are the archbishop and bishop, the members of parliament for the county, city, or town, all magistrates for such counties, the sheriffs, recorders, and mayors, all donors of 20*l.*, and annual subscribers of 3*l.*, and such as are elected by these governors, without the payment of any such sums.

"But though such facilities are afforded

by these acts for the establishment of houses of industry and lunatic wards, in each county, city, or county of a town, I find it stated in the report of the House of Commons' committee, of 1830, on the state of the Irish poor, that only eight or ten such institutions had been erected: of these, Leinster and Munster possess eight in the following places, Dublin, Wexford, Kilkenny, Waterford, Clonmel, Cork, Limerick, and Ennis. The latter seven are county institutions; the first is now supported by government, not by the city and county of Dublin, as it was originally, and is, therefore, apparently a house of industry for Ireland, not for the metropolitan city and county."

Practical Observations on Midwifery. By William F. Montgomery, M.D., M.R.I.A., Professor of Midwifery to the King and Queen's College of Physicians in Ireland, and Physician Accoucheur to Sir Patrick Dun's Hospital.

—

(Concluded from page 479).

CASE IV.—Early in the summer of the present year I was requested by Dr. Sparks to see a patient, in whom I found this condition of the uterus very strongly marked, and it had given rise to a suspicion of the existence of malignant disease, of which however there was, in my opinion, no trace. On inquiry I ascertained that the symptoms had been going on at intervals, from the time of a miscarriage on the 18th May, 1834, a second miscarriage having occurred at the latter end of July following, and a third on the 3rd February, 1835; all through, except when miscarrying, she has had little or no pain, has slept well, and preserved her appetite, in consequence of which, although her face is blanched by the repeated discharges, she has not emaciated. Under the use of tonics her health has greatly improved, and when I last saw her in July there was some reason to believe that she had again conceived, as she was experiencing many of the symptoms which had attended her pregnancy in former instances.

§ 2. The existence of relaxation of the uterine tissue after profuse hæmorrhage is what we would naturally anticipate under circumstances of such extreme exhaustion as almost necessarily follows such an occurrence; when the state of the organ appears to be identified with that of the other muscular structures throughout the body, participating in their loss of tone; and the observation of the fact promises to be useful so far as it suggests to us, in addition to other general considerations, that under such circumstances, besides the more obvious indications of using restoratives for the general powers of the system, the local application

of tonic agents, and the use of specific stimulants, for the purpose of bracing the uterus, may be resorted to with advantage. Hæmorrhage may of course be an adventitious debilitating cause in the case of abortion, as in Cases I. and IV., and then it and the relaxation will act and react, producing each other reciprocally, in the successive relation of cause and effect; which chain of morbid actions can only be effectually broken by withdrawing the individual from the possibility of conception, until by proper treatment the constitution is restored, and the organ more immediately disabled has recovered its healthy tone by being, as is said in agriculture, allowed to lie fallow for a season; the good effects of which is seen in some of the foregoing cases.

The various practical considerations connected with this part of our subject would, if followed out, lead into a very wide field of discussion, on which I do not propose to enter at present, beyond submitting the outline of a case in which this relaxed condition of the uterus was ascertained by dissection four weeks after labour, accompanied by profuse hæmorrhage.

CASE V.—M. T. was delivered on the 20th May, after profuse hæmorrhage, produced by the implantation of the placenta over the os uteri; for some days she went on favourably, but being exposed to much annoyance, and greatly mismanaged by friends about her, she was seized with low fever, and an affection of one of the limbs resembling phlegmasia dolens, and died at the end of a month. On examination after death the uterus was found considerably larger than it ought to be at such a period after delivery, measuring four inches and a quarter in length, and more than two and a half in breadth; its cavity would easily have contained a small hen-egg; the os uteri and cervix quite open, and sufficiently relaxed to allow the introduction of my forefinger; its parietes were about three-eighths of an inch thick, with their structure as soft and flabby as that of any other muscle in the body, so that it might be rolled round the finger, and when divided by the knife the vessels were found uncontracted and pervious. From the result of several instances in which I have had occasion to make examinations in such cases during life, I have learned that this state of the uterus is of very frequent occurrence under such circumstances; in connexion with which there is a question which very often meets us in practice, and which it may be proper to notice here—ought patients who have experienced considerable hæmorrhage in labour be allowed to nurse? In my opinion they ought, if there be not some other reason to object to their doing so, because unquestionably the mammary excitement and irritation which accompany the early part of lactation, propagate their influence to the uterine system, promoting there active contraction, and so assisting very

decidedly in speedily restoring the organ to a condition of permanent safety: indeed it appears to me very probable that the occurrence of chronic relaxation after early abortion (independently of hæmorrhage) so much more frequently than after delivery at the full time, or the more advanced periods of pregnancy, is probably to be attributed to the want of the mammary excitement occurring under the latter circumstances, especially when the mother nurses; and even when that is not the case she has at least the benefit of the stimulus given to the uterus by the increased action in the breasts for the formation of milk. But for the very same reason that we would sanction and recommend nursing for a short time, we may find it necessary to prohibit its continuance beyond half or quarter the period through which it is usually carried on, should it appear to be disagreeing, and producing the well known consequences of undue lactation, the injurious influence of which, let it be remembered, is to be recognized and estimated by the degree of disorder effected in the system, and not by the length of time the process of suckling has been continued; indeed this is a point of which every day's experience convinces us, that one woman will suffer more exhaustion and constitutional derangement by three months' nursing, than will another by twelve, or even more: and one of the ill effects thus produced is, I have reason to believe, this very condition of the uterus which we have been here considering.

§ 3. It is perfectly well known that when nursing disagrees, or has been too long continued, a very prominent group of the symptoms experienced are precisely those which are found to accompany relaxed states of the uterus induced by other debilitating causes: the patient complains of uneasiness and distress referred to the stomach, with disordered digestion, pain affecting the small of the back, leucorrhœa alternating with frequent returns of sanguineous discharges, and from examinations made under such circumstances I have learned that the condition of the uterus which I have been describing is very frequently, if not always, induced in a greater or less degree; of which the following case affords an example:—

CASE VI.—In July last I saw a lady of healthy aspect, and apparently sound constitution, who had been nursing for nearly seven months, with an inordinate quantity of suck; her system had become greatly affected, and she presented many of the morbid effects of undue lactation, such as derangement of the digestive organs, pain in the back and left side, with almost constant slight red discharges, and occasional leucorrhœa; an internal examination being considered necessary, I found the vagina greatly relaxed, the uterus had slightly descended, was evidently enlarged, and softened in its texture, and the os uteri sufficiently relaxed and open to admit readily the end of

my finger. Immediate weaning, attention to restore the impaired digestive organs, a few tepid salt water baths, tonics, removal to the shore of Wicklow, and sea-bathing soon completely restored her health.

This day, Sept. 9th, this lady called on me, and informed me that the irregular discharges have entirely disappeared, and that the catamenia have returned twice at the proper periods.

This subject of the morbid effects of undue lactation has been very ably treated of by Dr. Marshall Hall*, and I refer with much satisfaction to his highly philosophical account of the state of the system under such circumstances, because the symptoms he describes, and the altered conditions of certain functions, as observed by him, are perfectly in unison with the existence of such a state of the uterus as I believe to be the proximate cause of some of the morbid phenomena, while it is itself, in common with some others, a joint effect of the general relaxation and exhaustion brought on by the undue lactation. Thus he notices, as a prevailing symptom, profuse menorrhagia, alternating with leucorrhœa; he mentions that, in common with other organs, the "uterus suffers," p. 230, but he does not specify how; and the derangement of the alimentary canal appears to him to "consist in loss of tone and power," p. 233. In all this, as well as in the whole tenor of his observations, I fully concur with him, and have only to add to what he has said, that what "the uterus suffers" is relaxation, both of its tissue, by which its vessels are allowed to discharge their contents too readily, and of its connexions, by which it acquires a tendency to prolapse; and I wish to observe here, as confirmatory of a former remark on the same subject, that when patients who have been recently exhibiting the peculiar symptoms of undue lactation happen to conceive within a short time, they very generally miscarry; an accident which I believe to be owing to the relaxed and debilitated condition of the uterus at the time.

Treatment.—The plan of treatment which appears to me suitable is sufficiently explained in the cases related, to render it unnecessary to enter much into minute details. The class of medicines that will do most service are tonics, such as sulphate of quinine, or other preparations of cinchona, gentian, colomba, chalybeates, mineral acids, country air, bathing in the open sea, and cold tropical abluion. Should the hæmorrhage burst out so profusely as to endanger life, or produce great exhaustion, means should of course be adopted to arrest it on the instant, for which purpose the tampon with pressure and the ergot of rye are the means on which generally our greatest reliance ought to be placed. Occasionally an opiate, or the

application of cold, may be used with advantage; but I cannot avoid observing, that the indiscriminate liberality with which both these remedies are applied in practice is greatly to be deprecated. As to cold, the common modes of applying it are highly injudicious, and often absolutely hurtful: a napkin is soaked in cold vinegar and water, and laid on the external parts, or over the pubis, where it is allowed to remain until it is removed smoking with heat; this is mere trifling, a pretence of doing good, without the least probability of benefit. At other times the patient is kept for hours or for days, as in Case III., surrounded with wet and cold, chilled and shivering, until the powers of life are sunk to the lowest ebb; and I have before me notes of two or three other cases in which a similar plan was pursued, until the patients were reduced to a state of the most alarming depression, which was instantly exchanged for one of comfort and safety, by substituting dry and warm cloths for damp and cold, and excluding the chilling blasts from an open window at an inclement season of the year. The general principle on which we should use this remedy appears to me to be this, that its greatest benefit is to be expected from the suddenness of its application, acting as a stimulus to contraction, and not from the contracted influence of its refrigerating power*, the result of which is very often the increase of the prostration which we intended to relieve: *ne quid nimis* embodies a rule not less laudable here than on many other occasions in the practice of midwifery. The opinion of Pasta† so fully embodies my own ideas on this point that I must beg leave to quote his words. "L'emploi de ces moyens demande beaucoup de prudence, car il importe de proportionner les degrés et la duree du froid aux forces de la femme. Sans cette precaution, on risquerait de provoquer en elle des frissons qui mettraient la vie de la malade en danger, ou qui redoubleraient les accidents auxquels on se propose de remedier." It may not be considered misplaced here just to mention, that in a case which I lately saw of dangerous relaxation of the uterus, which occurred *eight days after delivery*, the lady experienced more comfort and support from swallowing a few spoonful of water-ice than she did from the use of any of the usual stimulants. With regard to the ergot of rye, I wish to observe that the benefit which is now so well known in many instances to follow its administration in cases of protracted menorrhagia‡ ap-

* Baudelocque, speaking of the use of ice and snow for such purposes, says, "Quand leur contact ne determine pas a l'instant le resserrement de l'uterus on ne doit plus guere compter sur leur efficacite, c'est leur premiere impression qui doit faire cesser l'inerie."—*Traité des Hæmorrhagies*, p. 240.

† *Traité des Pertes de Sang*, tom. ii.

‡ See a highly interesting case of this kind,

* Commentaries on Diseases of Females, Part I., p. 230.

pears, from what we know of the specific action of that peculiar remedy, strongly confirmative of a belief that those irregular and excessive discharges are often dependent on such a relaxed state of the uterine fibres as we have been considering.

"It remains for me now only to observe, that a correct appreciation of the nature and exact characters of this affection is of the utmost importance in practice. 1st. Because from the accompanying discharges, and the debility thereby induced, it constantly leads to a suspicion, on the part of both patient and practitioner, of the existence of organic uterine disease, a suspicion which a vaginal examination rather tends to confirm than remove, the organ being found increased in size, with the cervix and os uteri tumid and puffy, and I am strongly disposed to believe that this is really the condition of the uterus represented by Madame Boivin, 23rd Plate, Fig. 1, which she describes as "a scirrhus tumefaction of the posterior lip of the os uteri, taken from a woman who died of pulmonary consumption after an abortion in the sixth month of pregnancy*." 2ndly. Because if proper measures are not used to remove this condition of the organ, it breaks down the health by profuse discharges, and by inducing a repetition of abortions; for, instead of preventing conception, in the cases which I have seen, it has been already remarked that the subjects of this affection have proved pregnant more quickly than usual.

Foreign Medicine.

Case of Poisoning by the Vinous Tincture of the Bulbs of Colchicum—Death in Twenty-two hours. By Dr. Caffé, Chief of the Ophthalmic Clinic in the Hôtel Dieu.

JOSEPHINE DE BRESIGNE twenty-five years of age, (the adopted daughter of M. X.), of small stature, and a nervous temperament, enjoyed very good health, until she met with a sudden and violent domestic disappointment. This seemed to her to justify self-destruction; and the following were the means she adopted to effect it. M. X. being often affected with chronic rheumatism and fits of the gout, on every attack derived great advantage from frictions with the vinous tincture of the bulbs of colchicum. This he prepared himself, by putting into a

bottle two bulbs of colchicum, roasted and powdered, and then filling the bottle with equal parts of white wine and brandy, leaving the whole to macerate for an indefinite period. On the 2nd of June, 1835, at seven o'clock in the evening, two hours after a slight repast, at which she had taken only some broth and a few vegetables, Josephine drank a glass of this vinous tincture, which had been two months in preparation. The size of the glass (which she said was full) indicated the quantity swallowed to have been about five ounces. Immediately violent pains in the gastric region came on; and half an hour had scarcely elapsed, before the act of which she had been guilty was discovered. M. X. made her drink nearly two pints of milk, and had her taken to M. Martin, an apothecary, who immediately sent for a physician. The latter, M. Fièvreé, endeavoured to produce vomiting by irritating the fauces; but failing in that, he administered two grains of tartar emetic in solution. Vomiting commenced, and continued with intensity.

An hour after midnight I was called, and found the patient in the following state: general coldness; great pallidity; no stiffness of the limbs; decubitus on the back; no convulsive movements; pain at the epigastrium, especially on pressure; oppression at the chest; difficulty of breathing; lips of a violet colour; eyes generally shut, but from time to time the patient opens them, and distinguishes perfectly surrounding objects. The pupils are not dilated; the tongue is cold and discoloured; the pulse slow and thready. The abdominal parietes seem to be of a higher temperature than the rest of the body. No alvine dejection has taken place; but the excretion of urine is not suspended. The patient is consumed by a burning thirst. She retains the complete possession of her faculties; says she wishes to die; and entreats me not to save her. The cramps, which are very severe, are confined exclusively to the feet. Plaintive cries alternate with profound prostration of strength. The vomiting is renewed every instant, nothing but a little inodorous and colourless fluid being ejected. The persons present informed me that the first vomitings were abundant, and of a brownish-coloured matter. This declaration, together with the

which occurred after a tedious labour, a cause very likely to debilitate the uterus, in Dr. Hall's Commentaries, &c., p. 206.

* "A la suite d'un avortement dans le sixieme mois de la grossesse."—*Maladies de l'Uterus*, &c. Atlas, p. 22.

length of time which had elapsed since the ingestion of the poison, and during which period the vomiting might be said to have been uninterrupted, convinced me that there could not be left in the stomach the smallest particle of the vinous tincture of colchicum. Had there been any doubt on the subject, I should not have hesitated to administer gallic acid, or pure tannin, which would probably have precipitated the vegetable alkali, and would have reduced the veratrine to the state of an insoluble bitartrate. I had not forgotten the important researches of M. O. Henry, on the action of tannin on the vegetable alkalies*.

In this serious state of affairs, my only course was to grapple powerfully with the effects of the poison, without attending to the deadly substance itself. I ordered sinapisms to the soles of the feet, together with warm aromatic frictions of the limbs; and I made the patient drink effervescent iced lemonade.

The next morning, at six o'clock, there was an extraordinary abatement in the symptoms. There was less heat at the epigastrium, and the attempts at vomiting were at long intervals. The pulse had acquired more force and frequency. The cramps in the soles of the feet were less painful, but had not changed their situation. The eyes were hollow. I recommended sinapisms to the thighs, and ten leeches to the epigastrium. Professor Biett, who was called in during my absence, insisted on the application of the leeches, and added an infusion of mallows, with milk for drink.

At noon I again saw the patient, in whose condition there was no amendment. The loss of blood from the leech-bites had been very moderate. The eyes were rarely opened; the pupils were not dilated; notwithstanding the assertion of authors who give this as a constant symptom in poisoning by vegetable alkalies, and the narcotico-acids.

Three hours afterwards, the pulse could no longer be felt at the wrist, the carotids alone beating feebly, and at long intervals. There was general coldness; but the intellectual faculties were still entire. A drastic enema produced only one evacuation.

Hiccough and attempts at vomiting occasionally took place, and pains at the epigastrium recurred at intervals. The weakness was extreme; but there was no tetanic rigidity. Finally, death took place at five o'clock in the afternoon, in the presence of MM. Martin and Francon.

At ten o'clock at night the body was examined externally, first by M. Biett, and then by me. It appeared sensibly emaciated; the eyes were sunk in their sockets, and surrounded by a dark circle. The eyelids were closed, but on opening them the pupils were found not dilated. The abdomen was tympanitic, and the limbs were stiff. Over the whole body, touch imparts the sensation of a temperature much below that of the surrounding air.

The official examination ordered by the Procureur du Roi did not take place till seventy-two hours after the decease. It was performed by MM. Olivier (of Angers) and West, in the presence of MM. Fièvreé, Largé, Biett, (senr.) and myself. The bladder contained a little urine; the uterus was empty; the liver and spleen were gorged with black blood; the lungs were healthy; the heart was large and flabby, and filled with black coagulated blood. The head was not opened. The stomach and intestines were put into a jug, and sent to the Palace of Justice. There was no necessity for this, since the suicide was notorious: and it rendered it impossible for us to state the pathological condition of those viscera, and thus to complete a case which could possess no other than a scientific interest.

The investigation which I have since made into this species of poisoning has satisfied me that there does not exist another authentic example of death from the employment, in the case of the human subject, of the different preparations of the *bulb* of the colchicum; while poisoning by the tincture of its *seeds* is frequent, both in England and in Germany. In the present case one symptom struck me, from its singularity and its perseverance. I allude to the cramps—the pains in the soles of the feet. The same pains, but confined to the heel, I find mentioned in a case of poisoning by the tincture of the seeds of colchicum. It occurred in a man who worked in a pharma-

* Journal de Pharmacie, 1834.

ceutical laboratory, and who died after drinking an ounce of the tincture just mentioned, mistaking it for tincture of orange-peel. This case was published by Dr. Andrea of Magdeburg, in a German work, entitled the *General Bulletin of Pharmacy*, for the 15th of September, 1834.

The colchicum formerly enjoyed a reputation better merited than the neglect into which it has now fallen. This plant, which gives its name to a whole natural family, is very abundant in the environs of Paris—in the Bois de Boulogne, for example. It is known vulgarly by the names of dog's bane, bastard saffron, &c. It flowers in autumn. The bulb is as large as a pigeon's egg. If more than a year old it wastes, and is insipid and inert, and may be eaten without inconvenience. It contains much fecula—a discovery which is due to Parmentier. The bulb of the first year, on the other hand, which has begun to shoot in August, in order to increase during the winter, and to flower in the following autumn, contains a great deal of veratrine, an acrid and very dangerous milky juice. The bulb should be taken up in August, before it has produced a stalk and leaves. This, indeed, is difficult; since at that period there are neither leaves nor flowers to point it out. Nothing indicates the place of its growth, unless it has been marked previously. It is this difficulty—it is the error so easily committed of confounding the active bulb with that which is not so—that is to say, the old bulb with the new, which has caused the therapeutic properties of this substance, so energetic if properly collected, to be called in question. To obviate this inconvenience, we ought perhaps to make use of the leaves or flowers, which are annual, and contain active principles, fatal to certain animals which eat the plant. Already, indeed, the tincture of the seeds of colchicum autumnale is frequently used in rheumatismal ophthalmia, especially in Germany. Nevertheless, at the ophthalmic clinic of the *Hôtel Dieu* I have rarely seen it succeed, unless conjoined with other remedies, which might challenge the honour of the cure.

Storck, who composed a special treatise on the action of colchicum, gave it as a powerful diuretic in passive dropsies. Plenck, and many other practitioners, have given it

in the dose of two drachms daily, in the form of oxymel—stating that the vinegar moderated the too great violence of the bulb.

It was in 1814 that the English physicians discovered the properties of colchicum in acute rheumatism and gout, no longer employed in the form of oxymel, but in that of a tincture, or vinous infusion. Sir Everard Home used it on his own person for seventeen months. According to that physician, we may give the preparations of colchicum in very large doses, by commencing with fifty or sixty drops in the twenty-four hours, without fear of accident, provided we filter the wine or alcohol, in order to separate the dregs of colchicum; the latter being so virulent as to cause mortification of the mucous membrane of the mouth and stomach. Sir Everard assures us that fits of the gout are promptly removed; and that in all cases, the interval between the paroxysms is greatly extended.

Dr. Lignum, member of the Royal College of Surgeons in London, reports, in the *London Medical*, the case of a female, who, after an attack of gout had lasted four days, took daily, for two days, two drachms of the tincture of colchicum in three doses, and was cured immediately. The same journal reports the case of a physician, confined to bed for a month by the gout, and who drank a tea-spoonful and a half of the wine of colchicum in mint-water. At the end of two hours the fit was so well removed that he could mount on horseback.

Haden extols the colchicum as a substitute for bleeding in inflammatory diseases. He also ascribes to it great efficacy in nervous affections. Thirty drops of the tincture every eight hours, cured hysterical fits in a young woman*. Chaumeton says that the Turks procure a kind of exstastic intoxication by means of the wine of colchicum†. According to the report of Dr. Gumper, frictions with the tincture of colchicum had great success in rheumatism and gout, in the case of a priest fifty years of age, confined to his bed for six weeks, and who was cured by the fifth day. As for my own experience, I employed it without success in the case of M. de Bret, of the Institute, the venerable

* *Bibl. Medic.* vol. 40.

† *Flore Medic.* vol. 3.

author of the "Grand Voyage Pittoresque et Historique au Brésil." I enveloped the gouty foot with compresses of flannel, soaked in the tincture of the bulb of colchicum; but I did not know at what season the plant had been taken up; nor, consequently, what confidence it merited.

Dr. Chelius expressed a conviction that the urine of individuals who made use of the preparations of colchicum, contained a greater proportion of uric acid; which explains the relief they afford in gout. Professor Lobstein, of Strasburgh, confirms this fact by his authority*.

I am far from guaranteeing the authenticity of these marvellous cures performed on the other side of the Rhine and of the Channel. My eyes ought to have seen them in order to remove all doubt from my mind. But still I may ask, have we not less reason at this time of day for saying that gout is an incurable disease? If so, we may venture to console a very considerable portion of the intellectual and wealthy classes of mankind; these being the exclusive victims of that cruel disorder.—*Journal Hebdomadaire.*

Académie de Médecine.—The Plague.

M. Gueneau de Mussy read a report on the work of M. Simon, of Hamburg, relative to the contagion of the plague. The author gives his theory on the subject; thinks that experiments on it would be more dangerous than useful; and declares himself in favour of sanitary precautions.

M. Chervin maintained that experiments were the only means of determining the question, but thought they should be conducted on a large scale. The Lazaretto of Marseilles appeared a very proper place for their performance.

M. Rochoux.—The author has done nothing more than revive the superannuated theories of Frascator. He has not got into the current of modern facts; for the plague cannot be assimilated to cholera, with respect to contagion, even in places of the greatest filth and poverty. Of this the author is ignorant. Experiments are made every day on a great scale, through the medium of merchandize. The Pacha of Egypt, for example, during the last epidemic, sold his

cottons at a low price to the English, who carried them away without any ill effects.

M. Chervin.—Lazarettos have existed since the fourteenth century; but this has never prevented the invasion of various epidemics of the plague; and it never could be discovered how they gained admission. Preventive measures, then, are illusory. We have no examples of the porters employed in handling the bales contracting the disease. If they have had ulcers, it was owing to the injuries received by plunging their arms into the ill-packed bales, and because ulcers are common in the South. Never has a ship from the Levant transported the plague into England; for the sick who may have contracted the disease (at Smyrna, for example), die or get well during the voyage; and there the mischief ends. M. Chervin detailed the injury done to commerce by sanitary laws; and concluded by saying that the author of the paper appeared to belong to the dark ages.

M. Gueneau de Mussy disclaimed all responsibility for the opinions of the author, on whose work he would not have reported, had it not been for the courtesy due to a foreigner.

Creosote.

M. Martin Solon made a report of various communications relative to Creosote. The commission has tried this medicine in chronic maladies of the skin, indolent ulcers, cancer, hæmorrhage, phthisis, &c., and has come to the conclusion, that though sometimes useful, it is often without any favourable effect; and even when it appears to be attended with good results, it is not preferable to other means with which we are familiar, and which are less disagreeable to the patients. Its only well established advantage is that of preserving, very well, anatomical preparations plunged into a weak solution of it: a more economical means than many others.

M. Andral confessed he had obtained no other than negative effects from the employment of creosote in the treatment of phthisis, of cancer, and of leucorrhœa.

M. Emery had uniformly seen it produce a troublesome irritation in lupus, chronic ulcers, lepra, eczema, phthisis, &c.

M. Pelletier observed that it was incorrect to say that it might be freed from its disagreeable taste and odour; for that would be

* Kunh, Dissert. sur les Colchicacées.

to destroy its properties. Charlatans might avail themselves of such an assertion.

M. Velpeau had employed the creosote, without any favourable result, in burns, and in indolent, scrofulous, and syphilitic ulcers. If weakened, it is an excitant. If used in its pure state, it is a caustic, possessed of no superiority to other substances of the same kind. It was far, therefore, from meriting the praises bestowed on it.

The conclusions of the commission were adopted by the whole of the Academy. M. Comac was against presenting thanks to those authors whose works had no other effect than that of sanctioning errors. MM. Moreau and Girardin spoke to the same effect.

—o—

Artificial Anus.

M. Amussat was lately called by M. De-neux to a female child, several days old, which had passed nothing from the bowels. The anus and vulva were present, but both opened into the vagina; and injections through the anus returned by the vulva. This is an extraordinary conformation, of which authors (according to M. Amussat) report no examples. After long and minute investigations, the finger, introduced into the vagina, detected, at the level of the sacro-vertebral articulation, a moveable body, which was recognized as the termination of the intestine. Immediately a transverse incision was made behind the anus; and from the middle of this incision another was made towards the coccyx. Through this wound (which was in the shape of a T), the finger was introduced; and gliding along the sacrum, it arrived at the extremity of the rectum, destroyed its adherences, and brought it to the incision, where it was opened and fixed by sutures, in such a manner that the mucous membrane passed beyond the level of the skin. From a neglect of this precaution, in operations of this kind, the little patients have perished in consequence of an infiltration or effusion of stercoraceous matter into the cellular tissue of the pelvis. Here the success was complete, and promises to be permanent. During the twenty days which had elapsed since the operation was performed, the infant has continued well. M. Moreau observed that sufficient time had not yet elapsed to insure the

patient's safety, children having sunk after operations of this kind at a more distant period.—*Journal Hebdomadaire.*

New Caustic for the Treatment of Cancerous Diseases.

This new therapeutic agent, first proposed by M. Recamier, and of which he is now making very beneficial use in the case of many patients under his care, at the Hôtel Dieu, is *aqua regia* holding in solution a certain quantity of the chloride of gold. The following is the way in which M. Recamier was led to make trial of this new preparation:—

A goldsmith had a small cancerous tumour on the cheek. This tumour, the nature of which admitted of no doubt, excited uneasy sensations, which induced the patient to put his finger to it. After repeated touches of this kind, at the time the artist was dissolving gold in *aqua regia*, the aspect of the tumour was perceptibly changed; and at last it completely disappeared.

M. Recamier, attentive to these phenomena, immediately suspected the cause of the amelioration, and determined to ascertain if the cure of this cancerous tumour was not to be attributed, as he had presumed, to the application of the *aqua regia* containing gold in solution, and conveyed by the finger dipped in the solution. He did not delay making trial of the caustic in the case of a female, who had an ulcer on the neck of the womb, with hard, uneven, and ragged edges. The general symptoms left no doubt of the carcinomatous nature of this ulcer, which had destroyed a great part of the neck of the uterus. Lancinating pains in the hypogastrium, and uterine hæmorrhages, attested the progress of the disease, which, however, was put a stop to by seven or eight applications of the caustic above mentioned. The general symptoms disappeared, and both touch and examination by the aid of the speculum, proved the healing of the ulcer, and the removal of swelling in the body of the uterus, which existed at the time the employment of the caustic was commenced. Several other patients are under treatment in St. Paul's ward, at the Hôtel Dieu, and the result of whose cases we shall make known at a future period.

This caustic is made with six grains of the

chloride of gold, dissolved in one ounce of nitro-muriatic acid. It is used in the same manner as other caustic liquids, by dipping into it a piece of lint held with a pair of forceps, and cauterizing the surface of the diseased parts. The cauterization should be deep, and should give rise to the formation of an eschar, which is detached at the end of three or four days. After it has come away, we repeat the operation six or eight times, according to the extent of the ulcerated surface, and the depth of the disease. The application of the caustic is not at all painful; its action is altogether local; and in both these respects it offers incontestible advantages.—*Journal de Chimie Medicale.*

Herbivorous Man.

Several cases collected and detailed in the annals of science, have already proved that man, in a state of extreme hunger, and deprived of every ordinary kind of food, can maintain himself exclusively, either with marine plants, or with herbs and flowers, or lastly, with the leaves of trees, eaten in a crude state. This faculty results chiefly from some points in the organization of the human race, and which appear to enable it to choose its food from animal and vegetable substances indifferently. These points comprise the form of the teeth, the form and motions of the temporo-maxillary articulations, and the structure of the digestive canal, which is longer than that of the carnivora, and shorter and smaller than the alimentary tube of the herbivora. We are indebted to Doctor Layet for a new case of an herbivorous man.

Antoine Julian, born at Nice, and residing at present in the department of the Var, was subjected in his youth to such a degree of privation, as to be forced to resort to the mastication of leaves and crude plants, in order to make up for the deficiency in his food. But that which was at first but a kind of addition to his nourishment, soon became the only food he relished; and at the end of some months, Julian no longer ate any thing but raw vegetables, with the exception of three or four ounces of bread, and a little wine, which he sometimes added, but which he could do very well without. His stomach accommodated itself without inconvenience to this singular regimen, the

digestion of these unaccustomed aliments going on perfectly, and his strength and general health increasing in a remarkable manner.

The following are the plants to which Julian ordinarily resorts for his repasts:—*poterium sanguisorba*, *trifolium arvense* and *pratense*, *scorsonera pierioides*, *hieracium præmorsum*, *saturcia montana*, *ancethium foeniculum*, *senecio vulgare*, *fumaria officinalis*, *salvia officinalis*, *parietaria officinalis*, *triticum frumentum*, *avena sativa*, *agrostis vulgaris*, *dyanthus caryophyllus*, *anthemis nobilis*, *artemisia ponticum*, *apium petroselinum*, *vicia faba*, *ranunculus ficaria*, *rumex patientia*, *raphanus sylvestris*, *dipsacus fullonum*, *plantago lanceolata*, *sinapis alba*, *souchus oleraceus*, *leontodon taraxacum*, *brassica oleracea* and *naprees*, *bellis perennis*, *sinara scolimus*, *medicago sativa*, *cardus lanceolata*, *convolvulus arvensis*, *balsamita suaveolens*, *thymus vulgaris*, *pinus sylvestris*, *myrtus communis*, *hedera helix*, *cistus monspeliensis*, *rubus fruticosus*, *rosa gallica*, *citrus medica*, *rubia peregrina*, *quercus robur*, *arundo donax*, *olea europea*, *laurus nobilis*, *rosmarinus officinalis*, *jasminum officinale*, &c.

Julian has also sensations more or less agreeable, according to the species of herb he consumes; and this has led him to divide the plants which constitute his food into three classes. In the first, he places the orchideous plants, the *laitron*, the *pimprenella*, the *trefoil*, *vine-leaves*, *potato-leaves*, *oak-buds*, *mulberry-leaves*, and those of the *burdock*, the *thistle*, the *rose-bush*, &c. These plants particularly please his palate.

The second class, comprehending those plants which yield him only moderate enjoyment, includes the leaves of the wild carrot, of the cultivated turnip, of fennel, of the cabbage, of the common bramble, of the wild rocket, of pellitory, &c.

In the third division are found the leaves of the pines, of the rock-rose, of the white oak, of the green oak, of the rosemary, of the olive, of the box, &c. These afford no other pleasure to the individual in question, than that of satisfying his appetite.

Julian is distinguished by a good disposition, mild and compassionate; and his manners are quiet and simple, although

his intellect is sufficiently developed. His slumber is peaceful and light, like that of most of the herbivora; the lightest and most distant noise being sufficient to interrupt it. The cutaneous sensibility is not great. Cuts and excoriations do not occasion to him the sharp and sudden pains which they give to others. On account of this want of sensibility, he does not fear the cold, when every body around him complains of it bitterly.—*La Lancette Franc.*

The London Medical

AND

Surgical Journal.

Saturday, November 14th, 1835.

MEDICAL RELIEF OF PAUPERS—THE POOR LAW AMENDMENT ACT.

THE subject of parochial relief to the sick poor has been taken up in a proper spirit by both our weekly contemporaries. The able exposition of Ruricola in the Times Newspaper of November 2, has placed in a striking point of view the imbecility, to use no harsher term, of those who framed the clauses of the new poor law act which relate to the medical care of paupers in the country. The evils of the old system were obvious, though the remedy for them was less so; the new arrangements have merely had the effect of increasing existing evils, and adding considerably to their number—the only good resulting from them being the exclusion of improper objects from parochial assistance. Under the old system the number of parish surgeons was insufficient, so that it was impossible for them to fulfil their duty, however desirous of doing so; the remuneration likewise was so miserably small as to offer no inducement to exertion, even if there had been more likelihood of rendering it available; the patients were moreover subjected to great inconvenience, to loss and to dangerous delays, from the distance which they had to go to seek for advice.

Under the present system, the disproportion between the number of

surgeons and of patients appears to be still greater, and the remuneration offered to the former is so utterly insignificant that it becomes ridiculous, nay insulting; it would have been far better to put the thing to the benevolence and generosity of the younger practitioners of a district, and ask them roundly to look after the sick poor gratuitously—a very modest proposal certainly, but one which is cheerfully acceded to by the medical officers of dispensaries, to the great satisfaction and also amusement of the charitable, who smile with Christian amenity at the disinterestedness of the doctors, and with mundane facetiousness at their gullibility. In the old state of things we well know that the salary of a parish surgeon in the country was often barely sufficient to pay his tolls in going to visit the patients; but now he must not think of having his turnpike expenses covered, all his *fees* (!) will go to the blacksmith for shoeing his horse. The evils resulting to the paupers, from their distance from the surgeon's residence, are in a great measure irremediable, and are indeed experienced to a certain extent by the rich as well as the poor in country places; but even these evils have been multiplied with reference to paupers by the new regulations, since they have now not only a journey to fetch the surgeon, but another to get permission to do so. In the above-mentioned respects, therefore, the new poor law act places both patients and doctors in a worse predicament than they were before. But several evils of great magnitude, unknown to the old system, are created by the new. The pauper may not only have to go or to send a weary distance for the order which entitles him to medical advice, but he may be refused it after all, and a person entirely ignorant of medicine is to decide whether he stands in need of it or not! And since the surgeon is now paid, not so much *per annum*, but so much *per case* economy is

very likely to supersede humanity, and an order only to be granted when the necessity for it is too obvious and distressing to be called in question.

Trifling cases will of course not be heeded. For example—an aged patient, apparently in good health, presents himself with a dark spot merely, on one of his smaller toes, and complains of pain in his foot: “Why, you foolish old fellow,” quoth the man of charity, “how could you think of coming all this way about such nonsense?” The old man returns home and shortly after dies of senile gangrene. A rosy-cheeked buxom-looking girl comes and complains of a beating at her heart: “Pooh! The wench is in love; go about your business, you idle hussy—go, go, go!” She goes, and a little while after dies of hypertrophy. A person presents himself complaining of a continued pain in his head: “Nothing else, my friend—only a pain in your head?” “Nothing else, sir.” “Well, well, you’ve got a head-ach, what of that, it will go away, and so may you:” within a fortnight he dies of chronic phrenitis. A pretty set of practitioners too, the poor are likely to have to attend them. The place, refused indignantly (at least we hope it will be so) by all the respectable practitioners of a neighbourhood, will be filled at best by a raw lad who has just been *rhobarbarised* at Black-friars, and too frequently by some needy adventurer, some scamp who has left his creditors in the lurch, or eloped to escape the ignominy of his disgraceful conduct. We are seriously apprehensive that the new medical arrangements in the country may militate against the cleanliness and salubrity of the metropolis, by diverting some respectable persons from the contemplation of a *broom*, to that of a parochial surgeoncy in a desirable neighbourhood; though they can only be attracted by the *honour* of the thing, in as much as the deterrent branch of business is by far the more lucrative.

Half-a-crown for attending a patient for any time less than twelve months, and supplying him with all necessary medicines, apparatus, &c.!

Medical practitioners of England! Who has exposed you to such insult as this? *Yourselves!* Here you may see some of the fruits of the *gratuitous humbug*. This is what comes of gratis attendance at hospitals and dispensaries: if doctors value their own services at nothing, half-a-crown per annum is surely a very liberal consideration, and the Solons of the poor law amendment act may well expect to have statues erected to them, in lasting memorial of the benefits they have conferred on the profession.

We sincerely hope that no English surgeon will henceforth be found wicked enough, or mean enough, to lend his aid to a system at once so oppressive to the poor, and so degrading to medical men—a system which we call on our brethren throughout the country to resist, to combine against and to overthrow—it is in their power to overthrow it if they please.

—o—

MANUAL OF OPERATIVE MEDICINE.

BY M. MALGAIGNE.

FREELY TRANSLATED AND CONDENSED

By GREVILLE JONES, Esq.,

Lecturer on Anatomy and Physiology.

CHAP. II.—Of Operations practised on the Epidermis, or the Art of Chiropodism.

1. *Corns of the Feet—Anatomy.*—A corn is an excrescence shaped like a nail, the point of which is buried in the deep layers of the epidermis, sometimes even through the dermis—to as far as the periosteum or articular capsules (Dudon). Independently of such cases, which are not frequent, if we soak the skin well which supports the corn, the latter becomes detached of itself, and the surrounding epidermis appears sound and in a normal state. Corns seem to be formed of a concrete mucus, which easily imbibes liquid with which it may be placed in contact, and becomes softened in various degrees. We find in it neither vessels nor nerves. Laforest has met under some corns a serous cyst or a sanguineous extravasation.

There are three methods of operating, 1st by *Excision*. The epidermis and the corn are to be softened by means of a foot-bath.

Then the surgeon, with a curved bistoury steeped in water or olive oil, and held *en dedolant*, peels away the upper and central part of the corn until a red tint and the production of pain indicate the impropriety of excavating it further. He then parts the edges of the corn in the same manner, taking care not to intrude upon the skin. If in the centre of the corn several black or white points should be observed, it will be requisite to endeavour to raise them with the point of the bistoury. If a cyst or sanguineous extravasation be met with, this should be freely let out. 2nd. *Cauterization*. It has been advised to cauterize a corn with a bit of inflamed wood (Avicenna), or with a drop of melted sulphur (G. de Chauliac). Laforest applies spiders-web to the corn, lights it and leaves it to burn as *innoxia*. 3. *Extirpation*. If the corn be recent and superficial the common mode of proceeding is sufficient, namely to soak the foot for some time and then scrape it gradually with the nail or the point of a knife. For severer cases the following is the method adopted by Dudon. The foot is soaked for some hours before the operation; then the patient being seated in a convenient posture and good light, the chiropodist receives the foot on his knee, which is covered with a napkin, and proceeds to pare the corn with a sharp knife. Then he scratches round its circumference with a pointed bodkin called a *quadrille*, in order to separate the epidermis. He next proceeds with delicate forceps to lay hold of the corn and extract it, taking great care not to produce much pain or bleeding, in case of which, the finishing of the operation must be postponed for a week. When the corn is extracted the foot is to be again bathed. The parts above the corn now form a white and spongy swelling, which must be dried and shaved slightly with a cutting instrument. If pain continues, and we should perceive a brownish spot about the size of a pin's head at the bottom of the excavation, it may be touched with nitrate of silver.

2. *Of Callosities and Bunions*.—Callosities are mere thickenings of the skin; a bunion is a corn with a large base, presenting layers of epidermis, arranged like the layers of an onion, and adhering to the skin at several points. We may rasp them with pumice-stone, shagreen-skin, or a fine file; or they may be extracted by the means just indicated; but it is not usual to do more than pare off.

3. *Of Warts*.—*Anatomy of a Wart*.—If we cut one vertically we find it formed, 1st, by thickened epidermis; 2nd, by the chorion equally thickened and sending, into the thickness of the epidermis, prolongations which are named the roots of the wart. Sometimes these prolongations pass to the outer surface. Black points are often seen; Cruvelhier has once seen considerable-sized vessels following, in the form of bands, the

prolongations of the dermis. There are five methods of operating, 1st, by *ligature*. When the root has a narrow peduncle it may be tied tightly with horse-hair, silk, or thread waxed. 2nd, by *cauterization*. A drop of nitric acid may be dropped from the end of a pen, or the nitrate of silver applied. Dudon, in some cases where they were largely developed in the sole of the foot, and impeding walking, removed them quickly by caustic potass. 3rd, by *tearing out*. They are to be sucked some time with the mouth, till they become soft and prominent, when they may be torn out with the teeth (Galen). 4th, by *excision*. They are cut off, layer by layer, with a knife used *en dedolant*, and the bleeding arrested with cobweb. 6th, by *extirpation*. With the point of a bistoury the wart is to be circumscribed by two small semi-elliptical incisions, and their extirpation may be finished either with the same instrument or with a pair of curved scissors. Excision with nitrate of silver is very generally successful.

4. *Of Ampullæ*.—When the skin is fine they may be opened with a lancet; when hard a knife or the scissors may be used, and a portion cut away.

5. *Collections of Pus under the Nails*.—The nail is to be scraped as thin as possible with a piece of broken glass, and then opened with a lancet—the same method serves to extract splinters, &c.: extravasations under the nail may always be left to absorption.

6. *Enlargement of the Nails*.—The nails of the first and second toe have been known to grow to the size of a hazel-nut (Laforest). Rouhault has seen one four inches and a half long, and proportionately thick; they may be filed or cut down with a clock-maker's saw. Dupuytren excised them with cutting forceps.

7. *Of Nails burrowing in the Flesh*.—*Anatomy*.—Sometimes the nail becomes devious and plunges into the flesh, and even goes so far as to cause ulceration of the neighbouring toe. Sometimes the flesh is folded over the nail by the pressure of over tight shoes. In both cases, in the course of time, the nail becomes curved on one side, and the portion that is embedded in the flesh produces strangulation of the neighbouring tissues. There are several methods of procedure. Dionis files away the middle of the nail, so as to divide it into two halves, and in order to push the two parts together interposes charpie between them and the flesh. M. Faye bores a small hole in each half of the nail, and passes through both a metallic thread, which he twists like a ligature. M. Guilmot removes by very fine lamellæ, and without tearing one-third or one-half of the nail on the sound side, and, according to him, this is sufficient to retract in this direction the portion which has been buried in the flesh. Desault, who believed the curving of the nail to be essentially a diseased action, invented a process for re-

forming it. He made use of a tin plate about 18 lines long, 3 or 4 broad, the extremity of which, slightly curved, he introduced between the nail and the flesh. In this manner he raised the former and depressed the latter, which was previously guarded with a compress smeared with cerate. Then curving the tin plate from within outwards, so as to embrace the bulging formed by the flesh, he fixed it in its position by rolling a bandage round the great toe. Fabricius ab Aquapendente tore out the carneous portion of the nail. He cut the free portion with the scissors, and then tore up the diseased portion with a pair of pincers. He did this without much violence, and therefore had to repeat the operation during successive days. Dionis did the operation at once, with a bistoury or scissors. He ordered the bath previously, to soften the nail, and he cauterized the flesh afterwards if necessary. M. Dupuytren passed the point of one blade of a pair of scissors, well sharpened, rapidly down the root and divided the nail into two equal halves, then he seized the offending portion with a dissecting forceps and tore it away by twisting it upon itself. The Arabs, according to A. Paré, and recently Lisfranc, Brachet, and Levrat-Perroton, have removed the flesh, the former with the knife, the two last by means of caustic. All these means are merely palliative in many cases, because frequently the source of the deviation of the nail is in its matrix.

8. *Destruction of the Matrix of the Nail.*—This operation, which has been advised for the affections just mentioned, is restricted by M. Dupuytren to cases where there is some alteration in the matrix. His method of operating is as follows:—The foot being held with the left hand, a deep semicircular incision is to be made with a straight bistoury, about three lines above the apparent origin of the nail; then the flap is to be raised with forceps, and all the skin surrounding the root is to be detached together with the nail itself.

Another, and more expeditious proceeding, though not so sure, is to take the knife in the whole hand and shave off matrix, nail, &c., at once, like a shaving of wood: whichever operation be practised, it is essential to remove carefully all white and fibrous parts that may be seen at the bottom or in the corners of the wound, for we have seen such rudiments neglected, and they have reproduced the nail and the disease. If the matrix only be removed, the rest of the nail will always perish and fall off spontaneously.

9. *Exostosis of the Distal Phalanx of the Great Toe.*—An exostosis of this kind, which raises the nail, deforms it, and renders walking painful, is often mistaken for the preceding diseases. It is pyramidal in shape, soft and spongy interiorly, and on the outside covered with a thin compact layer. M. Dupuytren makes on each side of the

nail a semicircular incision, which insulates the tumour. This he cuts from its base with the bistoury, or, if necessary, the chisel and mallet, avoiding, if possible, the matrix of the nail.

(To be continued.)

Hospital Reports.

NORTH LONDON HOSPITAL.

Fractures of the Spine—Fracture of the Sternum—The Fourth and Fifth Dorsal Vertebrae—Third and Fourth Ribs—Rupture of the Gall-bladder—Concussion of the Brain—Clinical Remarks, by Mr. Cooper.

FRANCIS RANDALL, aged 22, was admitted about eight in the evening, on the 16th of October, under Mr. Cooper, having fallen from a considerable height. There were several marks of injury on the spine, the sternum was fractured across its middle, and the upper fragment projected a little forward. A vein had been opened in the arm, but no blood flowed*; pulse small, slow, and easily compressed; pupils dilated and immoveable; there was slight strabismus, and insensibility. A small quantity of wine or some other cordial or stimulant was given, and warmth applied to the feet.

At 10 P. M. the pulse was 66 and small; skin cool. He talked incoherently and did not answer questions. The strabismus was gone and the pupils active. There was paralysis of the lower extremities.

17th.—He has quite recovered from the state of depression or collapse, and is now quite sensible and rational; the bowels have not been moved; a few ounces of bloody urine were drawn off with the catheter; there was constant vomiting of bilious fluid; pulse becoming more frequent. The effervescing draught, with five drops of the tinct. opii were given every-hour, and a bandage applied round the chest.

18th.—Sickness stopped, bowels not moved, pulse 100, and feeble; pain in the chest from cough; breathing very difficult. On raising the patient for the purpose of applying a bandage round the chest, the dorsal vertebrae were observed to bend very much outwards. There was great oppression of breathing and faintness, which continued till half-past two P. M., when he died, thirty hours after his admission.

Autopsy.—There was fracture of the sternum and of the bodies of the fourth and fifth dorsal vertebrae, also of the spinous processes of several of them. The condition of

* The attempt to bleed this patient was made before he was sent to the hospital. The danger of bleeding patients in a state of collapse, cannot be too strongly enforced on practitioners called to accidents of this kind.

the spinal chord was not ascertained. There was effusion of blood into the cellular tissue, between the sternum and pericardium; also effusion of bile into the abdomen, resulting from the rupture of the gall-bladder. There was also fracture of the third and fourth ribs, near their tubercles.

—
Fracture of the Cervical Vertebrae—Death in Twenty-four hours.

Thomas Robinson, aged 21, was admitted, November 2nd, under the care of Mr. Cooper, having been struck on the back of the neck by the fall of a heavy piece of timber a short time before his arrival at the hospital. He was perfectly sensible—his pupils active; indeed, there was no symptom of any injury of the brain. The upper and lower extremities were so completely paralyzed, that they gravitated in any direction. All sensation was lost in the lower extremities, and in the trunk as high up as the middle of the chest; also in the arms, excepting from the point of the shoulder, down as far as the elbow; there was also priapism and emission of the seminal fluid. Respiration was imperfectly performed, being short and hurried. There was considerable pain in the back of the neck, but no crepitus could be detected. It was, however, quite evident that the cervical portion of the medulla spinalis had sustained severe injury; the skin was rather cold, the pulse 60, and feeble; warmth was applied, and hot tea given to him. Mr. Cooper saw the patient three hours after his admission.

3rd.—The skin was now warm, the patient had had no sleep, pulse and respiration more accelerated. He was placed on his side at his own request. There was no contraction of the abdominal or intercostal muscles in respiration. As no evacuation had taken place from the bladder or bowels since the accident; eight grains of calomel followed by some of the senna mixture were prescribed; but the last was rejected from the stomach. A catheter was introduced, and about a pint of urine drawn off. He died about 24 hours after the receipt of the injury.

Autopsy.—Several of the cervical vertebrae were found injured; the right articular process was detached from the body of the third. The left arch of the fourth was broken, but not displaced. The arch of the fifth was much comminuted, and the spinal cord exposed and pressed upon. The body of the same vertebra was also broken through, and the sharp edge of the fracture had caused copious extravasation behind the pharynx, in front of the vertebral column.

Mr. Cooper, in lecturing on these cases, made the following observations:—In the first case, he considered that the wound of the gall-bladder alone would have proved fatal had no other injury existed—he believed there

was no case on record in which recovery, after such an accident, occurred. With regard to the vomiting, it is frequent in concussion when the patient begins to recover; it is generally considered a favourable symptom, from the fact of its indicating returning sensibility. In this case, however, the injury was too complicated for any hopes to be entertained from such a symptom; indeed, it is probable, that had the patient lived a short time, inflammation of the brain had come on. It was worthy of notice, that in fractures of the sternum there is always a cough, which is generally attended with pain. Now, with regard to fracture of the vertebrae in general, he might remark, that where there was fracture of the lumbar vertebrae, the following symptoms presented themselves—paralysis of the bladder, loss of power in the lower extremities, and involuntary discharge of the fæces. If the accident occur to the dorsal vertebrae, all the above symptoms are present, with the addition of a torpid state of the bowels, and a considerable accumulation of wind in the abdomen; there was also priapism in some cases, but that is a symptom more frequent in fracture of the cervical vertebrae, as one of the above cases illustrated.

When the injury occurs in the cervical vertebrae, and the medulla spinalis is injured, there is generally paralysis of the upper as well as the lower extremities; this happens more particularly if the fracture occurs above the fourth cervical vertebra. The patient in the second case, you will observe, had sensation from the point of the shoulder to the elbow, but there was entire loss of motion even in that part.

Sir A. Cooper observes, that when the fracture is oblique, and occurs in the fourth or fifth cervical vertebra, and the medulla spinalis is only partially injured, the paralysis may be complete or not, according to the extent of injury the medulla has received. The case in question is interesting, from the fact of the fourth cervical being broken without displacement. Had there been displacement, the man would have died on the spot; this, Mr. C. would scarcely say ensued, because the injury occurred above the origin of the phrenic nerve, the only agent in supporting respiration. Now, most of the cases on record, as dislocations of the spine, are in fact merely fractures attended with displacement; very few cases of dislocation are recorded as happening below the vertebra dentata, without fracture; most of these cases are dislocation of the articular surface on one side from that on the other.

Mr. C. remembered, however, one remarkable case, which was taken to the Middlesex Hospital; it was that of a man who was driving an omnibus through a gateway which was not high enough to admit him, and his head came into contact with the top of the gateway and completely dislocated the fourth and fifth cervical vertebrae, without fracturing

them—the preparation from this case was to be seen over the way.

If the medulla spinalis is injured, what can be done? Why, very little, where the accident occurs so high up as in the above case, and yet, to look at the patient, whose countenance is generally of a healthy appearance, you might at first believe he would live for a length of time; he is, however, sure to perish. Sir A. Cooper remarks, that in cases where the fracture takes place between the fourth and seventh cervical vertebræ death takes place generally in about five or six days—our patient, you will observe, died in twenty-four hours; the period of death, however, generally depends on the amount of injury the medulla spinalis has sustained, and also on the kind of constitution the patient has.

Now, in cases like that of the first patient we have mentioned, should the pulse be high, blood may be abstracted from the arm, but he thought with Sir A. Cooper, any attempt at reducing the fracture is totally useless, for if the medulla spinalis is injured, no good results from such a step. Attempts, however, of this kind have been made; a case is recorded in the Medico-Chirurgical Transactions, in which a surgeon succeeded in procuring union in a case of fracture of the last dorsal vertebra; the patient lived some time afterwards, and died at last of another disease. On the post-mortem examination it was found that the bone was not united in apposition, but bent rather forwards; this case confirms Sir A. Cooper's opinion.

Mr. Cooper differed, however, from Sir Astley in considering that sawing away part of the neck of the spinous process, elevating it, and removing the pressure from the spinal marrow, could be attended with any benefit. The operation had been attempted both by Mr. Cline and Mr. Tyrrell without any successful result.

If a patient lives some time after fracture of the lumbar, or dorsal vertebræ, when there is paralysis, your treatment will tend to rectify every kind of inconvenience resulting from the injury—to attend to the state of the bladder; after a month it was to be remarked, that incontinence, instead of retention of urine might supervene—attention was also to be paid to the involuntary discharge of the fæces, or sloughing might result from the mischief they might produce in the neighbouring parts. Cases are recorded, in which patients partially recovered, but afterwards perished of gangrene, occurring in the parts on which they lay.

Would strychnine do any good in cases of fracture like the above? It is surely worthy a trial.

There is a preparation in the Hunterian collection, of injury to the dorsal vertebræ, in which the patient lived two or three years—on a post-mortem examination, the vertebral passage was found almost obliterated, scarcely allowing a small probe to pass. Yet, this

patient could, with assistance, come down stairs.

—o—

WESTMINSTER HOSPITAL.

Hydrocephalus Acutus, occurring as a Sequel of Scarlatina.

THOS. DUNBAR, aged 16, was admitted Oct. 13th, into King William ward, as a patient of Dr. Roe's. He is short-necked, and rather of a plethoric habit. Four weeks before his admission he had an attack of scarlatina, from which he became convalescent in a fortnight, so as to be able to return to his employment. In the course of a few days, however, anasarca made its appearance, first in the face and neck, and afterwards in the legs, to such an extent that he could not get his clothes on. The dropsical symptoms were a good deal subsiding, and his mother recollects his reading the day before his admission. On the morning of the 13th, he awoke with severe pain in the head, especially in the region of the temples, which caused him to cry, and his sight was affected in such a manner as to prevent him seeing to dress himself. Whilst waiting in the out-patient's room to be admitted, he was seized with a convulsive fit, not having had one before, which recurred with great frequency and violence upon his removal to the ward. During the paroxysms, there is involuntary expulsion of the fæces and urine. In the intervals he lays in a moaning and stupid state, from which he is only with difficulty roused, when a reply is wanted to any inquiries. Pulse 160, full and strong; tongue furred; exhibits signs of uneasiness on pressure being made on the abdomen; there is likewise some impediment to easy respiration.

V. S. C. B. ad. $\frac{3}{4}$ xvj.

Appr. Emp. Canth. Sterno. Abradatur Capillitium, et admoveatur constanter Lotio Evap.

14th 9 A. M. The nurse reports that he had several fits during the night. He now lays in a completely insensible state, grinding his teeth and moaning. The axes of the eyes do not appear to correspond exactly, and the mouth is slightly drawn to the left side. The right leg was not thought to respond so readily to stimuli as the left. The eyelids are kept constantly closed; the pupils are somewhat contracted.

App. Cucurb. Cruent. Nuchæ, et detract. Sanguinis $\frac{3}{4}$ x.

Rx. Mist. Diaphoretic $\frac{3}{4}$ j. 3 tis horis.

4 P. M. Much better; he answers questions, states that he does not possess any trace of vision, except so far as enables him to distinguish light from darkness. Has only had two fits since the cupping, and these were transient ones. The grinding of the teeth is gone, and he now enjoys a good degree of quiet repose.

15th. Is much better, has had no fit in

the night, and only a slight one this morning. He has regained the power over the sphincters, and has had several motions as the effect of a saline cathartic which had been administered to him. There does not appear to be anything like hemiplegia to-day, or if so, of a very indistinct character. The pulse is not so frequent nor full; he does not complain of much pain, except from the blister: has regained complete vision.

16th. Has now no pain remaining in the head, and he is evidently better: pulse 120, small. There is a good deal of œdema of the right upper eyelid, and also of the right hand. It appears that he has not yet such complete power in grasping in the right as in the left hand, but there does not now seem to be any lesion of sensation. He only had two fits yesterday, in one of which the excretions were expelled.

18th. Appears almost well; there are no convulsions, nor pain; pulse regular, and reduced in frequency; tongue cleaner.

27th. Has continued to go on well since last report, and now appears quite convalescent, except that in his general position of standing, his right arm hangs somewhat more motionless by his side than the other, and that the foot of the same side drags a little in walking. The shade of difference between the two sides, however, is so trivial that it is not perceptible to all the observers of the case. He was dismissed to day as cured.

Caries of the Atlas and Vertebra Dentata, with Abscess behind the Pharynx.

Anne Josey, aged 16, was admitted August 22nd, into Percy Ward, under the care of Mr. Guthrie. The complaint arose five months ago, after exposure to a draught of cold air, in the shape of a painful stiff neck, which at first affected the right side, but after some time became most severe on the left. This gradually got worse, up to the period of her admission.

Sept. 4th. There is great pain in the neck, with swelling, especially on the left side and towards the nape. The head is bent downwards and towards the left side, the face looking to the right, apparently in consequence of the contraction of the sternomastoid and other muscles supplied by the spinal-accessory nerve. There is paralysis of the upper extremities of both sides, both as regards motion and sense. The paralysis does not appear to extend to the lower extremities, nor is there any loss of power in the sphincters. The urine is sometimes retained, requiring the use of the catheter; there is a great deal of diarrhœa. The muscles of the face and jaws are affected with painful spasmodic affection resembling trismus; eyes prominent, pupils dilated; anorexia; tongue red; pulse accelerated, and other febrile symptoms.

The left arm was first affected with the

paralysis, and it is now œdematous, and on its surface presents several round or oval, elevated and circumscribed spots, some of them as large as a halfpenny. They have a reddish and inflamed base, and appear to consist of an elevation of the cuticle, occasioned by the presence of lymph in the areolæ of the so-called rete-mucosum of Malpighi.

She died on the 6th of September.

The autopsy revealed the existence of an abscess behind the pharynx, containing healthy pus, and involving the substance of the longi colli muscles. It was lined by a very thick velvety membrane, and extended from the base of the skull to the fourth cervical vertebra. The anterior arch of the atlas, and the body of the vertebra dentata were in a carious state, and the odontoid process was broken off. The membranes of the spinal cord opposite the diseased bones, did not present any unusual vascularity, but were slightly thickened. The spinal cord was somewhat compressed and darker in colour at this point. The brain was healthy; the other viscera were not examined.

—o—

CÆSAREAN SECTION FOURTEEN MONTHS AFTER CONCEPTION—RECOVERY.

THE history of the following case was read before the Medical Society of London on the 19th of October, 1835, by Mr. Hutchinson, and we extract the most important part of it:—A woman, aged twenty-eight years, of good constitution and lively disposition, had been married eleven years without having had offspring. The menstruation was normal until August, 1834, when it ceased, and she considered herself pregnant, a conclusion at which her medical attendant had also arrived. The uterus enlarged more rapidly than usual, so that in the middle of September the abdomen was "of a very great size." During the next month, the movements of the fœtus were felt, and from that period continued to increase. At the end of April the woman was seized with labour pains, but these ceased, and in two days afterwards the movements of the infant were no longer felt. The abdomen increased in size, and the legs became œdematous. On the 14th of June the symptoms were emaciation, countenance not unhealthy, pulse 100, tongue clean, bowels sluggish, pain in the lower part of the back in the erect position, and a great sense of suffocation in the recumbent. On making vaginal examination, the canal was shorter than natural, and its sides were compressed by the protrusion of a large tumour, occupying a portion of the pelvis, situated between it and the rectum, and the os uteri was indistinctly felt, the fundus being turned downwards and backwards, and the orifice being behind the pubis. On the 8th of July, Dr. F. Ramsbotham saw the case, considered it ovarian dropsy, and advised

paracentesis. On the 12th, Dr. R. and his father met, and the latter considered the disease ascites, with ovarian enlargement. Both advised the operation. It was performed on the 15th, about two inches above the umbilicus, in the linea alba, at which part the tumour was most prominent, when about six pints of dark chocolate-coloured fluid escaped, possessing a disagreeable but not a fœtid odour. The patient experienced considerable and almost instantaneous relief. At the end of a fortnight the opening had not healed, and a lock of fœtal hair escaped through it, and other pieces, as well as globules of oil; and portions of putrid skin and membranes repeatedly passed through it. A hard circumscribed tumour was now distinctly felt in the left hypochondrium, which was evidently caused by a fœtal head. In September the symptoms became aggravated, and there was increased constitutional irritation. A consultation was held, at which the former gentlemen and Mr. Mayo assisted, when the latter and Mr. H. agreed that the infant ought to be removed by the Cæsarean operation. Mr. Hutchinson then (September 21st) proceeded to perform the operation by enlarging the wound made by the trocar, both upwards and downwards, to the extent of five inches. Mr. Mayo extracted the right upper extremity in a transverse direction, which required amputation at the shoulder; a foot and the trunk followed, but the head was too large to be extracted through the wound entire. The funis was divided and left hanging out of the wound. The placenta was adherent and was not removed. Simple dressing and a poultice were applied to the wound, the inferior of which was left open, to allow the escape of any fluid "which might still remain in the cyst." The fœtus was as large as at the full term of gestation, and the cuticle was entire, except on the scalp. On the 25th the placenta was removed through the aperture, and appeared as if macerated for a long time in water. On the 19th of October the wound had closed, except about half an inch in length, and the patient appeared to be in a fair way of recovery. Thus the fœtus was retained five months longer than the usual period, and removed by gastro-hysterotomy fourteen months after conception.

—o—

Sulphuret of Potash in Asthma.

AN individual labouring under a severe attack of spasmodic asthma, applied to Dr. Carusi, who having ordered the aqua lauro-cerasi, internally, and frictions with tartar emetic ointment, without success, directed sixteen grains of the sulphuret of potash, rubbed into potash with honey. This quantity was divided into four portions, one of which was given three times a day. After the administration of the last dose, the asthma entirely disappeared, and the cure was complete.

Asphyxia of Infants in Pedal Presentations.

M. BAUDELOQUE has saved two infants whose bodies were born first, and whose heads were retained for a considerable time, by introducing into the mouth a silver tube of sufficient size to allow the ingress and egress of air into the lungs for respiration.

Natural Philosophy, arranged according to the Plan of Napoleon.

M. GEOFFROY SAINT HILAIRE announced to the Academie des Sciences, that during his residence in the country, where he was detained on account of bad health, that he had completed a work, the manuscript of which he presented, entitled *Synthetical and Historical Opinions on Natural Philosophy*. It is, he observed, in a great part, the development of an idea of Napoleon at the age of fifteen years; an idea on which he loved to discourse with his soldiers, the literary characters, poets, and savans, who accompanied him in his military excursion to the East. The work contains three chapters—1st, Documents on the subject of Universal Law; 2nd, Notions of Zoologic Philosophy, acquired during the last five years; 3rd, Entomologic Philosophy.

—o—

Dr. Ryan's Lectures on Obstetrics will be commenced in a fortnight, when some of the plates, which are splendidly executed, will be finished. This series of plates will amount to sixty, and illustrate the Anatomy of the Pelvis, Ovology, Natural and Difficult Parturition, and all Obstetric Operations. They will be the most extensive illustrations of obstetric medicine hitherto published in this country; and, with the Medical Botany, offer advantages to the profession which no rival journal affords. The plates in one volume could not be had separately for much less than the price of the letter-press.

This Journal will also contain condensed Reports of the cases, Medical and Surgical, with the substance of the Clinical Lectures of the Physicians and Surgeons of the North London Hospital. We select this hospital in preference to others, because there is much more attention paid to clinical instruction in it, than in any other in this metropolis.

We also hope to be able to lay some of the Dublin hospitals under contribution. Dr. Fletcher's Lectures will be resumed in a short time. The Foreign Department will be conducted in the same extensive manner as hitherto. Reports of Societies will also be given. The Review Department will embrace all new and important works, both national and foreign.

translated and revised*

BY JAMES MANBY GULLY, M.D.

LECTURE XXIII.

Treatment of Gastro-Enteritis.

ENTER we now upon our treatment of this important disease. In the commencement, when there are only symptoms of gastric disturbance, we do not give an emetic because, though it may occasionally cure, it more generally does harm. If the patient is plethoric and, together with his gastro-enteritis, has congestion of the head or chest, we bleed him, and on the same day, or even at the same hour, apply leeches to the epigastrium, according to his strength—from three for a child of from one to three years of age, up to sixty for an adult. For old persons the number is smaller: yet we must not act blindly in regard to them. Most persons, and especially young ones, have generally a false idea of old age; they imagine that every man that has white hair and some wrinkles is in a state of debility; but attention should be paid to the consistency of the flesh, to its nutrition and to their complexion; when it is firm, highly coloured, and well nourished, it matters not whether the hair be white or black: you may bleed. But when the individual is emaciated, and worn, as is more frequently the case—for a man rarely passes his fiftieth year without having some internal enemy, some *lethæis arundo*, that undermines him, or, to speak without figure, some chronic affection that deteriorates his nutrition, and to which an acute one has been superadded—such an individual, I say, should not be so boldly bled as a fresh subject unaffected by any previous disease.

After the leeches have fallen the bites should be allowed to bleed and poultices applied to facilitate it. The disease is frequently stopped by these first applications; the patient recovers his appetite, and might possibly be able to renew his functions; but

be not too hasty in giving food. We should ever have before our eyes the manner in which inflammation is developed, and remember that there is almost invariably a point where inflammation has reigned some time in a latent condition, and whence it has made an irruption. Even in the latter case, by keeping the patient on strict diet for a few days, both the old and the new points of irritation come round. Sometimes the phenomena of gastric irritation are renewed on the following day: the frequent pulse reappears, as well as the foul mouth, disgust, nausea, turgescence of the epigastric region, bilious regurgitation, &c. All these symptoms leeches will dissipate as completely as an emetic, and without the danger attendant on the latter.

It has been asserted that the bilious element said to exist in this case had such reality as to refuse to yield to antiphlogistic treatment. This is false: thousands of these bilious elements are cured by leeches. In this particular, both experience and reasoning are with us, the latter informing us, that if there be bile in the stomach, it is an irritation that induces it there, and that this irritation may be got rid of by leeches. Should they be insufficient, and should the symptoms reappear, the general bleeding must be repeated; at the same time mild drinks and clysters must be prescribed. If diarrhœa supervenes, leeches should be applied to the anus. Frequently vomiting, bad taste of the mouth, &c. coexist with the diarrhœa; in this case leeches to the epigastrium relieves the gastric disturbance, and one to the anus stays the diarrhœa: if you only apply leeches to the anus the gastric symptoms continue, and the same obtains for the diarrhœa if you only attack the epigastrium; both points should be simultaneously attacked.

If taken in time, these different cases may be acted on successfully; and when the contrary occurs, it is owing to the prolonged duration of the supposed prodroma, that is to say, the disease has been neglected and the irritation of the digestive canal not sufficiently rapidly subdued. You then have bilious, or mucous, or inflammatory fever; that is to say, in the first case, increased frequency of pulse, tongue more or less red,

burning thirst, debility, &c. In the descriptions of bilious fever that are given, you will find burning thirst, frightful headaches, occasional bilious dejections, a burning sensation, alternations of cold and heat, &c. These symptoms, which have procured for bilious fever the name of ardent fever, may be subdued as they appear, the headach by a bleeding of the jugular or cephalic vein, the heat and cold, as also the burning thirst, by bleeding the epigastrium; meteorismus and intestinal pains, yield to the same means if used in time. In the event of the disease not being completely obviated, the inappetence, thirst, nausea, &c. before described remain behind, but gradually dissipate.

If the disease be not annihilated, but becomes more intense, the nervous symptoms come on, and you have then the proof that the mucous membrane of the digestive canal is deeply implicated and that the gastro-enteritis has become typhoid.

These various windings of the disease are exceedingly remarkable. Among the patients under it you may observe three chances: some are cured, others remain in a feebly characterized febrile condition, and others again are seized with nervous phenomena. Let us now see what treatment should be pursued in these two last categories, commencing with the last but one, or that in which the fever continues without nervous phenomena. What should you do, after you think you have sufficiently reduced the patients? You should remain quiet, give mild drinks, and observe whether anything peculiar or prominent appears. You will find in authors that eurodynia, diarrhoea, and dysuria are symptoms of mucous fever; these symptoms shew that the phlegmasia is partaken in by mucous membrane of the lungs, of the great intestine and the bladder, in which organs you ought to combat it. When headaches supervene you should order pediluvia and apply leeches to the jugular or the temples. When diarrhoea is present give amilaceous clysters with a few drops of laudanum, or a decoction of poppy heads: should it persist, cause revulsion to the lower extremities with some stimulating tincture, with tartar emetic ointment and sometimes with blisters; but upon no account give strengthening soups, for if you do you will lose two-thirds of your patients. You are not to consider these symptoms as necessary attendants of gastro-enteritis, and you are bound to destroy them in detail as they present; just as an able general endeavours to prevent his enemies from uniting, and to attack them *seriatim*, the more certain to vanquish them; in this manner gastro-enteritis of moderate character, or such as have only produced slight disorganization, are brought round to convalescence.

As for those that are too serious when they are first presented to you, that have had protracted prodromata, that have been exasperated by stimulants, that are accom-

panied with nervous phenomena, and constitute our third category, you must not expect to cure them by sanguineous emissions; for ulcerations, softenings, and erosions then exist in the digestive canal, and require a long time for the cure, as is the case when the same disorders exist in the skin. During the time that nature is contriving their cure, and so long as the disease is not arrested, there is a febrile state, and some nervous phenomena: the irritation is repeated in the brain and spinal cord, and there is more or less stupor, subsultus, &c. The disease therefore is necessarily long, but simply because it was not stayed at the onset. Now, how will you manage these circumstances? As long as the stupor, redness of the eyes, tremor of the limbs, brown colour of the tongue, &c., persist, you must give no stimulants, and should administer the lightest drinks, slightly sugared or feebly acidulated water, gum or marsh-mallow water, orgeat, &c., in small quantities; and you should order ice to be taken, especially in summer. Generally when leeches have been employed in sufficient number there is not much thirst: and on this account you should not gorge your patients with drinks, for you will thereby give them fits of indigestion. Young physicians, who take pleasure in being exceedingly attentive to their patients, and who thirst for improvement, would do well to pass entire nights with them: they will thus learn to judge of the progress of the disease, and appreciate the effects of the remedies. I have seen pupils who had doubts of the truth of what I advanced, because of my opinion after having passed a few nights with patients whom they dosed with cinchona; they were converted when they beheld the body tremble, the muscles agitated, the pulse contract, a sweat cover the whole body to be followed by dry skin, when, in short, they saw all the symptoms exasperated after the administration of the remedy in question. They were convinced that whatever reaches the stomach is echoed throughout the system when the nervous papillæ of that organ are stimulated. During this period, therefore, you should only give mild drinks, and, if there be diarrhoea, emollient clysters, with fomentation of the abdomen. I herein suppose the period for bleeding to be past, for when there are nervous symptoms you can scarcely ever think of it.

When, by these means, the patient seems to arise from the night of the tomb, when he smiles, when his mouth ceases to bear a crust, and his breath to be fetid, his eyes again become moist, when he no longer thirsts but hungers—the physiological physician may render certain his safety, while the ontologist kills him by his haste to give food. But be you firm to your method; the amelioration shews that the phlegmasia of the gastric region has given way, and that a

degorgement has at the same time occurred in the head. Still there may be a considerable disorganization in the small intestines; continue, therefore, your remedies, and if you see this better condition, persist for two or three days, when the diarrhoea ceases, the meteorismus disappears, the pulse slackens, the strength revives, &c., you may begin to nourish, although there may be still some fever; you may give him a little chicken broth, milk and water, or slightly milked tisane—drinks which the ancients were in the habit of giving at the onset, and during the most acute period, as antiphlogistics.

I have lately administered cold clysters in gastro-enteritis in the nervous stage; when I could not venture to bleed I gave them with some benefit; but when there was ulceration and the disease serious, I ceased their use, being afraid of inciting either peritonitis or catarrhal complication: this treatment however requires great nicety.

Blisters and revulsives I have been obliged to give up in the majority of cases, because I feared either the absorption of the cantharides, or the influence of the cutaneous phlegmasia. However, I think I have seen cases where they might be useful, when, for instance, the patients have been freely bled and the skin is cold. Last month we had a man affected with such an intense gastro-enteritis that it might have passed for a case of epidemic cholera. During eight days we in vain strived to warm him: he vomited, was purged, had suffused eyes, and was truly *cadaverize*. An application of leeches to the epigastrium put a stop to the vomiting, and the same to the anus arrested the diarrhoea. Subsequently some leeches applied to the throat having produced no effect, we stimulated the skin with blisters and continued friction, and after combatting the cold surface and contracted pulse for a whole fortnight we had the satisfaction of curing him. When, therefore, there is no heat of the skin, when you think you have bled sufficiently, and there is concentration about the head, blisters may prove useful. All means, however, may be good, and there is none that should be absolutely condemned.

Such is the march and treatment of gastro-enteritis independent of all complications. To the latter we now proceed.

Peripneumony requires greater perseverance—in general sanguineous emissions as well as local bleedings over the engorgements of the pulmonary parenchyma.

Cystitis requires the application of leeches to the hypogastrium, the root of the penis, and the perineum.

With hepatitis you should not persist in the use of emetics and purgatives, but in sanguineous depletions over the region of the liver and the edges of the ribs.

The principal complication is the cerebral affection, and this you should well understand. If it occurs in the commencement,

when the subject is full-blooded, a general bleeding should be had recourse to, and, if insufficient, leeches should be applied along the course of the jugulars and on the temples.

The indomitable thirst, and the burning heat of the skin require acid drinks and external cold, not in the shape of ice, but of cold fomentations. If it be a hot summer, you may apply heat to the head, the abdomen, and even to the chest; but if the weather be cold and humid, or only temperate, as in the spring and autumn, or if you are operating on feebly reacting individuals, or of lymphatic or catarrhal constitutions, with hearts and lungs disposed to congestion, cold may determine peritonitis, catarrh, carditis, &c., that end in death in twelve or twenty-four hours. Energetic means, such as it should always be employed, with some anticipation of what may ensue on them.

External phlegmasia, about which the ancients made a deal of noise in reference to their crises, and which the moderns have revived in the same point of view, ought, they say, to be respected. This must be *physiologised*. At first sight it might appear that a serious internal disorder, that becomes transformed into an external disease, is not a thing to be afraid of, and that the physician's part is reducible to inspecting its progress, awaiting the formation of pus, and cicatrising the ulcer. But this question must be divided, and we must in the first place refer to our principles, which are not vague, but always resolvable into, or applicable to, facts. Inflammation, in whatever part situate, if too extensive, always produces disorder in the system. If a critical phlegmon be too intense, you must expect that it will renew the internal phlegmasia that has just been got under, or some other; and you must reflect that your patient, who is no longer so strong as in the commencement of the disease, having contracted a secondary phlegmasia by means of this supposed critical phlegmon, may probably sink under it. In the next place, the critical deposit may take place in important organs, for the preservation of which, the patients would readily give, as indeed, themselves say, many pounds of blood. To give instances: an inflamed parotid, say you, is beneficial when it suppurates. Yet if the inflammation be too intense, it may induce a fatal cerebral congestion. It is then clear that you must reduce this inflammation, and though the patient may be two or three weeks longer in gathering strength, you must take his blood from him if necessary; besides which, you have revulsion, sinapisms to the legs, &c., that prevent the extension of the inflammation to the brain. Secondly, an eye is implicated: do you mean to say that you would hesitate to apply twenty or thirty leeches around it in the fear of retarding convalescence? do you

think that a pretty woman would reproach you with a retardation that has been the means of saving her eye? Thirdly, an abscess of the anus, that might pass into a fistula unless you hasten to cure it. Do you not think there is some use in annihilating it, or at least, if you do not succeed in that, in managing to prevent more extensive mischief and sloughings? The application of what I here state concerning these inflammations, is so extensive, that I may spare myself and you more ample details; but you may observe how much the precept of the ancients requires to be modified.

Now of hemorrhagic crises. These frequently occur in the height of gastro-enteritis, when patients are in extreme prostration. Is it proper to favour them? That will depend on the seat of the hemorrhage. When it proceeds from the intestinal surface, and passes by the anus, it is not proper to allow it to proceed. I have often seen patients die from the consequences of those hemorrhages: they call for the close-stool, fill it with blood, and die upon it. When you behold hemorrhage going on in a weakly subject from an extensive surface, and that it may proceed without the possibility of your perceiving it, you have good right to tremble for the life of your patient; you must not then trust to antiphlogistics. In such cases I produce a powerful revulsion to the skin by blistering; I give clysters of solution of soda and yolk of egg, or even make them somewhat astringent. In some years gastro-enteritis are more hemorrhagic than in others; one of these was the year 1813, when the hemorrhages I observed in the army were frightful, and carried off great numbers; but I succeeded in saving many by means of rice water acidulated with sulphuric acid, and the application of a large blister over the abdomen.

Nasal hemorrhages are more commonly seen, especially in the spring and summer. However great the adynamic state, you have rarely anything to fear from it. Possibly the cerebral congestion, of which it is the index, may not be sufficiently diminished by it, or in other terms, that more blood reaches the head than there is from the nose; in which case you must have recourse to pediluvia, sinapisms, and acidulated, emollient, and cooling drinks. But how will you know all this? what signs are there to guide you? if the pulse is strong, the coloration of the face great, if the pulsations of the carotid and temporal arteries are violent, notwithstanding the hemorrhage, put leeches on the throat, and then cause revulsion to the lower extremities. If, on the contrary, the circulation is feeble, if the blood which the patient loses is decolorized or impoverished, do not bleed, but be content with revulsion to the hands and feet. Plugging is rarely applicable.

The crisis of diarrhoea should not be respected beyond two or three days. The

matters retained during the whole course of the disease may be expelled by a kind of effort accompanied with colics, and there may be a watery evacuation, which ceases after two or three days; but should it exceed that term, it signifies a phlegmasia that should be attacked by sanguineous emissions, emollient, narcotic clysters, and external rubefacients.

We read in Hippocrates, that during the course, and at the close of fevers, frightful and gangrenous erysipelas, with denudation of the greater part of the limbs, supervenes. I was struck with this fact when reading the epidemics of the father of medicine, and I saw that at that period, when the sciences were in their birth, this man of conscience and genius having no sufficient motives for action, confined himself, in the majority of cases, to observing, to hastening the termination of diseases, and to the employment of minor remedies, and that in this manner, when inflammation proceeded to the exterior it was so violent that extreme disorder followed upon it. Here, then, we return to our principles—we who think that the disease should not be allowed to be too intense at the onset, and that, if not called in at the very commencement, it is dangerous to allow a critical phlegmasia to proceed far, the more as it may produce extensive sloughings. If you observe a critical phlegmasia manifesting itself simultaneously with the internal phenomenon of an intense phlegmasia, you must have recourse to local bleedings to prevent the phlegmonoid state and consequent sloughings. If, on the contrary, it is exhibited in individuals that have already been treated in an active antiphlogistic manner, and if the redness tends to traverse the skin, it must be combatted by astringents, such as the acetate of lead, or by the nitrate of silver. Last year we had a consecutive erysipelatus epidemic at Val-de-Grâce, and I acted as follows, always starting from positive principles. If the subject had not been extensively bled, and the pulse was vigorous, I applied leeches and emollient fomentations: if the erysipelas was feeble, and the patient weak, I employed astringents and sedatives. Generally speaking, these kinds of erysipelas are far from being invariable; they are seen in persons in whom the gastro-enteritis is exceedingly obstinate in certain portions of the canal, though not sufficiently intense to produce the adynamic state; or when the gastro-enteritis, after bringing them to that state, allows of the relation with those around them, though it continues of sufficient intensity to cause partial disorganization of the digestive canal. Inflammation has infinite shades, as varied as the countenances of patients. There are gastro-enteritis that lead to adynamy, and others that do not: you have some that deceive you: the stomach of your patients seem to be re-esta-

blished, they are hungry, you allow them to eat, an erysipelas comes on, then hectic fever, and they die; others have boils and small abscesses that are multiplied, with increased frequency of pulse; in four or six weeks they sink into a state of consumption and marasmus. All these are diversified states of the same disease, a disease that you can only learn to comprehend in all its aspects by sound clinical teaching and the guidance of sound principles. Without these what can you do? Of what use are eighty-four cases of typhus, and the entities you extract therefrom, compared with the millions of individuals and different susceptibilities that people the world, and the millions of as varied diseases that depopulate it?

Reasoning must be applied to medicine, and the hope of expelling it is a vain hope: you reason in spite of yourselves. And when you behold an erysipelas supervening before the antiphlogistic treatment has been employed, or after the application of leeches, whose bites have been a starting point to it, you say, here is a complication: the patient has or has not appetite, he is weak or he is not, he has more or less frequency of pulse, he has or has not diarrhoea, &c.: you practise the medicine of symptoms: you treat erysipelas, according to your idea of it, either by the nitrate of silver, the acetate of lead, willow-bark decoction, &c.: the patient hungers, you give him food: he is purged, you give him opiate clysters, keep up his strength, &c. In all this you reason, but you reason falsely. What you ought to say is, this man has in his intestines a focus of phlegmasia, which is the cause of the erysipelas that appears in the skin; he must be kept to strict diet, to saccharine, gummy and lacteous drinks, or to very weak soups; his erysipelas must be treated on two very opposite principles, by antiphlogistics and emollients, if there be great intensity, or by astringents and caustics if there be but little. But never lose sight of the irritated digestive canal. If this same man has diarrhoea and inappetence, it is proof of an intestinal inflammation not yet terminated; for the small intestines are, as you know, long, and inflammation often traverses their entire extent, and remains obstinate in the large intestine.

Sometimes you behold a patient three-fourths cured of gastro-enteritis, who is attacked with erysipelas or boils. Now, to kill this patient, the inflammation must be renewed in the digestive canal, must be there generalized, or he must be exhausted by diarrhoea, or a peritonitis must supervene, or a cerebral congestion must arise, so difficult is the destruction of man in some instances. Ah! if the physician were always capable of appreciating morbid phenomena, and could modify them at his will, how few of his patients would die! But he is crossed by a thousand circumstances, too long to enu-

merate, and which you will not be happy enough to avoid in the course of your practice.

I pass to the use that has been made of stimulants internally, stimulants such as bark, camphor, wine, serpentary root, &c. I am aware that there are instances of cure by these means; but here is the place for taking account of and employing the numerical method, it being always understood to be applied to well-observed facts, without which none but false results would be got. If, then, a number of patients that have been stimulated in gastro-enteritis be compared with a similar number that have not been stimulated, the mortality among the former will be found to be four times greater. This I assert conscientiously. I think the calculation should be made by hundreds, especially in serious cases. Then, if it be required that I should give an account of the manner in which these have been cured, and the state of health of the patients after their cure, it will be seen that they have escaped the disease and the treatment by crises, that is to say, the irritation that has been produced in the digestive canal by stimulants, lights up the entire system, excites the circulation, forces the action of the secretory and exhalant organs, and gives rise to profuse hæmorrhages, to sweats, to external phlegmasia, &c.; whilst among those thus cured many go on with shattered health, remain with chronic gastritis or duodenitis, or in a state of incurable nervousness, &c. This is what I had in some measure discovered at the time I was only beginning the physiological reform, and I have since confirmed it by an immense mass of facts; for you can have no idea of the number of hypochondriacs who each year come to consult me, and in whom I detect a neuropathic condition that dates eight, ten, or fifteen years back. By questions I most commonly discover that they have had malignant fever that has been treated with stimulants; and this is the solution of the enigma. This, however, refers to the neuroses, which we have not yet reached: I will only make the passing remark, that it is very easy to accumulate sensibility in the digestive canal—a proposition that might make a good subject for a thesis. In general, if you stimulate a surface of relation that is rich in nervous papillæ, you communicate a degree of susceptibility to it that is truly horrible, and such susceptibility becomes a source of incessant perturbation to the system, that renders existence miserable. This is more particularly remarked in the digestive canal, independently of the consequences that inflammation may produce there, and which frequently prove fatal. Patients treated with stimulants in gastro-enteritis too frequently retain these susceptibilities.

A Sketch of the Medical and Statistical History of Epidemic Diseases in Ireland, from 1798 to 1835, with the Method of Prevention and Cure, as practised in the Fever Hospital, Cork Street, Dublin. By William Stoker, M.D., Hon. Fellow of the King and Queen's College of Physicians in Ireland, &c. &c.

(Continued from page 492.)

FOR a fuller description of the epidemic of 1831 than would be compatible with the space that remains, I must refer to the medical report from the Cork-street fever hospital for that year, and to my Comparative View of Cholera, published at the close of it. In the former of these publications, the epidemic of 1831 is thus described: "Its characteristic symptoms are great depression of spirits, irregular, small, and sometimes intermitting pulse, *tongue seldom dry*, but loaded with a viscid mucus, bowels torpid, *alvine evacuations, abounding with diseased fetid mucus, and deficient in bile, brain seldom engaged.*"* The following specimens are extracted from my Comparative View. (See Appendix, Note D).

December 8th, 1831.—Deborah Deane, ill six days of severe cholera, which commenced with painful and violent spasms in the trunk and lower extremities, with vomiting and purging of turbid serous gruel-like fluid, and attended with extreme debility. The surface everywhere cold, features shrunk. Her symptoms were quickly subdued, chiefly by a mixture with compound spirit of ammonia and camphor, and on the 9th December she was convalescent.

December 13th, 1831.—Charles Kelly, aged 70, ill seven days, of cholera, which commenced with violent pains in his stomach, and spasms in his legs, accompanied with vomiting and purging of gruel-like fluid, and extreme prostration of strength; his face and hands shrunk and blue; skin cold and clammy; no pulse at the wrist; voice scarcely articulate; lower extremities dark blue; spasms and a painful sense of stricture over the belly and chest. By the aid of frictions, warmth, and camphorated mixture with ammonia, which were remarkably successful in this case in producing reaction within its proper bounds, he was considerably improved. On the next day, inflammation of the lungs set in, which required bleeding, and the blood was slightly buffed, an event which often takes place after crises in fever, though it had not previously. His recovery from this time was progressive, and he was dismissed from the convalescent ward a few days afterwards. It was chiefly with a view to such cases as

this that I was led to recommend a more ready admission to the hospital than in ordinary times, and no part of the cholera regulations, afterwards published at the suggestion of Drs. Russell and Barry, appear to me more likely to save life than those which enjoin ready admission of those who sought it, and the conveyance of patients in an horizontal posture. As may be seen in the report of 1823, I urgently recommended such regulations.

The next table, taken from the journals I kept during my bimestral attendance, ending 4th February, 1832, includes those two months in which I first witnessed sporadic cases of epidemic cholera, approaching, on the one hand to the distemper of 1823, and on the other to the aggravated form it afterwards assumed in 1832, 33, and 34:—

Number in Cholera.		Died.	
Male.	Female.	Male.	Female.
10	35	6	12
Delirium Tremens.		Died.	
Male.	Female.	Male.	Female.
3	2	1	1
Typhus and Synocha.		Died.	
Male.	Female.	Male.	Female.
14	25	1	1
Phthisis.		Died.	
Male.	Female.	Male.	Female.
3	23	1	9
Inflammatory Fever.		Died.	
Male.	Female.	Male.	Female.
6	22	0	0
Rheumatism.		Died.	
Male.	Female.	Male.	Female.
10	54	1	0
Scarlatina.			
Male.	Female.		
2	5		
Small-pox after Vaccination.			
Male.	Female.		
1	4		

Besides those cases enumerated in the foregoing table, there were some nondescript or simulated, making the whole number that passed under my care during those two months, 60 males and 204 females, of whom 8 males and 16 females died. On the last day of that attendance 12 males and 42 females remained, some convalescent, and others still labouring under acute or chronic complaints, one only, of the latter, a female, had symptoms of cholera. The average mortality was 1 to 10. And it may be observed here that this as well as the general mortality in the hospital at that time, far exceeded that on the total at the close of 1830, which was scarcely 1 in 18. This difference itself indicated clearly the unusual severity of the epidemic; but the following report of some of the fatal cases in those two months, further shows what the epidemic truly was:—

* See Medical Report of the Fever Hospital and House of Recovery, Cork-street, for 1831. By P. Harkan, M.D.

† See my Comparative View of Cholera. Published January 30, 1832.

December 3, 1831, Anne Keogh, aged 20, some time in hospital, states that her illness commenced seven weeks ago with purging, vomiting, cramps in her bowels and calves of her legs. Although now somewhat relieved by chalk mixture, prescribed on her admission, yet is still distressed by diarrhoea: alvine evacuations, frequent and like thin rice gruel; skin cold, voice and pulse feeble, countenance shrunk. Under the use of various remedies, this patient continued for several days alternately better and worse, and was at length sent to the convalescent ward. There, in a few days, she suddenly relapsed into the most malignant form of cholera morbus, and died five hours afterwards: the body and extremities having become purple for some time before death*.

January 1st, 1832.—Brian Brady, aged 50, had been attacked six days before with vomiting, purging, and cramps in the belly and legs; on the 22nd December, he was admitted, and gradually recovered. But on the 7th of January he suddenly relapsed, in the course of the morning, with purging and vomiting of gruel-like fluid, which ceased in the afternoon. The skin was at that time cold, moist, and blue; his breath was cold, eyes hollow, and features contracted; no pulse perceptible; spasmodic pains in his belly and legs; no urine passed for eight hours, nor was there apparently any secreted, as the bladder was empty. No interruption of the mental faculties. Notwithstanding the employment of cordials, friction, and warmth, he died at six o'clock the same evening, about seven hours from the commencement of his last attack. On the succeeding day, the body was rather less purple, and had the appearance of being dead some days, as was usual in such cases. This too, as is well known, was constantly observed in fatal cases of cholera, after that disease had been officially announced in Dublin†.

January 7, 1832.—Patrick Dargan, an habitual drunkard, was admitted. He had laboured for seven days under cramps in his belly and legs, attended with great prostration of strength. At the time of admission, however, these symptoms had abated, and he was then principally affected with stricture and pain of his chest, especially at the region of the heart; his appetite was keen, pulse full and strong, skin warm. Under the employment of suitable remedies, particularly venesection and aperients, and a

mixture with ammonia, he gradually improved; but on the 12th, at 9 A.M., he was suddenly attacked with mucous purging, and at 11 A.M., with pain and spasm through his whole body, with constant writhing of his limbs, skin cold, shrunk, and livid, hands and lower extremities remarkably so, and partially occupied with extensive ecchymoses. The eyes, naturally prominent, were then hollow, and his countenance was pale, collapsed, and anxious; no pulse could be felt at the wrists even after warm drinks and warmth had been employed. These symptoms I have been thus particular in stating, as a very unfortunate difference of opinion arose between me and my colleagues, Drs. O'Brien and O'Reardan, who with Mr. Hale and Mr. Lawless, at my request, had seen the case. It was one of those cases I wished to be examined before and after death, and compared with those reported from England and the Continent; but my colleagues did not agree in these views, and both the Boards of Health and the Managing Committee were opposed to it. Not only was my proposition rejected but, wholly for proposing investigation, with a view to public safety, I have been since unrelentingly persecuted. Although very active treatment was adopted in Dargan's case (as ordered in full consultation), death took place seven hours from the period of the relapse. About half an hour after death, Dr. William Stokes inspected the body along with me, and the most remarkable circumstances then to be observed were the constriction of the abdominal muscles, the livid hue of the skin, and ecchymoses on the elbows and lower extremities. From such appearances, as well as the report the nurse gave of the symptoms and sudden death, Dr. Stokes expressed it as his opinion, and afterwards promptly repeated it in a letter to me, that the case appeared to him to resemble, and that he would pronounce it malignant cholera, if he had not on other occasions witnessed as sudden prostration of strength, and as sudden dissolution follow perforation of the intestines. He also joined with me in regret that the regulations adopted by the Managing Committee of the hospital opposed my urgent request of *post mortem* examination, to decide the nature of this interesting and important case—one, I certainly believed, of vital importance to the public at that time.

But the following table of admissions and deaths, constructed from the annual reports of the Managing Committee of the Cork-street fever hospital, being necessary to bring this sketch to the termination of the proposed period, and in willing compliance with a request by Henry Warburton, Esq., M.P., the able chairman of the Parliamentary Committee of Inquiry on Medical Education, I add it. Besides it affords valuable evidence on the important and still unsettled question in hand, whether the epi-

* This and five other cases which relapsed in the convalescent ward at the same period are detailed from the 16th to the 22nd page of my Comparative View, already adverted to in the text.

† In the manuscript accompanying the report of the months of December, 1831, and January, 1832, six other fatal cases of cholera and fever, in a severer form, were detailed.

demic constitution which has so repeatedly produced such dreadful effects in Great Britain and Ireland since 1832, was then the result of newly imported contagion *sui generis*, so as to be productive of disease, requiring distinct and separate modes of prevention and cure? or of atmospherical distemperature, producing an aggravation of disease to which it had previously approximated, and, therefore, requiring no more than active employment of the remedies previously in use?

Table of admissions, deaths, and average mortality, annually, in the Fever Hospital and House of Recovery, from 1831 to 1834½, inclusive.

Years.	Admitted.	Died.	Average mortality
1831	3602	307	1 in 11
Total for 28 years. }	88190	5659	1 in 15
1832½	3991	290	1 in 13
Total for 29 years. }	92181	5949	1 in 15
1833½	3332	293	1 in 11
Total for 30 years. }	95513	6242	1 in 15
1834½	4524	422	1 in 10
Total for 31 years. }	100037	6664	1 in 15

Comparing the average mortality in each of the years, in the above table, with that which occurred previously, the disproportion is very remarkable, especially in those years, during which restrictions on the admission of the malignant forms of the epidemic already referred to, was less rigidly enforced. On the other hand, comparing this with the statistical tables inserted in former pages, for the last fifteen years, it appears that the mortality in 1823, 24, 25, 26, and 27, when pestilence raged with characters in many respects resembling those in the last four years, was very nearly the same. But I cannot enter further, at present, on this important question. There is, however, an additional array of facts to illustrate it in a pamphlet I published on the subject, at the close of 1831, to which I beg leave to refer those not yet fully decided. There is also a memorial connected with that pamphlet which I presented in 1835, first to the King and Queen's College of Physicians in Ireland, and subsequently to the Irish government, praying of the former, adjudication, and the latter an impartial investigation, not less with a view to promote public security, than to obtain that justice which is the birth-right of every man.

A few abridged cases from the medical report for the year 1832, and there given as specimens of cholera morbus epidemic in that year, will assist, I hope, to settle this important, and to me anxious question, which, though it may have lost some of those features which excited universal panic at the

time I first proposed investigation, for the purpose of reducing it to its just proportions, yet must be still deemed deeply interesting, if the average mortality in hospitals in the current year, and the frequency of sudden deaths amongst all grades of society, be duly considered, with a view to the future, either as regards prevention or cure.

Case of Epidemic Cholera, No. 1. (See Medical Report for 1832, p. 18).

Bridget Kirwan, aged 60—seized April 10, 1832, at two o'clock A.M., with severe vomiting and purging. At five o'clock P.M., countenance collapsed and pale generally; eyes sunk; a livid circle around them; cheeks, naturally florid, inclining to blue colour; no pulse at the wrist; feeble in the carotid arteries; extremities quite cold and livid; voice nearly extinct; body cold; hands and feet shrunk; the discharge from the stomach dark-coloured and muddy, with a tinge of white: no urine passed for six hours, feet and legs affected with painful spasms. This train of symptoms, not seen before by the author of the report in question, he announced the case to be epidemic cholera. By friction and dry heat to the extremities, large sinapisms to the centre of the body, both before and behind, and two grains of calomel, and a quarter of a grain of opium, given every half-hour, with a spoonful of a stimulant mixture of compound spirit cardamoms and aromatic spirit of ammonia, the pulse and voice were restored, the vomiting and purging were checked, and the lividity of countenance disappeared the same evening. The patient was able to sit up in bed on the succeeding morning: she and her friends ridiculed the alarm of its being a case of cholera. The patient, however, relapsed on the next day, and died that night.

Case II.—R. W., aged 50, an embarrassed tradesman, attacked on the 27th April, 1832, after slight indisposition for two days, with sickness at stomach and severe vomiting; two o'clock, P.M., countenance pointed and pale; eyes sunk and languid; pulse quick, feeble, and irregular; skin soft and clammy, but warm; voice languid but distinct; constant painful spasms in the feet, and backs of the legs; no discoloration of the skin; tongue pale and shrunk. The author of the Report for 1832 pronounced this also a case of spasmodic cholera, which the patient's friends did not credit. The patient died within ten hours from the attack, notwithstanding the sedulous employment of the same remedies successfully administered in the case of Bridget Kirwan (No. I). The rapidity to a fatal termination, the intensity of the spasms, and the character of the pulse, left no doubt in the reporter's mind as to the real specific character of the disease. The two other cases of recovery, given in the same report, as specimens of epidemic

cholera, differ so little from the foregoing either in symptoms or treatment, that it is only necessary to refer to them as given at the 21st, 22nd, and 23rd pages of his report*.

In concluding this section, I have to offer as an apology for so superficial a survey of the many important subjects it embraces, that the original design of submitting this sketch to be read at a meeting of the College of Physicians, and of the British Association, in Dublin, necessarily restricted it. Besides, the want of free access to those medical records I in vain sought from the managers of the Cork-street Hospital, materially interfered with the execution of my task, especially on the leading question. These deficiencies, however, I hope I shall be enabled under the sanction and support of the parliamentary committee of inquiry, and its excellent chairman, Mr. Warburton, to amend at some future period. There are other reasons, however, which lead me further to regret being compelled to curtail or crush those illustrations of the pathology of the blood, which my experience enabled me to collect. The experiments of Sir D. Barry, MM. Magendie, Gaspard, and Orfila, had already extended these illustrations, and by comparing them with the experiments of Drs. Morgan and Addison, and with the able paper read by Dr. Macartney, at the last meeting of the British Association, at Cambridge, and his experiments on the nervous system, then detailed, I am sure sound pathology might have been greatly promoted.

(To be continued).

—o—

Observations on the Classifications, Etiology, Pathology, and Treatment of Diseases of the Skin, according to the most celebrated Authors of Ancient and Modern Times.

NOTWITHSTANDING the many instructive works which have appeared on diseases of the skin, a very small proportion of medical practitioners pay little, if any, attention to the subject. These diseases are, however, of daily occurrence, and ought not to be excluded from the study of pathology. They have been considered to be involved in obscurity, though there is no class of human infirmities whose characters and signs are more easily appreciated. The multiplicity of these diseases has discouraged the study of their nature, and has led to the most opposite classifications, as I shall speedily prove. The errors in classifications have very powerfully contributed to throw much difficulty on the study of cutaneous diseases, and they are as numerous as the authors who proposed them. The truth of this statement will be manifest on the perusal of

the following historical sketch of the best authors on this class of diseases. I cannot help observing that it is pleasing to know that the classifications of Willan and Bateman are most generally adopted, and are those of the most popular French writers, (Baron Alibert excepted), of M. Bielt, Rayer, Cazemann, and Schedel. They are also preferred in America.

Many of the diseases of the skin were described by some of the Greek, Arabian, and Latin physicians, but no attempt was made to classify them, so far as I can find, until the first quarter of the seventeenth century, and this was first done by Hafenreffer (Tubingen, 1630). His classification was, however, rude and unscientific: he included all diseases connected with the skin, such as wounds, ulcers, fistulæ, &c. About this period Mercurialis published a work exclusively on cutaneous diseases (*De Morbis Cutaneis*, Lugduni. 1630). He divided these diseases into two classes, 1, those that affected the head; 2, those that affected the rest of the body. Though this division is scientifically absurd, it seems to have somewhat influenced that of one of the most celebrated French authors—Baron Alibert, in his magnificent work on the diseases of the skin (*Monographie des Dermatoses, ou Précis Théorique et Pratique des Maladies de la Peau*, par Le Baron Alibert, Paris, 1832—a work the first edition of which was published in 1806). The immediate successor of Mercurialis was Turner (*Treatise on Diseases incident to the Skin*, London, 1736), in which the author adopted the division of his predecessor, and proposed a further ground of distinction, according as the diseases were produced by internal or external causes. This proposal was in turn adopted by Lorry (*Tractat. de Morb. Cutan.* Paris, 1777). Soon after this period, Retz divided cutaneous diseases into acute and chronic (*Des Maladies de la Peau*, &c. Paris, 1790). The next writer was Plenck, who classified cutaneous diseases according to their external characters; and this division was the first step towards the pathological anatomy of these maladies. He divided them into fourteen classes—1, *Maculæ*; 2, *pustulæ*; 3, *vesiculæ*; 4, *bullæ*, 5, *papulæ*; 6, *crustæ*; 7, *squamæ*; 8, *collositates*; 9, *excrecentiæ*; 10, *ulcera*; 11, *vulnera*; 12, *insecta cutanea*; 13, *morbi ungium*; 14, *morbi capillorum* (*Doctrinâ de Morb. Cutan.* Lovani, 1796)*. This was the foundation

* Derien classified them into essential and symptomatic (*Essai d'une Table Synoptique des Maladies de la Peau*, Paris, 1804; a classification republished by Joseph Frank, *Prax. Med. Univer. Præcepta de Morb. Cutis.*, 1821). Mr. Wilson divided cutaneous diseases into—1, febrile cutaneous eruptions; 2, inflammations, simple or constitutional; 3, papulous, vesiculous, and

* See Medical Report of the House of Recovery and Fever Hospital, Cork Street, Dublin, for the year 1832. By John O'Brien, M.D., &c., &c.

of Willan's classification—papulæ, squamæ, exanthemata, bullæ, vesiculæ, pustulæ, tuberculæ, maculæ*.

Bateman subsequently adopted this classification (1819), to which Baron Alibert, M. Biett, M. Rayer, Mr. Plumbe, and Dr. Pagett, have raised many well-founded objections, and to which M. Biett has added many improvements. Mr. Plumbe was the next writer on diseases of the skin (1824), and based his classification on the morbid anatomy of the parts affected. His classification is as follows:—

1. Diseases which obtain their distinguishing characters from local peculiarities of the skin—as acne, lupus, noli me tangere, herpes exedens, syccosis, porrigo.

2. Diseases marked by chronic inflammatory action of the vessels, producing the cuticle, &c. &c.—as lepra, psoriasis, pityriasis.

3. Diseases exerting probably salutary influence on the system, originally produced by, and usually symptomatic of, deranged digestive organs, and characterized by active inflammation—as porrigo favosa, strophulus lichen, prurigo, urticaria, herpes, furunculus.

4. Diseases of a mixed character, &c.—as impetigo, scabies, eczema.

5. Diseases dependent on debilitated and deranged states of the system, and consequent diminished tone of the vessels of the cutis—as purpura, aphthæ, pemphigus, pompholyx, ecthyma, rupia, erythema nodosum.

6. Fungoid diseases of the cutis and cuticle—as ichthyosis, warts, erythema, roseola, venereal eruptions, psoriasis, psoriasis decalvans.—(Treatise on Diseases of the Skin,

squamous eruptions; 4, eruptions proper to infants (Treatise, &c., 1814).

* Willan based his classification on the various primitive forms of the different cutaneous eruptions, which enabled him to make definitions with the greatest facility; but it has been objected to this arrangement, that the eruption may change its nature in the course of its development. Thus we find the same disease placed in different classes by different dermatologists. Ample illustrations of this will appear hereafter; and many may be seen in M. Rayer's work hereafter noticed, in Mr. Plumbe's excellent treatise, in Cazenave and Schedel's work, and in Dr. Pagett's Essay on the Classification of the Diseases of the Skin, to which Baron Alibert awarded his prize in 1832. This essay was fortunate enough to succeed against several competitors, French, German, and Italian. (Edinb. Med. and Surg. Journ., April, 1833). I cannot help observing that the author declared Alibert's classification the best. According to this writer, "the system of Willan must ever remain imperfect, for the character on which it is founded is neither constant nor essential;" but Biett, and his pupils, Cazenave and Schedel, declare it the best.

3rd edit., 1832; first edition appeared in 1824).

Mr. Dendy followed this author in 1827, and his classification is very nearly similar.

1. Diseases symptomatic of disorder in the alimentary viscera—as strophulus, prurigo, crusta lactea, follicular tumours, crinones, follicular wart, acne, syccosis capillitii, phlegmonous tumours, furunculus, phyma, epynictis, terminthus phygethlon, bubo benignus, parotis, urticaria, impetigo, and herpes.

2. Diseases symptomatic chiefly of deranged chylopoietic functions, usually marked by debility—as aphthæ, rupia, ecthyma, pemphigus, purpura, ichthyosis, chloasma, nomé, œdema cellularis.

3. Diseases usually symptomatic, arising also from extraneous excitement, depending probably on peculiar idiosyncrasy—as roseola, erythema, eczema, pityriasis, porrigo, paronychia, onychia maligna, erysipelas, lepra, maliaria, pompholyx.

4. Diseases consequent to specific infection—as rubeola, scarlatina, varicella, vaccinia, variola, pestis, syphilitic eruptions.

5. Local diseases, usually accompanied by little or no constitutional derangement—as scabies, pemio, clavus, verruca, encausis, lentigo, cyanosis, athrica, nævi, condyloma, phagades, intertrigo, morbus pilaris.—(Treatise of the Cutaneous Diseases incidental to Childhood, comprehending their Origin, Nature, Treatment, and Prevention, London, 1827).

The next classification is that of the justly celebrated Baron Alibert, which I copy from the last edition of his splendid work, 1832, the first edition of which was published in 1805 or 1806. He divides cutaneous diseases into twelve groups.

FIRST GROUP.—*Eczematous Dermatoses*.—Genus 1, Erythemata; 2, erysipelas; 3, pemphix; 4, zoster; 5, phlyzacia; 6, cnidos; 7, epinyctide; 8, olophlyctide; 9, ophlyctide; 10, pyrophlyctide; 11, charbon; 12, furuncle.

SECOND GROUP.—*Exanthematous Dermatoses*.—Genus 1, Variola; 2, vaccina; 3, clavelle; 4, varicella; 5, nirlé; 6, roseola; 7, rougeola; 8, scarlatina; 9, maliaria.

THIRD GROUP.—*Teigneous Dermatoses*.—Genus 1, Archores; 2, porriginé; 3, favus; 4, ichthoma.

FOURTH GROUP.—*Dartrous Dermatoses*.—Genus 1, herpes; 2, varus; 3, melitagra; 4, esthomene.

FIFTH GROUP.—*Cancerous Dermatoses*.—Genus 1, Carcine cancer; 2, keloide.

SIXTH GROUP.—*Leprous Dermatoses*.—Genus 1, Leuce; 2, spitoplaxie; 3, elephan-tiasis; 4, radesyge.

SEVENTH GROUP.—*Verolous Dermatoses*.—Genus 1, Syphilis; 2, mycoris fambræsia.

EIGHTH GROUP.—*Strumous Dermatoses*.—Genus 1, Scrofula; 2, farcin.

NINTH GROUP.—*Scabious Dermatoses*.—Genus 1, Gale; 2, Prurigo.

capitis, *P. pubis*; *pulex irritans*, *P. penétans*; *acarus scabiei*: *astrus*; *gordius*.

DISEASES PRIMARILY FOREIGN TO THE SKIN, BUT WHICH SOMETIMES PRODUCE PECULIAR ALTERATIONS IN THIS MEMBRANE.

Elephantiasis of the Arabs.

This author lays all preceding writers under contribution, and has properly excluded all terms which are either unintelligible, or differently employed by the ancients.

Thus the same terms were used for different diseases, and even now, no one can comprehend the meaning of the French terms, *dartres* and *teignes*, employed by some writers of that country, which comprehend every disease, and mean nothing; and are therefore excluded by MM. Cazenave and Schedel.

He candidly and justly admits, that of all the definitions hitherto given, Willan's are most constantly correct. He gives his own definitions of each disease before his description, and an anatomical account of many of the most intractable diseases. He praises the delineations of Willan, Bateman, and Alibert, but adds with reason, "most of the plates, however, exhibit only one of the stages of the inflammation which they are intended to represent.

Thus it happens, that some disease described as *pustulous* has been exhibited in the *squamous* state; that some other also, placed among the *pustulae*, has been represented in the *tuberculous* state; that others, lastly, have been only drawn in the state of *crusts*, a secondary character, and common to several very different forms of *phlegmasiæ*. These faults I have endeavoured to avoid in arranging the plates of this work. The primary forms of the inflammations of the skin, and the alterations which succeed them, have been represented carefully after nature, or the best engravings that have been published.

Mr. Plumbe had coetaneously, if not previously pointed out these defects, and illustrated the different grades of the same disease in his plates. M. Rayer has arranged his delineations in the same manner.

The latest authors are Dr. Green, and MM. Cazenave and Schedel.

Dr. Green's classification is the following:

Forms of inflammation of the Skin, and Diseases which appear under these severally.

Exanthemata: Erythema, erysipelas, roseola, rubeola, scarlatina, urticaria.

Vesiculæ: Miliaria, herpes, scabies, eczema.

Bullæ: Pemphigus, rupia.

Pustulæ: Variola (including varicella, vaccina, ecthyma, impetigo, porrigo, acne), mentagra.

Papulæ: Strophulus, lichen, prurigo.

Squamæ: Pityriasis, psoriasis, lepra.

Tubercula: Lupus, elephantiasis græca, cancer, molluscum, framboesia.

Furunculi: Furunculus, anthrax, pustula maligna.

Diseases which appear with the elementary characters of almost all of the above orders.
Syphilis.

Diseases which are severally types of new and additional orders.

Pellagra, purpura, elephantiasis Arabica, cheloidea, (keloide, Alib).

Original or accidental unusual states of the skin, not referable to Inflammation.

Achroa: Leucopathia, (Albinismus), Vitiligo.

Dischroa (Maculæ, Willan): Lentigo, Ephelis, chloasma, nævus.

Diseases of the appendages of the skin; more properly of the parts which secrete and support these.

Epidermis—ichthyosis, unguis—onychia, pili—plica.—(A Practical Compendium of the Diseases of the Skin, with Cases, &c., 1835).

M. Bielt's Classification is given by two of his former pupils, M. Cazenave and Schedel, in one of the best works on diseases of the skin, entitled "*Abrégé Pratique des Maladies de Peau*, d'après les Auteurs les plus estimés, d'après les Documents Puisés dans les leçons Clinique de M. le Dr. Bielt, 1834.

ORDER I.—*Exanthemata*: Erythema, erysipelas, roseola, rubeola, scarlatina, urticaria.

II.—*Vesiculæ*: Miliaria, varicella, eczema, herpes, psora.

III.—*Bullæ*: Pemphigus, rupia.

IV.—*Pustulæ*: Variola, vaccina, ecthyma, impetigo, acne, sycosis menti (mentagre), porrigo.

V.—*Papulæ*: Lichen, prurigo.

VI.—*Squamæ*: Lepra, psoriasis, ichthyosis, bronze tint, ephelides, nævi, decolorations, albinism, vitiligo.

VII.—*Tubercula*: Elephantiasis, græcorum, molluscum, framboesia.

VIII.—*Maculæ*: Colorations.

Diseases which cannot be referred to any of the preceding classes.

ORDER IX.—Lupus; X.—Pellagre; XI. Syphilides; XII.—Purpura; XIII.—Elephantiasis Arabum; XIV.—Keloides.

Having now enumerated the principal classifications of dermatic or cutaneous diseases hitherto proposed, it remains for me to introduce the Baron Alibert's conclusions on this subject. I shall then offer a few comments on the classifications of Willan, Alibert, Plumbe, Rayer, Green, and Bielt, and attempt to prove that a better system of dermatology than any one hitherto proposed is still a desideratum. But as Baron Alibert has long maintained the first position as an author on cutaneous diseases. I must introduce his views to my readers; I cannot, however, refrain from observing, that in my opinion, his classification is very objectionable, and that he ought to have explained more concisely and clearly the reasons which induced him to propose a natural

classification, which, permit me to observe, though applicable to botany and geology, is not to human diseases.

Baron Alibert, the celebrated author of this natural classification, has long possessed the greatest advantages of any physician of modern times, for investigating the nature and treatment of cutaneous diseases. As first physician to the Hôpital St. Louis, in which are congregated individuals from all parts of the world, he has with great zeal, devoted more than thirty years to the investigation of the science of dermatology; and in imitation of his illustrious countrymen, Jussieu and Cuvier, who so happily classified natural history, he has attempted to arrange diseases of the skin in natural order. He collected together all the genera that bore the closest resemblances, and formed them into the natural groups, which I have already described. In these, he includes all the diseases to which the tegumentary tissues are liable.

He commenced in his first edition (1806) to determine species and form genera, and in some years afterwards improved the nomenclature, and proposed a general methodical arrangement. These he promulgated in his clinical lectures at St. Louis in 1829, which he published in 1832, and from which I quote.

In the inductive lecture to the study of dermatoses or cutaneous diseases, delivered at the commencement of each clinical course, at the Hôpital St. Louis, this session, the Baron Alibert, after an eloquent and classical account of the anatomy, physiology, and pathology of the skin diseases, proceeded as follows:

Necessity of Classification to facilitate the Study of Dermatoses.

Gentlemen, to divide and classify, in my judgment, is to instruct; we trace the first lines of demarcation which exist in the great family, whose history we sketch. We apply the method of naturalists to this study, and abridge our course by the excellence of their arrangements. Twelve groups form the basis of their distribution, which I have established in the hospital, for your instruction.

You will bear in mind all that I have said in the commencement of this lecture, on the peculiar structure of the skin; it appears that this envelope, in modifying itself for new functions, acquires an aptitude for new sufferings. But we ought, at first, to allude to a particular group of diseases, called eczematous, as they are those which manifest themselves by inflammation, and a kind of intense heat in all the external teguments. Erythema is only the result of an irritation more or less vivid in the superficial tegumentary layer, (epidermis or cuticle). Erysipelas is deeper seated, but both succeed in nosological order; indeed, we find that nature unites all diseases by the most manifest relations. What is nearer than the

genera pemphix, zoster, *enidosis*, epinyctis, olophlyctis, ophlyctis, pyrophlyctis, phlyzacia, carbunculus, furunculus, &c., which show their phenomena of irritation even in the cellular prolongation of the derm (skin).

There is no physiologist who does not understand the extreme sensibility of the different tissues (layers) that compose the tegumentary apparatus. There is no person who does not know, that when these tissues are called into action, by a physical or moral cause, the blood flows to them. Is it not this phenomenon which causes the vessels to become the seat of eruptions called exanthemata, which ought to constitute a particular group or class, and to characterise dermatoses purely eczematous? You know that a critical function is ascribed to these efflorescences. In fact, nature has an evident object in view, in these eruptions, which are caused by a morbid taint, to remove an injurious and superfluous matter; but on account of the obstacles that this matter encounters, by the extraordinary irritation it causes, the skin must necessarily change its colour, and often undergo morbid alterations, according as the susceptibility of the layers, and the depth of the affected tissue.

It is unnecessary for me to describe the series of exanthemata, from the head, the seat of the African small-pox, which is as fatal as the plague, and which has carried its destructive influence to all nations; but I wish to allude to this extraordinary contagion, which found a Rhazes for a delineator, a Sydenham for a combatant, and a Jenner for a preventor.

The name of Jenner, gentlemen, cannot be pronounced, without recalling to your memory one of the greatest benefactors that science has ever given to humanity. His discovery of vaccination, by chance, is one of the greatest boons ever conferred on our species.

Gentlemen, we naturally find in this class vaccina, clavelle, (clavus) varicella, nirlle, rubella, roseola, and scarlatina, as well as military eruptions. These exanthemata interest curiosity, on account of the numerous differences in their configurations, colour, development, duration, and termination. The exanthematous dermatoses deserve to be most attentively studied, as they are liable to most fatal recessions, or repercussions. It is a fundamental fact in cutaneous pathology, that the eruptions seated in the cutaneous capillaries are most liable to this termination. We shall give the reason of this phenomenon, in demonstrating the constant sympathies between the external and internal skin. Who does not know, that the mucous derm has not, as some anatomists have pretended, a priority of origin to all the rest, and that it is by a successive progression from the centre to the periphery that it advances and modifies itself, to constitute the envelope of the human body?

We shall describe the various shades of the exanthemata, their period of apparition, increase, circumscription, confluence, the seasons that are favourable or unfavourable to their critical or secretory movements, the symptoms which constitute their malignity, the intercurrent phenomena, &c. The superficial layers of the tegumentary apparatus, being the most vascular, are the especial seat of the multitude of acute eruptions which occur in the early period of life, while the chorion is particularly the seat of chronic dermatoses.

We are next naturally conducted to the examination of the group or class *teigneuses* dermatoses, which comprehend all the depuratory diseases of infancy. By those morbid eliminations, the individual, during the period of youth, appears to purge all the superabundant humours of his economy. Some of these are benign, others obstinate, but civilization seems to require them for the presentation of life.

The *dartrous* dermatoses are clearly allied to the last group, though they occur in all ages, in all ranks and conditions of society. At the head of this class is herpes, whose varieties will demand especial attention.

The genus *various* is generally placed by the side of herpes, because the pustulous affections of it cause the same pruriginous sensation, give rise to the same inconvenience, undergo the same changes, and yield to the same treatment. The species of this class differ, however, from those of the former, as they are the result of idiosyncrasy of the teguments, or of individual temperament.

The more we embrace cutaneous pathology in its vast extent, the better we know the affinities and dissemblances; thus, in my reformed classification, I have separated from the genus herpes the crustaceous darte to constitute a new genus.

There is another which is manifestly connected with the dartrous dermatoses, the esthiomene, which is generally considered a phagedenic inflammation, since it attacks and destroys all the substance of the derms. The term *lupus*, which is employed to express it, is a barbarism, and ought to be excluded. The term esthiomene has long been employed, on account of the correctness of its etymology: the language of the sciences is common property, which everyone may enjoy.

We must not confound esthiomene with the disease called *noli me tangere*, for this takes its source from an isolated, hard, livid black tubercle, the seat of pungent, lancinating pain, which the slightest injury exasperates, enlarges its base, and ranges it with the *cancerous* dermatoses. It is in this group we should place anthracine, &c.

The alterations known by the name of cancers are neurites which implicate the surrounding cellular tissue*. Observe es-

pecially that this neuralgia is constantly the signal, the precursor of the future disease; and remark, when the predisposing cause exists, a fall or contusion is sufficient to develop the malignant disease.

The *leprous* dermatoses contaminate all the humours, affect all the functions, change all the tissues, accumulate and simulate all diseases, and produce the worst effects. We maintain, in their true acception, all the denominations attributed to them by the historians of antiquity. Lepra, though most frequent in warm countries, is not entirely banished from the European territory; it still appears among the great scourges that inflict the human race: *morbus herculeus quoniam eo nullus major, neque valentior*.

Among the important diseases that range in this positive classification are the *verolous* dermatoses: to this group belong the polymorphoses, syphilis, the primary symptoms of which appear on the skin.

By the side of the *verolous* dermatoses are naturally placed the *strumous*. We insist particularly on the genus scrofula, which affects whole generations, and disfigures them by indelible cicatrices.

The genus *farcin* establishes an alliance between veterinary and human medicine. Sauvages and others, ascribe the swelling in the course of the lymphatic vessels in horses, to scrofula. These tumours present the same organization, development, and undergo the same modifications as in man (Dupuy.) Dr. Elliotson has recently described glands in the human subject. The disease is not, however, observed in horses in the wild or savage state. The *scabious* dermatoses affect the papillary body. We hold that each bulb of the hair, each gland, each vessel, has an emissary nerve, if I may use the term, from the great organ which innervates (animates) all the functions, a nervous ramuscle, which vivifies and renders it susceptible of pain. It is to the history of these affections, we must refer that of parasitic animalcules, which lodge themselves in the superficial layers of the teguments, whose mode of propagation is still a problem for naturalists.

There is another group observed in large cities, the *hematous* dermatoses, vulgarly designated *scorbutic*. We place in this class sea scurvy, peliose (ecchymosis), petechiæ, &c. These are caused by a hemorrhage, almost passive, from the cutaneous vessels.

The next group is *dyschromatous* dermatoses. These are caused by alterations of the pigmentum in its reservoirs. Some of this genus are general, some partial, others congenital, and more accidental. Among these are the discolorations, pannus, achromia, albinisme, vitiligo, &c.

means determined as yet, and the conclusions regarding it are very different. Pain is one of the first symptoms, but every one knows that malignant scirrhus may exist for years without it.—Ed.

* The pathology of carcinoma is by no

The last group is termed *heteromorphous* dermatoses, and comprises all the diseases, whose organization and progress are anormal. We class here indurations, hypertrophies, all deviations of the nutritive function, all alterations of structure, &c.

I have adopted for the classification of dermatoses the method of botanists, and I have conformed to the view expressed by Sydenham in the preface of his admirable work. This method consists in acquiring a complete knowledge of the symptoms of the elementary phenomena, and the laws on which the diseases are organized. Nothing, then is more fixed and constant than the morbid productions which are the object of the philosophical classification, which I have proposed. These productions no more change than the fruits of a tree, or the constant and necessary effects of any vegetation. Thus *esthiomene* shews itself in all races of men which are susceptible of this degenerescence, and furnishes us with the results of phagadenic inflammation; thus *melitagre* reproduces itself as a gummy gelatiniform exudation, of the appearance, colour and fluidity of honey. Since the human race is subject to diseases, *lepra*, *herpes*, *favus*, *pemphix*, &c. have always shewn themselves with the same characters; the appearances by which these eruptions differ or resemble each other, are immutable in each group, and in each family. It is, therefore, easier than one would think, for an individual engaged in a methodical distribution of diseases to establish groups, genera, species and varieties. The groups ought to be compared to the tribes of animals: morbid affections cannot be defined but by greater leading traits; but the genera are more circumscribed, are particularly destined for the collecting of species; these are determined in their turn by characters the most constant and marked; in fine, the varieties are commonly arranged according to certain changes of colour and of form, to the temperament, idiosyncrasy, age, climate, predisposition of organs, or other accidental circumstances which almost always have influence in dermatoses.

Such is the arrangement which has always appeared to me the best for a just co-ordination of the facts in this branch of science. A great deal has been said of late years about the elementary physical phenomena, according to the classification of Plenck, reproduced by Willan; but this has a manifest disadvantage of frequently separating that which ought to be united. It is when the cutaneous disease is fully developed, that it is proper to assign it a place in the different nosographical orders; for what would be said of a botanist, who amidst the collections of a long and laborious herborization, would not denominate the plants, but according to their most obscure characters, or the rudiments of their existence? What would be thought, says Sauvages, of a zoologist, who would have the pretention to classify animals

according to the consideration or examination of their eggs? Who does not see, therefore, that this method has the disadvantage of all artificial systems, since it is based on the consideration of a single character only?

After eulogizing the great Linnæus, and Jussieu, Baron Alibert concluded in these words:—"Nurtured by the doctrine of these great masters, I wished in my turn to classify the facts which I observed in the clinic, which I was the first to establish in this hospital (St. Louis). I have delineated a genealogical tree prefixed to my work, which presents, in regular order, the groups, the genera, and the species of the family of dermatoses. It is upon its branches I have placed a nomenclature, which I believe is required by the wants of the epoch in which we live. The terms which I have adopted are not new: the language of Hippocrates, that of Galen, of Celsus, of Rhazes, of Avicenna, &c. generally suffice to express all.

"The sciences could not be perfected by the labours of one individual—our most religious duty is to render justice to our predecessors, our contemporaries, and those who co-operate with us." The Baron then recommended the works of Lorry, who explored the doctrines of the ancients in an elegant style, full of clearness, demonstrated the lacunæ, intimated the points of research, and elucidated the synonymes. He next spoke of Willan's work, as follows:—"A work not less remarkable but more modern is that of Willan. You already know his doctrines, and his faithful translators have endeavoured to enlighten your minds with the precise notions which it contains. This author excels all others in his description of the acute exanthemata. He has particularly explored elementary lesions, and it is impossible not to profit by the light he has thrown on the multitude of facts which he examined with the greatest care. But Willan practised at a dispensary; and it can be readily perceived, that the chronic diseases of the skin passed too quickly before him, and that the phenomena of this order were wanted to him. The reproach which we can, therefore, address to him is, his having altered the acceptations of words, and of having created a nomenclature, which throws a confusion upon the genera and species. There is no doubt, the best language to describe all the elements of this determined branch of art, is that which suddenly recalls to the mind a known character. This language is easily comprehended; it is the rich, abundant, representative language of Linnæus, now classic, which we can understand, and with which we can correspond in all places."

The plan of M. Rayer, and his description and treatment of each disease, are preferable to the last. He first describes the causes, then the symptoms, pathology, diagnosis, and lastly, the treatment of each complaint, according to the best authors, and his own ex-

perience. He also adds the ancient histories and synonymes; and he deduces, from nearly two hundred cases of each disease observed at the hospitals St. Antoine and la Charité, the characters and treatment. He describes their salutary and injurious influence, their relation to former complaints, their progress and connexion with maladies, which are more or less likely to occur. He likewise appreciates the effects of regimen and habit in producing cutaneous complaints, and includes the effects of age and organic changes. He gives a full account of therapeutical agents. He appends an atlas, containing twenty-six folio plates, which illustrate 400 diseases of the skin. This is so well executed, that any one can distinguish the different diseases. An English version of the work has been published, with the atlas, on the same terms as in Paris, and reflects great credit on the translator for his accuracy, and on Mr. Balleire, the publisher, for undertaking it. I have reason to know, that the work has been most favourably received, and cannot fail to be encouraged. It is, however, an expensive one—four pounds eight shillings sterling is a long price, but not too much for such a useful publication.

The work of Cazenave and Schedel has two plates, which illustrate the diseases of the skin, and may be purchased for a few shillings. The Brussels edition is better and cheaper than the French.

It is to be regretted that the celebrated Alibert did not prefix to his classification an account of the relations between natural arrangements and that of diseases of the skin; and I agree with one of his countrymen, that "we have also to regret that instead of imitating the precise language and short terms of naturalists, he has employed an imaginative style, brilliant and metaphoric it is true, but enables us with difficulty to learn the exact meaning of the author, in the midst of the tropes and figures with which it is surcharged."* The writer whom I quote raises numerous feasible objections to the natural arrangement, which I am disposed to think cannot be answered; but which are too long to be inserted in an essay of this description. I am, however, ready to state, that no living author has been more successful in the treatment of the diseases under notice than Baron Alibert; but I must take leave to declare, that his attempt to classify such diseases, according to the method of naturalists, appears to me to be a failure. The diseases of the skin are 120, according to Willan and Bateman, and 141, according to the last edition of Baron Alibert's work (1832). When an attempt is made to classify these according to the natural order, one is disposed to inquire, if the disorganizations of any other tissue can

be so classified? If they can, we ought to have similar classifications of the diseases of every tissue in the human body. We have not, however, such classifications of diseases, and none hitherto proposed, those of the cerebrospinal system perhaps excepted, were ever correct, unless based on pathological alterations, their complications and consequences. This is the plan adopted by Rayer, and in my opinion the least objectionable.

It is also to be recollected that the structure of the tegumentary system, even according to the latest descriptions, is by no means determined. We can however attempt to establish an anatomical and pathological classification of its diseases; the first by observing the lesion of structure and not by functional derangements; the second, by estimating the morbid appearances during life, and the derangements which they produce.

I am perfectly aware of the recent account of the structure of the skin; but years must elapse before it will be generally received. In fine, I have to observe, that I have taken the liberty of commenting on the classifications of the most celebrated modern authors on cutaneous diseases, MM. Alibert, Bielt, Rayer, Cazenave, and Schedel, with a view, on a future occasion, of attempting to offer an anatomico-pathological classification of the disorganizations of tegumentary tissue, and one, which I hope will be more accordant with the real state of science and terminology, than most of the preceding.—R.

(To be continued.)

Reviews.

An Introductory Address, delivered at the commencement of the Tenth Session of the Manchester School of Medicine and Surgery, Pine-street. By James L. Bardsley, M.D. Lecturer on the Principles and Practice of Medicine, &c. 8vo. pp. 47. London: Burgess and Hill. 1835.

An Address, delivered at the First Anniversary Meeting of the Birmingham School of Medicine and Surgery. By James Thomas Law, Chancellor of the Diocese of Litchfield. 8vo. pp. 24. Birmingham: Wrightson and Webb.

THE perusal of these essays has afforded us great pleasure, as they show the vast improvements that have been recently made in diffusion of true medical knowledge *ubique gentium*. There was a time when "sound chirurgical knowledge" could only be obtained in London, according to the then council of our sapient college in Lincoln's Inn Fields; *sed tempora mutantur*. The old gen-

* Philosophie Medicale-Maladies de la Peau. Par M. Martin. Revue Medicale Française et Etrangere, October, 1835.

tlemen of the past century, who lived until the last few years, and stultified the college, could see no talent in the provinces—all sound chirurgical knowledge was confined to themselves; the rest of England, and indeed, of the world, was involved in impenetrable obscurity. According to these sages, his Majesty's lieges were wofully treated in the country, and when a nobleman was ill, he was expected to send express to London, for one of the sound chirurgical oracles. But a free press has put an untimely end to this folly. It also enabled our brethren in the provinces to keep pace with the rapid advances of science; it afforded them every opinion of the metropolitan lions, which was worthy of notice, and led them to the unfortunate conclusion, that they could treat diseases upon the same principles, and with equal success as the primitive sources or sound chirurgical knowledge. Here was a terrific reformation! The press, the most powerful of all human inventions, proceeded, and insisted that medicine could be as well taught in Manchester or in Birmingham, as in London. It contended that the structure, functions, disorders, and diseases, were the same in all parts of this kingdom; that provincial physicians and surgeons could possess the same works, were taught the same principles of physiology, pathology, and therapeutics, as the self-constituted sources of sound chirurgical knowledge, and their formidable opponents, the Rhabarbarians, and, therefore, ought to have the right of teaching. This was at first considered outrageous; but the press, that sways all classes, from the monarch to the peasant, acted on the grounds of reason, justice, and common sense, and was not to be opposed. It acted according to the axiom,

"Fiat justitia, ruat cælum,"

and carried its point. It compelled the College of Surgeons and Apothecaries' Society, or Company of wholesale druggists, to abolish their unjust by-laws, and to recognize lectures delivered in regularly appointed medical schools in the provinces. What has been the result? Simply, that the limpid sources of sound chirurgical knowledge are nearly dried up; empty benches distress them, when compared with the by-gone days of their glory and monopoly. To crown all,

VOL. VIII.

a free and independent medical press brought about a parliamentary committee, to inquire into the present state of medical education and practice in Great Britain and Ireland, which has given the *coup de grace* to medical monopolists. Such has been the influence of the *Lancet*, of this *Journal*, and the *Medico-Chirurgical Review*. We place our contemporaries in the position to which they are entitled, and we exclude the *Lizard*, which always defended every abuse and rascality as long as possible, and now advocates reform at the eleventh hour, when it is inevitable!

Having premised these remarks, we now turn to the essays before us. That of Dr. Bardsley is equal, if not superior, to any published in this metropolis. This address is characterised by elegance of diction, purity of style, real learning, considerable erudition, extensive experience, and genuine philanthropy. It is not one of those hodge-podge introductions, delivered too often in London.

The learned author describes the advantages afforded by the Manchester Medical School, the extent of its museum, library, &c. It appears from his statements, that the means of teaching in that institution are not surpassed. This is also the case at Birmingham School. The Rev. Chancellor Law, in a beautifully written address, gives an account of the numerous improvements made in that institution, and names a long list of its patrons and supporters. It appears that the number of students is now ninety, every one of whom, in the olden days of monopoly should have come to London. It likewise is a fact, that not a single student of the school has been rejected at Lincoln's Inn Fields. How these facts must delight the examiners and council of the London College, especially those of the old school, who would, if possible, suppress every provincial school in the kingdom! —o—

The Cyclopædia of Anatomy and Physiology.

Edited by Robert B. Todd, M.B., Lecturer on Anatomy and Physiology at the Westminster School of Medicine, &c. &c. Part III. October. Illustrated with numerous Engravings. Sherwood, Gilbert, and Piper. This splendid work maintains its excellence. The present part is devoted to the following subjects:—*Arachnida*, by Dr. Audin; *arm*, Dr. Hart; *artery*, normal anatomy of, Dr.

Hart; abnormal, anatomy of, W. H. Porter, Esq.; articulata, R. Owen, Esq.; articulation, Dr. Todd; asphyxia, Dr. Alison; aves, R. Owen, Esq. The names of the writers stand so high, that it is scarcely necessary to state that these authors have treated their respective subjects with their wonted ability, and with great credit to themselves. The illustrations are numerous, and executed with the greatest accuracy. Such a work as this, which contains human, as well as comparative anatomy and physiology, and was long a great desideratum, cannot fail to obtain extensive patronage in this and other countries. It only requires to be known, to be universally encouraged; and we understand it has already a large sale, which it well deserves.

—o—

A Literal Interlineal Translation of the First Ten Chapters of Gregory's Conspectus Medicinæ Theoreticæ, with the Original Text, to which are added, an Ordo Verborum, and rules for Constructing and Arranging the Words of Latin Sentences in legitimate order for Translation; illustrated by Examples from the more difficult passages of Celsus and Gregory. By Robert Venables, A.M., M.B., Oxon., &c. 12mo., pp. 122. London: Sherwood and Co. 1835.

THIS is a useful work to students preparing for examination at Apothecaries' Hall. It is to be regretted that productions of this kind are at all necessary, but they are, and will be so for some years to come. It is easy to account for this state of things. The Apothecaries' Society, which is now in reality the London Faculty of Medicine, so far as education is concerned, does not require an examination in Latin of those apprenticed to its members, and consequently, few of them possess a good knowledge of this language. The Society, however, tests their acquirements in this branch of literature, and those who are ignorant of it, stand in need of the assistance of works such as that under notice. We trust, however, the time is approaching, when no one will be allowed to enter on the study of medicine, unless he has received a good general and classical education. This is the opinion of all universities and colleges, and ever must be: but until such a system of education is required, there will be many who must resort to translations of the medical classics, and even to interlineal ones.

We, therefore, do not agree with some of our contemporaries, in condemning works like that before us, by wholesale; for daily experience in instructing students in some of the elementary branches of medical science, proves to us the necessity and utility of such works. We sincerely hope, however, that in a few years such productions will be unnecessary.

—o—

On Blood-letting.—An Account of the Curative Effects of Abstraction of Blood; with the Rules for applying both Local and General Blood-letting in the treatment of Diseases. By James Wardrop, M.D., Surgeon to the late King, &c. 12mo. pp. 148. London: J. Balliere. 1835.

THIS is a very instructive essay to students and junior practitioners. It contains a great mass of practical information in a small space, and at a very trifling expense. The opinions delivered are generally correct, but there are a few open to some objection. The author too, ought to have alluded to Dr. Marshall Hall's admirable work on the same subject, which contains many important facts, which should have been included. But as the last work is a treatise *ex professo*, and the former an essay, perhaps the author did not feel bound to notice the matter to which we have alluded. Here we differ from him, as we think that this essay ought to be as perfect as possible. There is, however, a vast difference of price between a twelve, and a three shilling volume. We strongly advise students and junior practitioners to add this work to their libraries. It is a cheap, instructive, and valuable manual.

Foreign Medicine.

Hopital des Enfants Malades.—Angina Tonsillaris.

NICOLAS DUPONT, aged twelve years, of a strong constitution, habitually enjoying a good state of health, and not subject to sore-throat, after having been exposed to rain during a part of the day of September the 9th, was taken in the evening with a violent shivering, followed by heat, attended with pain in the throat and sleeplessness. The next day vomiting was provoked by the smallest quantity of food, the other symptoms continuing. He was taken into the hospital on the 12th, the fourth day of the

disease. The face appeared emaciated, and of a red colour; pain in the forehead; skin hot and moist; pulse 116; the tongue covered with a thick white crust; mouth clammy; breath foul; pain in the throat; difficult deglutition; voice nasal. On examining the fauces, great swelling of the amygdalæ and soft palate was discovered. All these parts were red; and their surface, as well as that of the pharynx, was covered by a mucous exudation, which could be removed with the points of the fingers. Constipation; no pain in the epigastrium, or any other parts of the abdomen. The respiration was free; auscultation and percussion of the chest give only negative signs. The inflammation of the palate, pharynx, and amygdalæ, was intense, but without any complication. The exudation, which covered the inflamed parts, was not a false membrane, as was proved by passing the finger over them; the matter being removed in this way with the greatest facility.

Twenty-four grains of ipecacuanha, in two doses, were immediately prescribed by M. Guersent, together with a gargle composed of half a drachm of sulphate of alumina, two ounces of syrup of mulberries, and ten ounces of barley-water. Lemonade for drink.

Vomiting occurred two or three times after the emetic, with yellowish-coloured stools. Next day the cephalalgia continued; the face was flushed; and the deglutition, according to the patient's report, was more difficult than on the day before. The pain in the throat was also great; the voice much altered; and the thirst urgent. The patient complains of pain in the epigastrium, increased on pressure. Pulse 124; respirations 30, oppressed; skin hot; pain in the course of the larynx and trachea. The treatment was limited to a gargle and refreshing drinks.

On the following day (the sixth of the disease) the pulse had sunk to 96; the epigastric tenderness had disappeared; but the swelling and redness of the throat continued. M. Blache, who had temporarily taken charge of the patient, thought he perceived on the posterior part of the pharynx a yellowish spot, which appeared to him of a fibro-membranous nature. It was removed by the nitrate of silver. The gargle was

continued, increasing the alum to two drachms.

Epistaxis appeared on the ninth day, with herpes labialis. The respiration was more difficult: but the tonsils were reduced nearly to their natural size, and scarcely any trace of exudation remained on their surface. Epigastrium completely free from uneasiness; the tongue has become clean; and the appetite is very good. Solid food was allowed. In two days more the patient was completely cured.—*La Lancette Française*.—*Gazette des Hôpitaux*.

—
Extraordinary Case of Dystocia. By Dr. Thirion.

Madame Lagrange, thirty-two years of age, born at Lamy, and the wife of a merchant in that city, the mother of eight children, of a sanguine and nervous temperament, not tall, but well formed, and who to a fine complexion added the precious qualities of a good spouse, a good mother, and a good housewife*, found herself, on the 5th of August, 1833, at the end of her sixth pregnancy, and at the commencement of labour. She sent to request my assistance.

Examination *per vaginam* placed me in great perplexity; but after a long and attentive examination, I recognized in the pelvic cavity a hard furrowed mass, which I judged to be half the size of an infant's head at the full term. It was placed in the anterior part of the right side. I ascertained distinctly that it was formed in the thickness and at the expense of a full half of the uterine neck; for I could trace, without any interruption of continuity, the rest of the orifice, which dilated itself during the contraction of the womb, and through which I could feel the head of the infant, in the left occipit-anterior position.

After several hours of labour, during which this mass pressed down, I felt myself obliged, on account of the patient's weakness, and my fear of a rupture of the uterus, to call in the assistance of a colleague; when, all at once, while the messenger was gone for him, the tumour was depressed more than ever, in consequence of redoubled

* It is scarcely necessary to remind the reader that this is a French case.

contractions, and of sustained pressure which I exercised; and the infant was expelled dead. A strong dose of the ergot of rye had been given. In taking away a portion of the placenta, in order to arrest a commencing hæmorrhage, I found that this mass was prolonged into the right side of the body of the uterus, where it had a lengthened pyriform termination, while its base was at the neck of the uterus. The accouchment was followed by nothing unusual.

I felt myself obliged to represent to Monsieur Lagrange the danger which might accrue to his lady, in the event of another pregnancy; giving him a black catalogue of the serious, and perhaps fatal accidents to which it might expose her. But this narration, dictated by the philanthropy of our art, produced only a temporary effect. Passion made him disregard the danger of sacrificing his wife, and Madame L. became again *enciente*. This pregnancy offered nothing remarkable in its course; but delivery took place at the end of six months. It was accomplished with ease, from the small size of the fœtus. The tumour, which I have before mentioned, was still in its place; but had increased in size. The fœtus had been some time dead; and the epidermis peeled off. Her convalescence was favourable.

I repeated my observations to the husband on the danger his wife incurred from pregnancy; for the philosophy of our art, like every other kind of philosophy, makes it imperative on us to avoid misfortune and death, whatever may be the means necessary to accomplish this benevolent object. All my admonitions ended in another pregnancy. It was very obscure, until half its term had elapsed. Madame Lagrange repeatedly felt strong pains in the abdomen. Examination, which was repeatedly instituted, always discovered the tumour in the pelvis. The uterus was bi-lobed; but the pregnancy went on to its full term; and on the 22nd of July, 1835, at two o'clock in the morning, her husband summoned me, announcing that his wife was in labour, and that the water had just escaped. Examination quickly informed me that the tumour, hard, furrowed, and as large as the head of a full-grown fœtus, was in the cavity of the pelvis; and that it was

impossible to get by it in order to tell what was beyond. The uterine contractions were strong; and every time they recurred, the tumour was violently forced downwards. Blood was poured out rather copiously; for before the patient lay down, about ten ounces escaped. The horizontal position was rigidly prescribed; and I allowed the labour to go on for an hour; when, convinced of the impossibility of delivery by the natural passages, I called in Dr. Evrard, who coincided with my views on all points. We likewise sought the assistance of Dr. Mercier, whose opinion agreed with ours; but at this period of the labour we perceived between the pubis and the tumour a part of the fœtus, which by its density appeared to be the head. We then thought of having recourse to one of the most serious operations of surgery, the Cæsarian section; but previously to this, I went to request Dr. Darigarde, whose experience is always resorted to on these occasions, to favour us with his advice. His decision was the same as ours. The Cæsarian operation then was determined on, without hesitation, by the four physicians present; and Madame Lagrange performed her religious duties. While we were commenting on the peculiarities of this rare, and perhaps unique case, I felt desirous of attempting to push back the tumour. The project seemed chimerical; and I confess I hardly thought it could succeed. Nevertheless, my attempt was crowned with success. The enormous mass was pushed back, during an interval of the pains, into the posterior part of the right iliac fossa; the uterine neck was thus placed in the centre of the superior outlet, and a violent contraction made the head of the fœtus descend into the cavity of the pelvis, where the tumour had previously been; and another pain caused the expulsion of a full-grown living infant. The placenta quickly followed, and the patient found herself in the usual situation of lying-in women.

We could each of us then, through the walls of the abdomen, recognize a great part of the tumour occupying the right side. A few days afterwards I made an internal examination, and found the inferior part of the tumour in the cavity of the pelvis. I remarked at the same time that the neck of the uterus had been torn to a considerable ex-

tent. Except these peculiarities, every thing was as I had found it after the sixth accouchement. Madame Lagrange quickly regained her usual state of health. All the functions went on naturally; but the secretion of milk did not take place. The tumour gave her no inconvenience.*—*La Lancette Francaise.*

Internal Exhibition of Cobweb.

Dr. Bertrand, of the School of Medicine at Montpellier, has addressed to us the following observations on the good effects of this substance. Its external use is well known; and it has also been recommended internally; but its employment had been abandoned. The singularity of the medicine ought not to prevent us from making ourselves acquainted with the experience of a distinguished young physician on the subject of its efficacy.

I have employed with success, says M. Bertrand, this remedy in palpitations of the heart. Two Sicilian physicians (the brothers Candiloro) had told me that it was a powerful sedative to the movements of that organ; and that they administered in doses of twelve or fifteen grains. I have had occasion to state, several times, the good effects of this remedy, even in cases of palpitation depending on hypertrophy of the heart; but I have been obliged to increase the dose to fifty grains three times a day. The patients have never been fatigued by the action of the medicine, which has none of the disadvantages attached to the employment of digitalis. Several of my colleagues to whom I communicated the results I had obtained, have had occasion to congratulate themselves on the employment of this new means.

I give the cobweb in powder, beginning with ten grains three times a day, in three or four ounces of water, sweetened with sugar or syrup. Every three or four days I add five grains to each dose. The powder may also be incorporated with honey or sugar, and made into pills; of which the size may be varied according to the facility with which the patient can swallow them.—*La Lancette Francaise.*

* No mention is made in this case of any attempt to induce premature labour, or to extirpate the tumour.

Cyanuret of Gold as an Emmenagogue.

Dr. Carron has made with this medicine the experiments which we are going to relate. The idea of employing it was suggested to him by Dr. Furnari, who, in endeavouring to resolve glandular affections by this new metallic combination, perceived that in addition to the marked influence it had over them, it had also another more evident still—that of producing a flow of the menses, even in the case of women who had long passed the critical period of life. The following are the experiments which he made in concert with Dr. Furnari.

1. Madame P., about 42 years of age, had been the subject of amenorrhœa for about twelve months, at which time I had extirpated a breast affected with very decided cancerous disease, and from which operation she recovered very well. We gave her the emmenagogue mixture of Dr. Furnari, to take by tea-spoonfuls morning and evening, a fortnight before the ordinary period, and we were not a little surprised at finding the catamenia appear in great abundance. For two months they returned regularly and copiously: the third month there was a diminution. We recommenced the medicine, and the discharge in consequence flowed anew at the proper period, and in sufficient quantity.

2. A young woman was sent to me by my friend, Dr. Lacorbiere, and was received into the dispensary. She was the subject of very considerable scrofulous swellings, for which various modes of treatment had been tried. Her age was seventeen, and the catamenia had never but very imperfectly appeared. All the common emmenagogues had been employed without avail. After preliminary evacuations of blood, to subdue an inflammation which was present, I gave her the mixture of Dr. Furnari, with the double object of reducing the glandular affection and restoring the uterine evacuation. The latter effect was produced in a fortnight. It returned in abundance for three months, with complete suppression at the fourth. The mixture was given again, and the menses returned.

3 and 4. Two women presented themselves at the dispensary. The youngest, affected with almost complete amaurosis, went out of the hospital, where she had re-

mained four months, and from that time the catamenia were suppressed. The other, affected with marked sanguineous congestion of the eye, had not menstruated for three months. Both were put the same day on the use of the emmenagogue mixture, and both menstruated anew eight days after commencing the use of the medicine.

5. Mademoiselle P., of Bourdeaux, nineteen years of age, of a scrofulous constitution, with very irregular and scanty menstruation, was submitted to the action of the emmenagogue mixture, and after a fortnight's trial the uterine flux appeared copiously. For four months afterwards their course was only once interrupted, and that slightly, and the medicine very quickly restored its regularity.

6. In this case only the medicine failed. It was that of a young lady, at Lyons, affected with chronic iritis, and effusion into the chambers.

In a consultation, at which several physicians were present, I was obliged to mention this medicine and its efficacy, and this has forced me to give this account of the trials instituted by Dr. Furnari and myself before our investigations are finished. The cyanuret of gold ought to be given in solution, in the proportion of three grains to an eighth-ounce mixture. It can only be held in suspension by a spirituous menstruum of eighteen or nineteen degrees. The preparation requires the greatest care: we generally confide it to M. Deschamps.

After what we have just said, it will be readily understood that this medicine is not applicable in cases where the stomach is weakened or irritated.—*La Lancette Française.*

The London Medical

AND

Surgical Journal.

Saturday, November 21st, 1835.

THE SYSTEM OF MEDICAL CHARITY.

As we have some reason to believe that the state of the Royal Hospitals throughout the Kingdom may ere long become the subject of Parliamentary inquiry, we will call the present attention of

our readers to the defects in these and other medical charities—to the insufficiency of the whole system now in operation for the medical relief of the poor.

We have repeatedly made separate allusion to the existing economy of hospitals, of dispensaries, and of parishes; we shall now endeavour to show that the two former are not only individually open to much censure, but stand altogether in a wrong relation to each other; and that the last is essentially bad—that no parochial system ever will or can afford effectual relief to the sick poor—that all such systems of medical charity ought to be entirely done away with, to make room for one more humane in its aspect, and more extensive in its provisions.

1. The magnitude or number of hospitals in the metropolis is altogether incommensurate with its population; so that supposing the conduct of these institutions to be altogether faultless, a large proportion of the poor labouring under acute diseases must go unrelieved, or seek for relief elsewhere; if to this we add the difficulties opposed to the admission of patients, even when there is room for them, by the clumsy and barbarous regulations about letters, proper days, and proper hours, the amount of actual relief extended to those who want it is—better than nothing, and that is all that can be said for it. Again, the out-patients of hospitals are miserably neglected, for the obvious reason that the medical officers have quite enough to do and to think about within doors. Lastly, the system of medical instruction is meagre and inefficient, because the physicians and surgeons have no salary, nor any inducement to the assiduous discharge of their functions! for the same cause the pupils are ruthlessly pillaged by their instructors, who prefer rifling the pockets of poor lads, who are many of them badly enough off already, to making a straightforward manly declaration that they do not mean to work

for nothing, and that if the hospitals want their services they must pay for them.

2. Dispensaries cannot give effectual aid to acute cases which require to be visited at home, because it is not to be expected that the medical attendants will undergo a tremendous degree of labour and annoyance, merely as a pastime—it is not to be expected that men possessed of their senses will trudge night and day through every street and alley of an extensive district, exposing themselves to fatigue, bad weather, contagion, filth, brutality, and every thing else that can injure the body and disgust the mind, all without any kind of remuneration or benefit, except that of being thought very charitable by some, and very foolish by others.

The truths above-mentioned are exceedingly obvious; they can be denied only by those interested in the perpetuation of evil. And what are the inferences from these truths? That *hospitals* should be enlarged, or multiplied, to meet the exigencies of society; that they should confine their ministration to in-door patients, to whom poverty and disease should be a sufficient recommendation at any hour of the night; that they should give ample salaries to able and experienced medical officers, who should be obliged to fulfil their duty effectually and punctually, both to patients and to pupils: that *dispensaries* should take cognizance only of those cases that can attend at the institution; that a sufficient number of well qualified medical men should be engaged to give every case that presents itself a full and deliberate consideration, instead of driving helter-skelter through a hundred cases in an hour—that a just compensation should be offered and an honest discharge of duties required. And how are these desirable ends to be attained? We answer, they will not be attained till the whole system of medical charity is placed on a broad, a solid, and a *national* foundation. They will

never be attained as long as the poor remain dependent for relief on the disinterested, but ill-directed charity of a few benevolent individuals, and the interested pretence at charity of a set of knavish treasurers and secretaries, with the addition of doctors, who are admitted into the number either of the *cheats*, as at hospitals, or of the *cheated*, as at dispensaries.

3. The parochial arrangements for the relief of the poor are at present so execrable, that exculpation from malignant intentions are at present all that can reasonably be expected by those with whom they originated; but supposing such arrangements to be much better than they ever have been, or are ever likely to be, it is evident that they must still be utterly inadequate to their end. A country parish, for instance, where, as often happens, there are many more paupers than rate payers, could never bear the expense of a proper medical establishment for the poor. Many of the peasantry, also, who are able to live comfortably enough when they are in a condition to work for their livelihood, are reduced to the greatest distress when overtaken by illness; they have no claim on the parish, they have not the means of paying for medical advice, and country practitioners are, for the most part, far too poor themselves to give their time and labour for nothing: there ought, therefore, to be some effectual provision made for persons so circumstanced—for those who, as they mainly contribute by their toil to the prosperity of the state, have a right to expect some support from it when they are disabled. An infirmary and dispensary should be instituted in every town, proportioned to its population, and that of the surrounding country; and these, like the metropolitan foundations of the same kind, should be under the auspices of government; the parishes should have nothing to do with them, but they should be open to all poor

persons who are ill, whether they have or have not a claim on the parish. There is need of a new department of legislation to preside over all matters relating to the public health, and particularly the medical relief of the poor. We have little doubt that this, like other wants of society, will one day or other supply itself; we have as little doubt that the one medical faculty which we have always advocated, will be established before the world is many years older: this faculty ought to be much consulted by government on all matters relating to the public health, but ought not to be invested with the entire management of them, because medical men, like all other *classes* of men, have some interest apart from the rest of society which, even unconsciously to themselves, have a tendency to warp their views of public affairs. For what we have just now said we shall doubtless be denounced by many as insane. How can this taxed and burdened nation bear the expense of so vast an establishment as that proposed? Answer, the nation bears the expense already, without deriving the advantage; there is more than money enough *now* spent on medical charity to do all that is needful, but it is squandered away by a system of humbug and delusion, which robs the rich without materially benefiting the poor.

—o—

Hospital Reports.

NORTH LONDON HOSPITAL.

Lepra Syphilitica.—Use of the Hydriodate of Potash. From a Clinical Lecture by Dr. Elliotson.

THIS case, gentlemen, is one of lepra syphilitica, occurring in a female patient, aged 49, who was admitted on the 15th of August. She stated on her admission, that she had been a widow for eleven years, but married for the second time about six weeks ago. About three weeks since, after having drank freely of cold water whilst very warm, an eruption appeared over the face and chest, extending shortly afterwards over the whole body. Now, you will notice, how cautious it is necessary for you to be in receiving the statements of patients; you observe she attributes her disease to the cold water; but

I have no question she had had primary venereal sores, though she denies it, and we have no evidence of it. The eruption, says the report, on her admission, appears in the form of tubercles, hard and dark-coloured, and in some places covered with scales. Now, the common form of lepra is detected by solid elevations, around which, small patches are observed, about a line in diameter, reddish, shining, and circular, and which are prominent; but you will observe that in this case, which was a well marked one of the syphilitic species of this disease, that the red spots were of a dingy colour, and very hard, almost worthy, indeed, of the name of tubercles.

The soreness of the throat still continues, and the right tonsil is ulcerated. Though there is no sign of venereal sores or gonorrhœa, as I before stated; she complains of pains which have affected her legs for some time, and which are worse at night. She had been taking mercury before her admission, for the eruption, and her mouth was tender, and she had a copious flow of saliva. Her bowels were open: appetite good. I ordered her two scruples of our solution of the hydriodate of potash (five grains hydr. potash) three times a day. After taking this medicine for a few days, the eruption was decidedly better, but I did not attribute this to the effects of the hydriodate, but rather to that of the mercury. Anxious to try the effects of the hydriodate, given alone, I omitted its further use till the effects of the mercury were entirely gone. The eruption did not seem quite so well three or four days after this omission, but on the 5th of September, about a fortnight afterwards, the eruption was decidedly improved, and an ulcer which she had on the inner side of the lower hip had healed.

On the 8th I resumed the use of the hydriodate of potash, by giving her half a drachm of the solution three times a day. On the 12th, the report says that the pimples are rather sore, several new ones having appeared, whilst others have disappeared: one of her eyes which had been red and painful, was better. You will frequently find the mucous membrane of the eyes and nose become inflamed and painful when this medicine is given; it also sometimes produces pain in the frontal sinuses. The dose of her medicine was increased to day to two scruples and a half.

On the 17th, her urine was more abundant, and there appeared a number of large vesicles on her legs and thighs, of a dirty hue, interspersed with tubercles; there was no pain in them, except when they were broken by chance, when a watery fluid was discharged, and dark scabs remained; the eruption is disappearing from the face, leaving only red spots: you often find in cutaneous diseases, that the marks of red spots will remain.

On the 13th of October she was still improving. She now takes two drachms of

the solution, having gradually increased it. She was discharged on the 27th, cured.

This case is a very satisfactory one in regard to the use of the medicine employed. I have lately relieved with the hydriodate, a case of nodes of a syphilitic character, which had resisted every species of medicine for fifteen years. The present case no doubt could have been cured by mercury, but I consider the hydriodate of potash preferable to that medicine.

Cases of Erysipelas.

Mary Perks, aged 30, was admitted October the 22nd, under the care of Mr. Liston. She is a servant, and had attended her mistress with great assiduity both day and night, with puerperal fever and erysipelas, of which she died. On the day of her mistress' death she was attacked with idiopathic erysipelas, which appeared on her head, scalp, and face, and extended some distance down the neck. She was admitted in this state, and the eyelids were so distended that vision was impeded. She was violently delirious. The strait waistcoat was obliged to be employed.

23rd. Pulse 120; delirium violent; vesicles formed on each eye, filled with a purulent kind of fluid. The face was freely scarified, and afterwards fomented. There was great tenderness on pressure over the stomach.

Rx. Vin. antim. tart. ʒ iii;

Sol. muriat. morphiae, ʒ ss.

Aq. destillat. ʒ vss. M. coch. mag. ij, 3tis horis. A line was drawn with the nitrate of silver about an inch below the inflammation in the neck.

24th. Less delirium; pulse 110; erysipelas not extended beyond caustic; the tenderness on pressure over the stomach remains; twelve leeches to be applied; the scarifications were repeated, as were also the medicine and fomentations. Bowels open.

25th. Delirium less; pulse 100; face again scarified; collections of pus forming round the eyes.

Rx. Vin antim.,

Sol. muriat. morphia, ā ā gutt. xx.

2nd, q. hora.

26th. Delirium entirely gone; pulse 98, weak; collections of matter forming in various parts of the scalp, and particularly round the eyes. Beef tea; no sleep in the night. Bowels open.

28th. Pulse 90; very weak; several incisions were made in various parts of the scalp, and a quantity of unhealthy pus evacuated. Three ounces of port wine daily, with beef tea.

Nov. 9th. Has been gradually improving since last report; there have been several more incisions made in the scalp, and a quantity of matter evacuated. She is now in a convalescent state.

Georgina Wallis, aged 25, admitted Oct. 28th, under Mr. Liston, who on Friday last removed a small warty tumour from her forehead, just above the nasal bones; the operation was very speedily performed by an elliptical incision; the edges of the wound were brought together by three small needles and the twisted suture. She did not choose to stay in the hospital, but went home, and it appears from the statement of some of her fellow servants, indulged in drinking spirits to some extent. On the Wednesday afternoon her face and head were entirely enveloped in erysepatous inflammation; pulse 105, full.

Rx. Vin. ant. tart. ʒ ss;

Solution muriat. morphia, ʒ i;

Aq. destill. ʒ vss. Coch. mag. ij, 3tis horis. A dose of house medicine.

29th. Erysipelas extending down the neck; pulse 110; bowels confined. Pil. colocynth, c.; Hyd. gr. x. Head and face much distended; extremities cold; slight picking of bed clothes. Port wine to be given; bowels open.

Nov. 2nd. Pulse 130, "small, weak; delirium rather less; subsultus tendinum; picking of bed clothes much increased; extremely cold. Typhoid symptoms supervened; and though every means were resorted to, the patient sunk and died on the 7th.

Mr. Liston remarked that these cases were as severe as any he had seen; and he had had opportunities of seeing a vast number of cases of this disease. This complaint is apt to mar the best effort of surgeons to relieve disease by the knife, as it might come on after trifling operations and destroy the patient. The causes of erysipelas were various; it might be the result of injuries, or it might be idiopathic; it is met with in different degrees of severity; sometimes attacking only the surface of the body, like that inflammation seen after the application of a blister, sometimes the whole substance of the skin becomes affected; sometimes the subcutaneous cellular tissue is implicated; the muscles and even the bones had been known to suffer from this disease. After giving some very excellent remarks on the causes and symptoms of this complaint, which we are sorry we have not space for, Mr. L. proceeded to the treatment. Local blood-letting, in some cases, was of the greatest advantage; but the abstraction of blood was always cautiously to be resorted to: for though the inflammation appears very great, there is not much resistance to debilitating causes in the system; and it is apt to run into typhus: puncturing the affected parts was also good, as it prevented the formation of matter and sloughing of the cellular tissue; in cases where the scalp is affected, incisions may be made in it with great advantage; indeed, if the matter be allowed to remain beneath it, the scalp may be lost, the bone be exposed, and the patient

generally sinks ; immediately matter is detected in any part, it is well to open it, not to wait till it points. If the disease happen in the extremities, incision may be made, but not a foot and a half long, as recommended by some surgeons. One or two moderate-sized incisions, well placed, are as beneficial as a dozen. Fomentations are the best local application, applied after the punctures, as in the above cases. The digestive organs are to be attended to, as there is generally some disorder of them in this disease. The nitrate of silver, as applied in the above cases, Mr. L. considered a good application ; but he considered that washing the affected parts over with caustic solution was injudicious, as the disease was likely to attack the internal parts, and it was more easy to drive the disease outwardly than to get it back again to the surface.

—o—

Some Practical and Medical Contributions to the Science of Mineral Magnetism. By Dr. Charles Schmidt. Read before the Westminster Medical Society, November 14th, 1835.

In treating of mineral magnetism, in reference to its curative powers on the diseased human frame, it seems necessary to premise that it is totally separate from animal magnetism, and that the magnetic influence operates through, and consists wholly of, the physical properties of the magnet exercising an agency on the nervous system.

Mineral magnetism, like many other excellent remedies, has not escaped the injury resulting from falling into the hands of charlatans : thus it lost its value in the opinion both of the medical profession and of the public, and fell into disuse.

Many have, since its first adoption, essayed at different times to revive its application. In regard to myself, I may remark, that the natural bent of my mind was to natural philosophy, and to the rapid progress with which the different kinds of electricity were developed. About six years since, my attention was particularly directed to the magnet by some cures in headach and toothach effected by its means. The person who performed these cures was an illiterate man, who travelled through Germany vending magnets, with which he pretended to perform the most wonderful cures.

Some of the effects I found could not be denied ; I procured, therefore, some of the magnets, in order to try experiments, and soon found that, though capable of producing an effect in some minor evils, I was not able to act on others more serious, though in nature the same. I concluded thence, that if I could produce more powerful magnets more striking effects would result. To gain this power I studied all that had been written regarding the magnet ; collected many va-

luable facts, and, at the same time, met with contradictory, absurd, and unsatisfactory statements ; finding also, that on the point most important in my estimation, *that of constructing powerful magnets*, no information could be gained ; the rules laid down for this purpose by writers proved imperfect. Disappointed, I inquired, and soon found that some of the fundamental laws for regulating the construction and the application of the magnet were utterly erroneous. Not wishing to enter into a philosophical discussion regarding the nature of magnetism, or of the sources of these errors, I may remark, that in the construction of magnets under the regulations referred to, I could not get beyond a certain point. Convinced thus that the principles upon which magnets were constructed must be wrong, I was led to examine the manner in which the communication of the magnetic fluid is effected, and was astonished to find, that *the magnetic poles, instead of producing*, as was hitherto supposed, *the opposite*, produce *similar* poles ; that is, a north pole is produced by a north pole, and a south pole by a south. This led to other experiments. A new truth was established, and, at length, I gained the reward of my labours, in getting possession of a method of *constructing magnets of any power*. Gaining the power thence derived, I was enabled to experiment to any extent ; and from these experiments the hope has arisen that my labours may be, in some degree, instrumental towards the re-establishment of a very efficacious, forgotten, and by too many, I am sorry to add, a despised remedy.

The history of Mineral Magnetism may be traced to remote ages. The power possessed by the magnet would necessarily strike the observer. Egyptians, Chaldeans, Hebrews, Greeks, Romans, Arabs, and Chinese, held it in high estimation, both as a valuable and magical remedy. Some, however, considered it as not only dangerous, but even venomous. Others, who thought it salutary, combined it with many remedies, external and internal. Thus, the most ancient nations wore loadstones in the forms of amulets, inscribed with magic characters. In Paracelsus' writings, are the first rules for the application of magnets, unfortunately associated with such immoderate praise, as to have raised the monkish superstition of his time, to proscribe magnetism, as an invention of hell. It is curious to observe, that, in the writings of Paracelsus and of his followers, Helmont, Reuchlin, Thremitius, Turneysen, Cornelius Agrippa, Fludd, Maxwell, and others, when treating of the loadstone, the first principles of animal magnetism, concealed by magic formulæ, are to be met with ; and, in connexion with this, it is worthy of remark, that animal magnetism, as it now exists, was discovered by Messmer, in consequence

of applying metallic magnets. Magnetic and electric phenomena being at this time little understood, Messmer thought the effects produced could not proceed from the magnet, and ascribed them to the manifestations in the application. Acting upon this idea, he published his famous system, the futility of which was first proved by the Academy of Medicine at Paris.

Messmer called his new practice magnetism, because an imponderable power, or fluid, as in *mineral* magnetism, is supposed to be the chief agent. Nothing could have been more injurious to the cause of mineral magnetism, this being continually confounded with animal magnetism. And, in regard to animal magnetism, it may be observed, that though we cannot deny all its phenomena, we may safely assert, that no cure has been effected by its means; and that the whole subject belongs rather to physiology and psychology, than to the therapeutic art.

To continue the history of magnetism, however, it may be recorded, that before the invention of artificial magnets, Talban, Wecker, and Burelli treated headach and toothach successfully with the magnet.

About the middle of the last century, artificial magnets were invented. Many experiments were made by the physicians; they re-adopted the practice which the common people, as may be seen from many of the herbals and old traditions, had never wholly given up.

The appearance of the report of Clarich, on toothach, at the Society of Sciences, in Gottingen, in 1765, excited some sensation, which was mightily increased by the magnetic cures in Vienna, by Maximilian, Kell, and Messmer, in 1774. The conflicting opinions of the learned, on the subject, induced the Royal Academy of Medicine, at Paris, to appoint a committee of their own body to investigate the cures by *mineral* magnetism. This committee consisted at first of Manduyt and Andry, afterwards of Thoniet and Andry, aided by Le Noble, who constructed the magnets, and gave in their Report in 1782, which appeared in the *Memoires de Medecine et de Physique Medicale*. This was translated into German in 1785; but was not, as far as I know, ever translated into English.

This report, encouraging to magnetic practice, contains the history of magnetism up to that date, including every thing of importance; correct reports of cases; accurate and well founded deductions, and all matters of interest to the therapist. The chemical relations only are imperfectly noticed.

After this, in 1829, the work of Dr. Becker appeared: the most ingenious and complete in regard to the chemical relations of this valuable agent, the magnet. So high was the opinion of Vilesins, of this remedy, that he recommended it in Asiatic cholera; and I myself, applied it with success, in relieving the spasms of patients in the chief

hospital of Vienna, to about two hundred cases of this tremendous disease.

And here, before leaving these historical notices, it is my duty to remark, that, from the works referred to, a basis of facts may be drawn, in which successful experiments, and these most extensive, may be founded.

To produce the grand effects from the use of the magnet, powerful instruments are required, and many of the failures are to be ascribed entirely to the imperfection of the instruments. Fully, aware as I am, of the difficulties in the way of discovering the laws upon which magnetic phenomena are founded, still, I am convinced that these difficulties may be surmounted; at the same time, here acknowledging that the circumstance of the use of the magnet having fallen into the hands of the charlatan, has rendered it a difficult task to any one who undertakes to urge its adoption.

The physician who employs the magnet cannot, however, be accused of empiricism, inasmuch as this certainly deserves a distinguished place among those remedies which most beneficially operate on the diseased nervous system; and physiology will, it is likely, enable us to assign to mineral magnetism its therapeutic place, when the relationship of *telluric* magnetism to life, shall be ascertained. Its analogy, perhaps identity, with electricity and galvanism, affords less light than might be supposed, because the relations of these to organic life, have not as yet been discovered, though it cannot be doubted that their influence is considerable.

The influence, chemically, of metallic magnets, has been established by experiments in reference to *crystallisation*. Of *cosmic* magnetism, though every where influencing life, our slight physical and chemical knowledge of it obliges us to seek from *metallic* magnetism the knowledge of its grand fundamental principle, and the therapeutic art affords the field in which successful experiments must be first made. Till isolation be effected, it seems impossible to make the effects of telluric magnetism visible; and thus adds still further to the necessity of having recourse to metallic magnets; recourse to which we can now the more easily have, because able to construct magnets of any power.

Still, we can hardly expect that the etiology of magnetism will make rapid progress, because the experiments are very expensive, require much time, and great accuracy.

It seems necessary to remark, that, in the application of the different kinds of electricity, comprising magnetism, electricity by friction and galvanism, we are not to imagine that they can be indifferently applied. I warn, and I believe with good reason, against the application of electricity or galvanism during menstruation and pregnancy, and in cases of fever, inflammation, plethora, and great irritation; while, in all these cases,

magnetism may be applied without danger and frequently with success, the violent inflammations, those attended with swelling, being excepted. Yet, even in these latter, the state of general irritation *preceding inflammation*, and, during which, the vascular system is still under the influence of the nervous, may often be removed by magnetism, and the inflammation itself will subside.

The effects of magnetism on the diseased nervous system is either calming or strengthening, according to its quality or quantity.

All effects produced by magnetism on any diseased part must be considered as subject to, and entirely dependent upon the action of the magnetic influence on the nervous system; a circumstance explanatory of the effect produced by magnetism on so many different diseases.

As facts are established that many nervous disorders, cramp, colic, &c., disappear almost instantly on the application of even a small magnet, it seems incomprehensible that medical men do not use it before resorting to other remedies. Richter, in his therapeutic work, expresses his astonishment that a remedy so efficacious, and of such calming influence, was not used more frequently. "Most physicians," he observes, "it would seem are of Van Vysten's opinion, who will have it used only when all other antispasmodics are of no avail. How often does toothach, tormenting the poor patient to distraction, embarrass the practitioner by resisting all remedies? Most toothaches are either of a rheumatic or nervous kind; and, those accompanied by inflammation are mostly secondary, and, generally speaking, created by the common treatment of the teeth. How very few know or use the magnet! Narcotics, preparations of ammonia, severe caustic remedies, burning of the nerve, are nothing in comparison with the magnet, putting aside the destruction of the teeth occasioned by the other means.

In deafness and weakness of the eyes, the sanitary influence of magnetism is established, though not much employed, notwithstanding the practitioner is, in these diseases, often at a loss to proceed.

In recent nervous affections, the magnet has not been much employed. The cases treated with such brilliant results by Andry and Thanet, were severe and obstinate. The magnets used, were after the method of Le Noble, which are very imperfect.

Notwithstanding these results, notwithstanding the condition displayed in the Report by Andry and Thanet, little attention seems to have been paid to the curative power of the magnet: a circumstance which I am inclined to ascribe to the difficulty of constructing magnets of sufficient power, and of keeping them continually of the same force. These advantages, as I have stated before, I have been enabled to realize.

Another great obstacle to the extension of the practice of magnetism originated in the opinion that *the cures effected by the magnet are not lasting*; an opinion partly justified, because the magnet was never applied systematically, and never combined, as it ought to have been, with other means of cure.

Magnetism is not one of these visionary remedies so often cried up as omnipotent. Its effects are on the nervous system, and these effects are to be seen. To cure is what is wanted, not merely to try experiments; cure being the prime object of medical science.

One great benefit connected with the application of the magnet is, that no injury can possibly result from it, as any unpleasant effect can be immediately destroyed by the removal of the instrument, or by some touches applied in a contrary direction. Neither the quickness with which it operates, nor its unalterable power, (not affected by temperature), nor any other circumstance, occasion any degree of periculum in moræ. The apparatus for treatment can be always ready; the application itself requires but little time, and but little practical dexterity. How very different is it with electricity and galvanism!

Even if viewing the effects of the magnet as merely palliative, it still must be acceptable in the symptoms of many diseases; for symptoms are very troublesome; indeed, many have died of "symptoms."

To effect cures three different kinds of magnets are made use of, namely:

1. Horse-shoe magnets.
2. Magnetic staffs.
3. Magnetic plates.

1. *The Horse-shoe Magnets.*—The curative powers of the instruments, being in direct proportions to their power of attraction, it necessarily follows that the horse-shoe magnet is the chief instrument in performing magnetic cures. How far art had succeeded in their construction, so far back as the year 1754, we see by the magnets which Le Noble laid before the Royal Society at Paris. One of them weighing 9lb. lifted 103lb.; the other of 15lb. weight, raised 205lb. It is to be regretted that no cures were attempted by these magnets; for since then no one has succeeded in making such powerful ones. What became of these instruments afterwards is not known. The fivefold magnet is in point of size and power the principal instrument. Its power of attraction varies from 70 to 120lb. power; larger magnets are only necessary in extreme cases, or where it is wished to conduct the magnetic fluid to interior organs. In deafness, for instance, magnets from 200 to 500lb. power must be employed.

2. *Magnetic Staffs*—are only applicable in cases of toothach; and even here they may be dispensed with. A number of staffs bound together form what is termed the magnetic magazine, which, however, is of no use in medicine.

3. *Magnetic Plates* were chiefly used by Le Noble. Most of the cures effected by Andry and Thouret were performed with them. They are fitted to any part of the body; and are very useful where horse-shoe magnets cannot be applied—at the extremities, &c.

There are two kinds of treatment with the magnet. The one requires the application of large and powerful instruments, with which we operate from time to time; the other the continual influence of magnetism. The latter is produced by the patient wearing small magnets for some time on the part affected. The former treatment again is either topical or general. The topical treatment is performed according to the prescribed method—either using one or both poles at a time, and with one or with two instruments. One, or both poles are to be fixed at the same time on the part affected, or it may be treated by them in the same direction, always following the course of the nerves. One or both poles of a second magnet may also be fixed in such a manner that the part affected lies between the two magnets. According to the theory hitherto established, one should suppose that the “friendly poles” as they are called ought to be placed opposite to each other in order to lead a magnetic stream through any part of the body. Experience, however, the result of a series of experiments, convinced me that the magnetic stream exists between the same poles, the “inimical poles” as they are called. By placing the friendly poles opposite each other they mutually destroy themselves; whereas in the other case not a point is to be found which does not shew polarity. Commonly the patient stands with the parts affected towards the north, to bring the complaint into the stream of telluric magnetism. This is, however, not strictly necessary, because the power of the magnet is always superior to tellurism, and can derive no sensible aid from its influence. The eyes and ears require a peculiar treatment. The eyes are acted upon by first fixing the magnet for some minutes on the eye itself, and then passing it several times across the upper and lower edges of the eyelid, commencing in the corner of the eye. Last of all, the magnet may be passed several times, from the forehead downwards, in such a manner that both eyes are touched at the same time. Sometimes the desired effect is not obtained till the poles have been changed several times.

The ears are treated differently. The patient afflicted with deafness is seated between two magnets, so that the poles exactly fit on the small plates of two little instruments, which are introduced into the organ. These instruments consist of an oval disc, one inch long and half an inch broad, of soft iron, in the centre of which is fixed a blunt pin, one inch long and one line thick. These serve to conduct the magnetic fluid deeper into the ear. The operation may last from five to fifteen minutes; commonly until the

sensations caused by it have subsided. The magnet is then passed over both sides of the head downward, ending about the clavicle.

The treatment of the teeth also requires some notice. Usually, I fix the north pole first on the diseased tooth, and if the pain does not cease I then apply the south pole. Sometimes it is advisable to touch the gums with either of the poles, or pass them across the cheek where the pain is most acute. In applying the magnet to the teeth, it is better to warm it, because the peculiar coldness of the steel might otherwise augment the pain during the first few moments.

The general magnetic treatment ought to follow, in most cases, the topical application, particularly when the patient suffers from debility. For this, one or two instruments are requisite, according to circumstances. In this operation it is only necessary to observe that the north pole should always be turned towards the spine, and if two magnets be employed, the like poles must be opposite to each other.

The continual influence of magnetism is produced either by wearing small horse-shoe magnets, or magnetic plates, belts, rings, armlets, necklaces, &c. The mode varies according to the malady, and in any case must be determined upon by the physician. It would lead me too far, were I here to enumerate all the rules which have been prescribed or observed by different practitioners. For those directions I refer to the writings of Andry and Thouret, and Dr. Becker, which contain everything that is at all interesting on this subject.

Effects of Magnetism.

1. On the healthy.—2. On the sick.

The assertion, which till now has generally been received as true, that mineral magnetism has no perceptible effects on the comparatively healthy, is, according to my experience, altogether unfounded. The easiest way of proving this is by magnetizing the eyes of a healthy person. All objects appear in a clearer light, and the person magnetized believes that his eyes are freed from a dimness. Sometimes it causes in this organ a feeling of pressure, fulness, or warmth, and its power of motion is augmented. If we lead a stream of magnetic fluid from two, or, according to circumstances, four powerful magnets, through the body, peculiar sensations are excited, arising, undoubtedly, from the magnet—more or less shivering, particularly towards the spine, cold, warmth, and even heat. These same sensations are not felt by every one, they vary according to the constitution of the individual. Sometimes, however, all these sensations are experienced by one person, and in the order above mentioned, and last of all the individual will perspire more or less. The motions, immediately after being magnetized, are always quicker and more easy, and the sensibility to the changes of temperature is consi-

derably lessened. Some particularly plethoric subjects, complain a short time afterwards of being tired and sleepy: with most, however, this is not the case; on the contrary, they feel, for a longer or shorter period, in a peculiarly pleasant state, without any other consequences. These experiments require the most powerful magnets, even to four at a time.

2. On the sick, magnetism operates, like all remedies acting on the nervous system, according to the quality and quantity of its application; and is either soothing or exciting; this is proved by experience. The effects and phenomena which follow the application of magnetism are, therefore, not to be doubted: though many of the profession, Van Vysten in particular, ascribe all to the imagination of the patient. This supposition, however, is totally disproved by its efficacy when tried on little children and animals; on both of whom I have myself made many experiments. Magnetism, certainly, in common with every other remedy, derives advantage or disadvantage from the imagination of the patient. And physicians would do well not to despise so powerful a physical agent, nor consider it as belonging to the sphere of charlatans only.

In applying powerful magnets in the manner prescribed, the effects of cold and heat arising from the steel, cannot be considered material, because the application is made through the clothing; and such sensations, as they could be but slight, must naturally be very transient. Andry and Thouret, who performed most of their cures by means of the continual influence of magnetism, of necessity paid great attention to the share which the metallic properties of the steel had in producing magnetic influence: the question was decided in favour of the imponderable power.

Regarding the sensations produced on the sick, Dr. Becker says, "Very often the patient has at first no sensation at all: this, however, proceeds more from want of attention to his own feelings, for generally in course of time he experiences one or other of the usual sensations. When the magnet is merely passed over them, they seldom feel any thing; but only when it is fixed for some time in the same place." According to my own experience it appears that the sensations actually commence after some time, because patients who have been magnetized often, and whose attention has not been taken up by the novelty of the experiment, did not feel any thing at first; but after some time they always declared that they experienced some sensation proceeding quite distinctly from the magnetic influence, for, on the magnet being removed, the sensation immediately ceased. If the patient distinguishes quite clearly the sensation produced by magnetic influence from those proceeding from the mere act of applying the magnet; if, moreover, the pain be at

all great, it naturally follows that this only is felt so long as it is more intense than the sensations created by the magnetic influence. When the pain has disappeared, there follows that numbness of the affected part, which Dr. Becker has also observed, and which is very like that caused by cold, or by medicine containing lead.

The sensations experienced are, with some slight modifications, the same in all cases. They are the following:—

1. *Cold*.—Dr. Becker believes this to proceed from the cold of the steel only: according to my experience, it is felt also when the magnets are heated, or on their being applied through the clothing, as is usually the case. It is felt particularly by patients who suffer from disorders of the membranous tissues. In such cases the feeling of cold is very similar to that experienced in fever, and frequently all the symptoms of fever follow in succession.

2. *Warmth*.—This is most frequently felt in the eyes and ears. It is experienced mostly when the activity of the nerves is suppressed, and when the patient complains of general or partial cold.

3. *A Drawing Sensation*.—From the slightest degree, when it is a pleasant feeling, to the severest, when it becomes almost painful, like cupping. It is experienced when inflammation exists, and in toothach.

4. *A Pulsation*.—It might at first be taken for the pulsation of small arteries, but the throbs follow so quickly, that it cannot be mistaken for that. It appears before the pain changes from one place to another; and it follows very often the movement of the magnet.

Here I must remark, that there is no danger whatever of the pain settling on any of the interior or nobler organs, in consequence of its changing its seat.

5. *Actual Pain*.—Piercing or cutting: this however appears very seldom, and only in very susceptible nervous subjects, suffering from an entirely disordered nervous system, accompanied by extreme morbid sensibility.

6. *A Numbness, Deafness, or Insensibility in the Part Magnetized*.—These sensations I have observed also, but very seldom, and only when on account of the violence of the pain, I was obliged to fix the magnet longer than usual in the same place.

All these sensations, the last excepted, have this peculiarity, that they increase gradually, and then become weaker, till at last they disappear entirely; even if the magnet remain fixed in the same place during the whole time, if it be taken away they disappear in a moment. These sensations are not felt in all places, they change their locality. I am led to infer from this, that the sensation is caused only when the magnetic stream passes over the nerves which suffer most.

The continual application of the magnet produces effects which cannot be attributed

to magnetic agency only, because they are more evident when the instrument comes in contact with the skin, than when it is sewn up in some covering of silk, velvet, &c. From this it is quite apparent that the steel operates according to its other qualities, besides its magnetic property. Among these effects, I am disposed to include the changes in the excretions and secretions, arising chiefly in consequence of the continued de-traction of warmth. The effects observed from magnets placed under bedding on which the patient slept, would seem to contradict this remark; but they cannot disprove the experience, that a non-magnetic steel plate, worn on the præcordia, causes indigestion and diarrhoea, as I have myself experienced. Descemet has also observed, that a magnet worn too long near the stomach, causes indigestion, which must be removed by stomachics. The best effects from wearing magnets I have seen when powerful ones were applied at the same time; particularly in asthma, rheumatism, gout, and deafness.

From what has been said, the following conclusions and observations can finally be deduced.

1. The effects of the application of the magnet appears very often instantly.

2. These effects are not merely local. Many patients feel their general health improved, and parts which were before cold, have their natural temperature restored.

3. The nervous diseases in which magnetism has proved its curative powers, are those in which the sensibility or the mobility of the nerves was augmented; or in which the nerves were over-excited. To the first class belong *tic-doloureux*, headach, tooth-ach, pain in the stomach, hysterics; to the second, cramp in the stomach, general cramp; to the third, palpitation of the heart, whooping-cough, hysterical convulsions, epilepsy.

4. In other diseases also, caused by a weakness and want of energy in the nervous system, magnetism has been found very efficacious. For instance, in tumours, dizziness, fainting, numbness, weakness of the stomach, cold, shivering.

5. Some diseases, in which magnetism has been found beneficial, are not purely nervous, but have some material cause: e. g. gout, rheumatism, suppressed menstruation. In these, the magnet removed often, only the nervous affection, but could effect nothing against the original cause of the disorder.

6. If it cannot be positively affirmed that the magnet produces all the effects mentioned, because the experiments have not been sufficiently numerous, it is nevertheless proved, that magnetism has a decided and certain influence on the nervous system.

7. On the whole, we must ascribe to the magnet, as its essential property, a calming, and at the same time, enlivening effect, which stands closely allied to that agency we call

nervous power. And although the effect of magnetism in some cases has been only palliative, there can nevertheless be no doubt, that if applied in the right place, and with sufficient power, it is able to cure radically. My own experience has proved this to be the case in rheumatism, neuralgic affections of all kinds, cramps, diseases of the eye, deafness, &c. Indeed, it is my firm conviction, that in the diseases I enumerate, it deserves the preference before all other remedies.

Dr. Schmidt then proceeded to illustrate his views by experiments; and the discussion was finally adjourned to the next meeting of the Society, on Saturday, November the 21st.

MEDICAL BOTANY.

PLATE IX.—*ÆTHUSA CYNAPIUM*.

(Fools' Parsley).

Fools' parsley, so called from the deleterious properties of the plant, and the resemblance it bears to *parsley* (for which it is sometimes unfortunately used), is an annual plant, common in gardens and cultivated grounds in every part of Britain and Ireland; flowering from June to September. From a root which is slender and spindle-shaped, the stem rises to the height of two feet: it is erect, striated, and generally of a dark purple colour at the base. This plant being so abundant a weed in rich garden soils, is frequently mistaken for common parsley, and therefore deserves to have its character and noxious qualities universally known and exposed. Although it bears a strong resemblance to the garden parsley, it exhibits differences in its botanical characters, by which it may at once be distinguished. The leaves of fools' parsley are finer, more acute, decurrent, and of a darker green; and, instead of the peculiar parsley smell, have, when bruised, a disagreeable odour. When the flower-stem of the fools' parsley appears, the plant is readily distinguished from all other umbellate plants, by what is called its *beard*, three long, pendulous leaves of the involucre under the partial umbels. The flowers, too, of the fools' parsley are white, those of the garden parsley pale yellow. In order to prevent mistakes, it is best to cultivate the *curled* variety of the common parsley only, as it not only possesses the same virtue, but also makes a more elegant garnish. Buckhave states, that "a boy, six years of age, having eaten this plant at four in the afternoon, which he took for parsley, began immediately to utter cries of anguish, and complain of cramps in the stomach: while he was going to his father's house, the whole of his body became excessively swelled, and assumed a livid appearance; his breathing became every moment more difficult and short, and he died towards midnight. His tongue was black; a brownish serosity was found in the stomach, and the

liver was hard and of a yellow colour: the spleen livid; but the body was not at all emphysematous." When eaten in small quantities, it occasions vomiting, which may be stopped by a very large dose of brandy. Most cattle eat it: yet it is said to be very deleterious to geese.

—o—

THE NEW POOR LAW.

To the Editor of the London Medical and Surgical Journal.

SIR—My last letter on the subject of the new poor law, drew from you two queries, which I shall notice as concisely as possible, previously remarking that the first implies a perversion of my argument, therefore demands not a categorical reply. I did not contend that the practitioner of yesterday was fitter for the practice of his profession than his senior of twenty years' standing; but I stated an indisputable fact when I said that such a man had generally little time to spare among the paupers, therefore they were given over to the care of an assistant. Further, I asserted that the poor would be better treated, more diligently attended by a young man in practice for himself. These assertions remain undisputed. Now to your second question, "Do I suppose that young men who have received diplomas are competent to treat disease?" A diploma in itself is no proof of competency in the healing art, whether its possessor be old or young. "The law," you say, "presumes it is; but the profession is of a different opinion." I do not know whom you call the profession, but let us divide it into a senior and a junior class, I am sure there will be found a majority of the latter. Do you think that majority will coincide with you? No, no, it will be of a different opinion.

Now, Mr. Reviewer, since you have ranked yourself among the "exclusives," I do trust you will clearly answer the very few questions I have to ask but; which nevertheless, deeply concern the interest of junior practitioners, for were the public once to embrace your views, "Othello's occupation would indeed be gone."

Suppose, then, a young man after five years' apprenticeship, and two more spent in hospitals and lectures, obtain his diploma, the law presumes him competent to treat disease, but you say, no, not experienced enough to treat the parish poor. Well then, Sir, I ask, What is he to do? What steps are next to be taken? Where, and, how many years of his noviciate are yet to be endured?

Why, in this particular instance, under the new poor law, young practitioners should be deemed culpable or incapable because they undertake office at a lower sum than older men are willing to accept, I cannot conceive. We see the same thing done every day at our own doors: you know, sir,

there are physicians in London who visit twice for a guinea, others only once—the former being generally young men, the latter more advanced in years, ergo, more experienced—more competent to treat disease. Would you advise the public never to consult gentlemen of the first class while their elders are to be had? Would you say, these men are dear at any price? would you counsel all, when a consultation is requisite, to call in only the experienced head of age, overlooking the acknowledged talents of younger physicians, by whom we are surrounded? No, sir; what man knows better than yourself that, as a diploma is no proof of medical skill, neither is age. The possession of a diploma added not one iota of strength to the genius of an Armstrong, nor would fifty bestow his talents upon many who sought to crush him.

I remain, Sir,

Yours, &c.

W. DYER

Liverpool Road, Nov. 12, 1835.

—o—

MEDICAL REFORM ASSOCIATION.

To the Editor of the London Medical and Surgical Journal.

SIR—After a patient perusal of the various Essays forwarded to the Medical Reform Association, the Committee of Examination have decided that there are not any three deserving the prizes, although many deserve considerable praise from the talent and research displayed.

It is my duty, therefore, to inform the Essayists that they can obtain their Essays by sending a note, with the motto, when any more specific communication that it is necessary to make will be made.

I am further directed to communicate the fact that the 100l. will still remain in the hands of the Treasurer, Joseph Hume, Esq., M.P., and that the Association will be happy to receive any Essays on the question originally propounded, which must be delivered in to the Secretary before the end of December, 1836.

Further particulars I shall take the liberty of requesting the insertion of in the pages of your Journal, in the course of a fortnight or three weeks.

And I have the honour to remain,
Sir,

Your obedient Servant,
JOHN EPPS, M.D.

Hon. Secretary to the Medical Reform Association.

89, Great Russell Street,
Nov. 17, 1835.

SELECT LECTURES,

FROM

M. BROUSSAIS'

*Course of General Pathology and Therapeutics ;
translated and revised*

By JAMES MANBY GULLY, M.D.

LECTURE XXIV.

*Treatment of the Inflammatory, Bilious, Mucous,
Cerebral, Miliary and Dysenteric forms of
Gastro-Enteritis. Convalescence from the
Disease.*

I HAVE not yet exhausted what I have to say concerning the treatment of acute gastro-enteritis and its cure by stimulants. This cure, as I told you, is the effect of a crisis produced by the stimulation and sympathetic influence of the stomach, to obtain which, it is essential that phlegmasia should not predominate in that organ: its irritation then extends to the secretory apparatus by which the crisis is effected: or if this does not take place, the heart, whose action is augmented by these stimulants, induces an hemorrhage, or else an external inflammation is developed. Moreover, the stimulation of the stomach is more tolerable when previous evacuations have been practised.

There remains something to be said relative to the different forms of gastro-enteritis.

Inflammatory fever, which you must needs imagine, is a form for the most part common to several visceral inflammations on their onset. It is a kind of inflammatory state, of no great intensity, of the mucous membranes of the viscera, or of the viscera themselves, in which the cellular tissue takes no part, and together with which there is neither catarrh, nor pneumonia, nor pleurisy, nor carditis, nor encephalitis: for if there were anything of the kind, the authors who have allowed the existence of an inflammatory fever would have said so. But because they do not say so, does it follow that there is only a febrile movement without any local affection? I certainly think not. In fact, no inflammatory fever can be quoted in which there is not some redness of the tongue and where thirst does not take the place of hunger, and where, consequently, there is not a super-stimulation of the gastro-intes-

tinal mucous membranes, and especially of the upper portion, a super-stimulation which is nothing more than an incipient inflammation, not sufficiently intense but that it can be arrested by a general bleeding, or the application of leeches to the epigastrium.

Sometimes when we trust to nature for the cure of these supposed fevers, something besides a gastro-enteritis may ensue: the inflammation may become predominant in the head, and in a few days afterwards, in the lungs or in some other organ; but, at present, we are speaking only of the commencement of the disease. You may ask me whether there is not an inflammatory fever, which is nothing but an effervescence and inquietude of the blood, in which all the living molecules are excited by that fluid, without any lesion or affection of the solids? Absurd! you have simply a simultaneous irritation of the mucous membranes and the brain. But it is not, as has been affirmed, a phlegmasia of the vessels? If it be so you will soon detect it; you will have the signs of carditis, arteritis, or phlebitis that will have commenced with the symptoms of inflammatory fever. But why advance this supposition? Wherefore create entities? So long as this is done there will be no understanding each other; for four thousand years medical men have been disputing, and they will dispute to the end of time, unless they have some more fixed idea of diseases. When a man comes to me with red tongue, thirst, loss of appetite, halituous skin, acceleration of the pulse, without the mouth even being bitter, or the epigastrium tender, I pronounce him to be labouring under an attack of gastro-intestinal irritation. You may tell me the want of appetite, the thirst &c., do not proceed from irritation of the gastric apparatus, but from acceleration of the course of the blood. There, I have you on the hip—run, dance, take a vapour bath, accelerate as you will the circulation, and you will see whether it will take away your appetite. This assertion, or, as some call it, argument, is worth nothing.

When a patient that is said to be affected with inflammatory fever is presented to you, you must hasten to discover the seat of irritation; and if you seek properly you will readily find it. After this you must not wait for a favourable crisis, but bleed at once;

for the blood is in a state of commotion, and though it does not produce gastro-enteritis, it may produce encephalitis or some other affection, because there is a simultaneous influence of an inflammatory irritation.

As regards the bilious form, I have already answered the question, whether, when the bile regurgitates, it is necessary to have recourse to emetics. I do not give an emetic twice in the year for this purpose, and yet I treat hundreds of such cases. A simple application of leeches to the epigastrium dissipates these symptoms; and if they continue it is because there is a predominant gastritis, and if they return, it is because the patient has been badly treated; in either case they are to be combatted in the same manner but with greater activity. You ask me, do you then never allow of emetics, though success has followed their employment? Yes, I do, when the disease is not intense, and in particular circumstances; but when it is even moderately intense, the patients, if they do not die, are thereby driven into a more serious state; I, therefore, do not see the necessity for emetics. Besides which, they may cause laceration, or perforation of the stomach, or determine the rupture of an aneurism; accidents of this kind I have seen. Since physiological physicians have raised their voices, these irritating medicines are no longer administered with the same rashness as formerly; they are scarcely ever used except in desperate cases of peripneumonia after bleeding has been urged to the utmost limit, and, above all, when the stomach is in sound condition, agreeably to the maxim, *ancps remedium melius quam nullum*; away then with emetics in the bilious variety of fever. If spontaneous vomiting comes on encourage it with warm water; this eases the patient. You will conclude that it would, therefore, have been well to provoke it: not at all: if nature chooses it, aid her gently, but do her no violence. Were you to excite vomiting in all your patients, in less than every thousand there would be one that would die in the act.

Does the mucous form require any specific medication? There are aphthæ for which local bleedings are necessary as well as lotions, at first emollient and subsequently astringent. There are catarrhs, particularly cystitis, that also require their particular treatment. But ought we to fly to drastics that excite the secretions and the mucous evacuations? I see no necessity for it; better to destroy the irritation that generates these matters; in the end they always evacuate themselves. By giving a purgative you may cause a phlegmasia that was on the point of terminating to retrograde; with purgatives and emetics we can answer for nothing*.

Does the cerebral form require a particular treatment? You should first of all act upon the epigastrium and then upon the head, unless the encephalic congestion be too predominant from the commencement. Most frequently this congestion is owing to the state of the gastric passages: I have at this very time a patient who has twice given me proof of it. He had been attacked with gastro-enteritis, with cerebral congestion, which an application of leeches to the throat dissipated. During his convalescence he was again seized with cerebral congestion from which he was again rescued by a second bleeding with leeches. This is more espe-

which most practical men must differ from him. It is opposed to facts, and is, moreover, no necessary deduction from his doctrine of fever. On all occasions he professes to draw his ideas of internal inflammation from the same phenomenon as developed in external parts. Now, there are many cases of cutaneous phlegmasia in which he extols the use of the nitrate of silver, one of the most potent irritants of the *materia medica*. He has, therefore, no good ground on *theory* for his expressed horror of purgatives, in their character of irritants, in internal phlegmasia; and *practice* is assuredly against him. Besides he puts altogether out of sight the physiological fact, that morbid secretions—the result of irritation—incessantly react upon the tissue that secretes them, and maintain or more possibly increase the abnormal condition that generated them. General and local bleeding with plentiful dilution may certainly reduce the irritation or inflammation of the intestines, and render less noxious their morbid secretions, but so long as the latter remain in any quantity or of any quality, the former is always liable to be renewed. Instead, therefore, of saying that “with purgatives we can answer for nothing,” it should rather be “without purgatives we can answer for nothing.” So, on the one hand, reduce the phlegmasia, by the positive part of the Broussian practice, and on the other, avoiding the *negative* precept of the same—to rid the bowels of their irritating contents, appears on sound theoretical and practical grounds to be the more rational treatment. At the same time it cannot be denied that in Britain, more especially, purgatives are too often given with a recklessness that sets at defiance alike the precepts of national and empirical medicine; and it would be well were the enormous doses of calomel and the resinous drastics made to give place to castor oil, manna, and similar mild laxatives, aided by the copious dilution above recommended.

M. Broussais' objections to the frequent use of emetics will be supported by all those who have seen—and there can be few who have not—their transitory beneficial, but, ultimately, injurious effects. J. M. G.

* This prejudice against purgations is a weak point in M. Broussais' system, and one on

cially applicable to children: in them, if the gastritis be severe, a cerebral congestion soon comes on; put the leeches to the epigastrium and it will disappear; if it persists, place them on the throat, or behind the ears. But remember, that as long as the congestion of the stomach remains, that of the head will not entirely cease; the connexions of the stomach with the head are more rapid and intimate in infancy than at other ages.

As for the nervous phenomena that arises towards the close of the disease, and are owing to the alteration of the mucous membrane, you cannot hope to do away with them, and above all, refrain from stimulating the mucous membrane with purgatives. You have nothing else to do than to produce revulsion by the application of heat to the lower extremities, and making proper use of cold, if the patient be not disposed to catarrh.

Neither the miliary, nor the petechial variety require any thing specific; they are owing to heat, and appear in the summer. Adhere to your resolution of destroying the visceral irritation.

The dysenteric form is frequently very intense. It is sometimes determined by epidemic influences and then constitutes the dysenteric epidemics, descriptions of which are to be found in the works of Tissot and Zimmerman, who have not described the pure dysentery, limited to colics and alvine dejections, but dysentery with fever, delirium, and nervous symptoms, in such a manner that it has been mixed up with malignant fever—a chaos which the physiological doctrine alone can bring into order. When circumstances favour the irruption of colitis—for instance, had nourishment, moist, cold, alternating with heat, as happens at the beginning of spring, and the close of autumn, when cold nights are opposed to warm days, you often see gastro-enteritis commence in the lower region of the digestive canal, or the great intestines. It is no longer a slight diarrhœa, proceeding from above, as in the supposed dothinentery, but a painful tenesmus with incessant desire to stool and impossibility of passing more than sanguinolent mucosities; to which are added, more or less violent colics, pains of the loins, thighs, and legs, anxiety, and restlessness, and sometimes dejections of pure blood.

One thing had struck Zimmermann—the non-evacuation of the matters contained in the colon; the irritation is confined to its lower extremity, and there is no effort to drive downwards the matters retained within the whole circle of the intestine. In this state of things, several events are possible: 1. The inflammation may proceed so rapidly, that the patients, without having any fever, die with horrible colics, convulsions, and gangrene of the colon. Of this I have seen one instance: it was that of the patient who for several days had suffered frightful agony, and had only evacuated the lower portion. Care had not been taken of him, because in the army, where the case occurred, the ne-

cessary means are not always at hand; and he died with the colon gangrened through its greater extent, and filled with fœces; but the disease very rarely exhibits such intensity as this. 2. After some violent fits of tenesmus, succeeded by no stercoral evacuations, the latter at length arrive; a disengagement of the digestive canal takes place, and the patient is relieved. Proceeding on this fact, Zimmermann laid down the maxim that purgatives were the best remedy in dysentery: the disease being confined to the inferior portion, he produced revulsion by exciting the superior portion. It was not because the matters were expelled, but because a pancreatico-bilous and mucous flux from above caused the resolution of the congestion below. He then gave emollients, sedatives, and narcotics, and then again returned to purgatives. This was also Sydenham's practice, who had specialised the facts. Tissot said that the disease was wrongly attributed to fruits, for that they were the best remedy against it; he says he saw a whole regiment of soldiers that were affected with dysentery, cured by eating the grapes of a vineyard where they were halting. These are certainly interesting facts, but they by no means answer any question. Such means may succeed when the phlegmasia is confined to the lower extremity of the colon: but it frequently does not stop there; inflammation holds no compact with malady-makers. An individual who appears only to have a dysentery, is often in a febrile state in spite of the purgative, or before its administration; the irritation, starting from below, finally predominates above, and becomes a gastro-enteritis. Some have attempted to make entities of such cases, and, by amalgamating essential forms with dysentery, to establish bilious dysenteries, adynamic, ataxic dysenteries, &c. You perceive that the fact in itself has been observed, but has not been understood. When a patient comes to you, you know not what is going to happen; but you have a duty to perform—to combat the inflammation in its locality. If therefore an individual comes to you without fever or symptoms of gastritis or enteritis, and with strong tenesmus, instead of running the risk of a purgative or emetic, which would perhaps bring the inflammation upwards, combat the partial colitis with antiphlogistics. You can have no idea of the beneficial results of this practice: by an application of leeches to the margin of the anus, you immediately destroy an inflammation from six inches to a foot in extent; the matters contained in the digestive canal find their own exit, and the patient is cured. Hereby you dispense with the purgatives recommended by Zimmermann and Tissot for the purpose of evacuating the bile, to the acrid quality of which, they attribute the disease. Leeches, therefore, to the anus, and emollient enemata should be your practice. Suppose the phlegmasia not to be confined to the inferior

portion of the intestine, but extended to the superior, constituting a gastro-enteritis; you will then attack the latter, without troubling yourself to seek out a lost entity or to discover a new one.

Proceed we now to the conduct of convalescence from acute gastro-enteritis. When there has been no stupor, adynamy, in short, no cerebral symptoms, you may allow alimentary fluids as soon as the appetite reappears; but when ataxic and adynamic symptoms have existed, and the patient comes out of his stupor and demands food, you may also begin, but more tardily, with nutritive liquids of lighter quality, for the simple reason, that the autopsy shows that the inferior portion is not cured when the superior is, particularly if the disease has commenced with diarrhœa and meteorismus, and if the latter has continued. Indeed, whenever meteorismus—not that from below, proceeding from the colon, but that of the umbilical region—has persisted during the disease, be assured that inflammation has predominated in the intestines; and if a patient so affected, asks you whether he may eat, after ten days or a fortnight of such meteorismus, have a care how you grant his request. When the proper times arrive, give him only a spoonful of milk, with five or six of gum or barley water. The meteorismus gone down, and the belly pliable, you may go on to broth, and after that to light soups.

Now that your patient eats something, he will be tormented with a voracious appetite; notwithstanding which, when you are certain that the intestines have undergone great suffering, when some diarrhœa remains, with a tendency to the reappearance of meteorismus, you must be especially cautious in returning to food properly so called. I do not here speak of sensibility, because it is too various: I have read in some work, that it is met with when the patient has been treated in the mixed manner; but what is certain, is that it does not exist at all, or not beyond the first few days, when he has been antiphlogistically treated. If the patient has had diseased intestines, you should keep him for a week or two on the lightest aliments, on rice, well-boiled meat, &c., and continue this regimen until the frequency of the pulse has entirely ceased, and you are beyond the fear of perforation.

When you have reduced an incipient ataxic or adynamic gastro-enteritis or dysentery, by the application of leeches, and you find the patient on the following day free from fever, upon no account give him food—confine him to water, however weak he may be. You will hear physicians saying, that tone should be given to him because he has lost blood, and is not feverish; but I say, unless the loss of blood has been excessive, leave him in his debility for some time, and then only give him a spoonful of weak broth or milk diluted with water; for, as milk coagulates in the stomach, it

might be better to give the broth mixed with three parts of water. Wait a day or two until you see the patient get up in his bed before you allow him anything else. This method applies to children and old persons as well as to adults, without consideration of sex or climate.

If patients eat too freely during convalescence, they may have fatal indigestions. Death then exhibits some interesting considerations, and a phenomenon of vitality, that has not, perhaps, been sufficiently explained. Convalescents have been known to die after eating hot bread, and coarse food of vegetable nature, without the stomach subsequently presenting any alteration. The death of such, I believe, to have been owing to a nervous irritation, and to be the consequence of the irritation or the pain. But accidents of this kind are more rare than is generally thought, and we need not be too quickly alarmed at an indigestion. More frequently the patients have vomiting or diarrhœa, with some colic, and on the following day the pulse is accelerated—they have digested, but with a certain degree of irritation. In such cases you will have no occasion for purgatives nor leeches; merely leave them on low diet, give them eau-sucrée, emollient clysters, and in the course of a day the appetite will return. In other cases, something else will occur; the stomach will remain full, which you may ascertain by pressing and percussing the abdomen, or by the cructations that take place; you must then stimulate the stomach in order to produce vomiting—this is a case for emetics. If the patient has taken putrescent aliments that exhale ammonia or sulphuretted hydrogen gas, it will be proper to expel them from the stomach by means of acidulated drinks and purgatives.

Convalescents should not be too much fatigued by exercise, which should be graduated according to the progression of the strength.

Chronic Inflammations of the Digestive Canal in General.—As it is my intention to treat fully of this subject, I shall, after having described the ordinary gastro-intestinal phlegmasiæ, exhibit them under the influence of causes that give them a specific character. The question now before us is the chronic inflammation of the digestive canal. I do not pretend to exhibit a line of demarcation, founded on a difference of nature between them and the acute; but as the indications as well as the symptoms of both decidedly differ, each should be treated separately.

Chronic inflammation of the digestive canal may be primary or consecutive on the acute state. When primary it depends on the same causes as acute gastritis or gastro-enteritis, only that these causes are less active, or, falling on a subject less predisposed to the acute state, they act with less intensity. In a slightly intense shade it may last a long time; a phlegmasia of this kind, which does

not disorganize rapidly, and which makes no sensible progress in the space of twenty-four hours, has no tendency to become acute: and this it is that authorizes the physiologist to say that inflammations may be chronic from the onset, that is to say, they may have so little intensity as to continue for a long time without altering the tissues.

These primary chronic phlegmasiæ may develop in any of the three regions of the digestive canal, and be the preliminaries of acute inflammations; or, to express the same in other words, an individual with an inflammation of the digestive canal so slightly intense as not to hinder him from attending to his affairs, and cause no fever in him, may suffer two different fates—the inflammation may either pass into the acute state, or it may remain chronic. If it passes to the acute state a manufacturer of entities would consider it as the prodroma of that state, whereas a physiological physician would regard it as the same disease in different degrees. In order to throw light on this question, give the latter twenty patients attacked with chronic gastritis, enteritis, or gastro-enteritis; of these I suppose him to treat ten in whom he will arrest the phlegmasia, and to leave the ten others without treatment. Five or six of the latter will pass into the acute state. Suppose now, that the ten former who have been cured had not been treated, or had been treated differently, in this case also there would have been more or fewer in whom the disease would have become acute, and the ontologist would have given to the symptoms of this disease the name of prodromata. He has not given it, because it has been cured: still in both cases the thing is the same, as far as it is possible for diseases to be alike. Herein you observe the difficulty and contradiction in which the makers of diseases plunge, constructing, as they do, an entity on a certain number of cases that go on to death. They announce their predictions *apres coup*—they are prophets after the event.

Chronic gastro-intestinal inflammation consecutive on the acute state, is seen under different circumstances: 1, when the acute state has been imperfectly cured; 2, when too early stimulus has been used in convalescence, and the disease has been thus returned to the chronic stage; for it is difficult for an individual to have twice in quick succession the same disease in its acute character—his powers are insufficient. The foundation is always the same, though the form is not; the disease remains in a chronic condition, as well as that consequent on imperfect treatment, so long as there is nothing to change it.

These inflammations may occupy the entire mucous membrane, or its three divisions at once; this, however, is rarely the case: most frequently their presence is confined to one. When general they are al-

most always purely inflammatory, but at a less degree. When partial, they are at the same time inflammatory and subinflammatory, that is to say, that being circumscribed to one point of the canal, and holding to that point with persevering obstinacy, they produce in their vicinity lymphatic hypertrophies, cellular and tubercular enlargements, as also engorgements of the appendical parenchymata of the digestive canal: whereas when the inflammation is extended equally over the mucous membrane, it rarely tends to such degenerations. Understand, however, that when I say that partial and circumscribed gastro-intestinal phlegmasiæ produce indurations, thickenings, or tuberculous alterations, I do not mean to affirm that they necessarily and always do so: such results depend on the individual.

General Chronic Gastro-enteritis.—Proceeding to the descriptive part, we commence with general chronic inflammation of the digestive canal. It is not always vigorously general: but still less is it fixed in one region: it is disseminated through several portions, and ambulates, as was seen in the acute stage: in some cases it is altogether and utterly general. It is more particularly met with in warm countries and during the summer. These are the symptoms: redness of the tongue, which is pointed and contracted, with large reddened follicles at the base; redness of the gums, lips, and eyes; complexion of the skin and countenance inclining to reddish-brown; belly drawn in; no meteorismus; depression of spirits; features lengthened; face dry and shrunk; the patient is motionless, like a mummy, taciturn, stupid, and looks at you like an idiot: he is unable to eat, or vomits almost everything he takes; he even sometimes goes to stool, but has no tenesmus; frequently has a slightly febrile commotion, which, for the most part, comes on in the afternoon; he has vague shiverings mixed with heats, especially if the phlegmasia be not too general; after taking some food or drink he has in the evening a kind of exacerbation, with dry and hot skin, which on the following day disappears; he has variable pains, fixed in no particular region, and constituting rather a sense of uneasiness than actual pain; the abdomen can frequently be pressed without causing any, or pressure even gives relief. At the end of two or three weeks he sinks into a complete marasmus, and actually seems to dry up; he is said to be attacked with hectic fever, and he dies.

After death a general redness of the digestive canal is found, the canal itself contracted, for the most part with nothing in it, and so diminished in calibre that it is scarcely possible to introduce a quill into it.

This shade is rare in this climate, though it is occasionally observed, particularly in those who have abused strong stimulants, such as spirits and wine, in hot weather. It

is not so difficult to cure as you might imagine: the most efficacious treatment is by strict diet and some bleedings.

To this is allied enteritis, without fever or meteorismus, and with retraction of the abdominal parietes: it is the same disease confined to the intestines. Patients have constant pains which do not extend to the anus, and are not followed by tenesmus nor desire to stool: their pulse is slow, beneath the normal condition: I have seen it not exceeding thirty-five beats in a minute: they are debilitated, and in a state of extreme malaise. If the phlegmasia be not arrested it becomes general in the digestive canal, and may pass to the acute state. This shade is cured in the same manner as the preceding. Local bleedings are of more use than general. If you neglect to follow this method of treatment you fall into polypharmacy: some will tell you they have a nervous colic, others a brass colic, others a lead colic, others, again, an iron colic; they will take opium, calomel, emetics, purgatives, &c., yet the disease does not stop; instead of which, if you pursue the rational treatment, you will soon put an end to the disease, and it will only have been like a tempest in a glass of water. Nevertheless, when this affection has lasted for a long time, and has left a blackish tinge on, and a scorbutic state of the skin, it is incurable.

A Sketch of the Medical and Statistical History of Epidemic Diseases in Ireland, from 1798 to 1835, with the Method of Prevention and Cure, as practised in the Fever Hospital, Cork Street, Dublin. By William Stoker, M.D., Hon. Fellow of the King and Queen's College of Physicians in Ireland, &c. &c.

(Continued from page 521.)

Period from 1798 to 1834, inclusive.—Medical statistics.—Their deficiency in Dublin a chief cause of abuses in the direction and management of public institutions, originally devised for the prevention and cure of epidemic and pestilential diseases.—These abuses exemplified by the records of the Fever Hospital and House of Recovery in particular, and also by the statements promulgated by the general Boards of Health, especially in the years 1817, 18, 19, 31, 32, 33, 34, and 35.—Concluded.

STATISTICAL inquiry has become, of late years, interesting and instructive as generally as its application to improvements in the state of society, even in the most civilised countries. I, therefore, very willingly aided the commissioners appointed by government, to extend its benefits to this country, as far as long experience and close observation in the chief charitable institutions of Dublin enabled me; and this section is chiefly compiled from my replies to

their queries. The defects of statistics in the British metropolis, since the commencement of the 19th century, are deprecated by all who have been anxious to learn the causes of its immense population and wealth, and surely the total neglect of even bills of mortality in the Irish metropolis is much more to be deplored by all who feel desirous to know the causes of its comparatively slow advance, either in wealth or in population, during a period in which the number of the inhabitants of Ireland is stated to have nearly trebled, with a view to promote its prosperity. In drawing up the annual reports of the Cork-street fever hospital and house of recovery since it was opened, in 1803, I have often complained of the deficiency in Dublin of bills of mortality, and endeavoured to remedy it as respected that institution; and now, under the hope of obtaining more attention, I do not hesitate to express my opinion, founded on all my experience for nearly forty years as student and physician in the chief of our charitable institutions, that to the want of well kept registries or medical statistics, is mainly to be attributed the sufferance of increasing misery and mortality which have occurred among the sick poor of Dublin for the last seven and thirty years, but more especially within the last twelve. By correcting the mischievous errors and prejudices which unfortunately guided those intrusted with institutions intended for prevention and cure, but more particularly the otherwise valuable one to which this section will be chiefly confined, statistics would have been most salutary. Instead of wasting in vain the funds, munificently supplied by the humane and affluent, and by government, I am sure these institutions would, of themselves, have been sufficient for the attainment of the great objects for which they were first designed.

The failure of the fever hospital and house of recovery, in Cork-street, contrary to the ardent hopes with which, in my youth, I joined it, on its first opening, namely, to avert those calamities which had previously to a very remarkable extent both depopulated and demoralized it, is manifest in the comparative view afforded by the census of 1798, 1804, and 1835. This failure I have repeatedly stated, in vain, to the managing committee, and to the members of the Irish government, to have arisen from causes wholly beyond its control;

“Statists, indeed,
And lovers of their country, as may seem.”

The following comparative view taken also from authentic documents will, I trust, gain more attention.

The population of the original district of the Cork-street fever hospital, the first of the kind opened in Dublin, comprising the five parishes of St. James, St. Katherine's, St. Audeon's, St. Nicholas Without, and part

of St. Nicholas Within, of St. John's, and St. Peter's, especially in those parishes heretofore chiefly occupied by manufacturers, such as St. Katherine's and St. Luke's, not only has not increased, but actually diminished in the last seven and thirty years. This will appear by comparing Dr. Whitelaw's census in 1798 with that by the commissioners appointed by government in the present year, 1835, (e.g.) The total number of inhabitants in St. Katherine's in 1798, was stated in Dr. Whitelaw's tables to be 20,176, but in the same parish, as at present appears by the tables of the commissioners appointed by government, the number of inhabitants in 1835 is but 17,800. In St. Luke's parish the inhabitants amounted in 1798 to 7,241, but in 1835 the inhabitants amounted but to 6,605. As the relative state of these two parishes in 1798 and in 1835, consisted at the former period, chiefly of weavers and other manufacturers, must be particularly interesting at present, the following table is extracted from one of Dr. Whitelaw's, constructed in 1798, and from the census taken by order of government in 1835.

I should further premise that, did the occasion allow, the progress of the depopulation of the liberty, about to be exhibited, might be exemplified, not only by individual cases of actual starvation, but of the total disappearance of entire families under the pressure of famine, and its close attendant, pestilence. Such exemplifications having added to the interest excited by the replies of the physicians, on the same subject, in the rural districts of Ireland, I regret the more, being precluded from attempting to enter on them, on the present occasion. To the annual reports of the fever hospital, on which I have already so often relied, I beg to refer for explanation, on this part of the subject especially, to the medical report for the years 1804, 5, and 6, by the physicians then attached, and to that for 1815, by Dr. Robinson, M.D. (See Appendix, Note H.)

This decrease of inhabitants since 1798, amounting in St. Catherine's to more than 2500, and in St. Luke's to 636, cannot fail to incite public attention; but if the proportion of the upper and middle classes, and their servants, stated by Dr. Whitelaw in 1798, and still more if the absence of prostitution in the liberty at that time, which he also affirmed, be compared with its present state of degradation, especially of the female part of the population, it cannot fail, I hope, to excite not only the commiseration of all the humane, but the active interference of those who have power to interpose, or knowledge to suggest some adequate prevention and remedy for such deplorable declension. (See Appendix, Note H.)

Many of the houses in the liberty have fallen into ruin. All the remaining parts of the city within the Circular-road, were subsequently included in the Cork-street fever hospital district, and by comparing the population of Dublin, in 1753 and 1798, with that in 1835, as given in the following table, the increase in the intervals may be perceived, viz:—

By Dr. Rutton, in 1753, population } 128,570

Total population of Dublin, in 1798, according to Dr. Whitelaw's census, } 182,370

In 1835, according to the report of the Commissioners by Government. } 234,408

By this table it appears that the increase of the population of Dublin, in the interval between 1753 and 1798, a period of 45 years, amounted to about 53,800, and that in the interval between 1798 and 1835, an interval of 37 years, it amounted to 52,038. Now from all that is certainly known of the population of Ireland since 1753, it appears that its increase was beyond all comparison more rapid than is exhibited with respect to the metropolis in the above table. But I wish more particularly to observe here of the dispropo-

portion between the increase of population in the country in general, and in the metropolis since 1822, when, as will appear in the subsequent part of this report, that the epidemic diseases of Dublin assumed peculiarly fatal and pestilential characteristics. In 1821, the population of Ireland, then amounting to 6,811,827 is said to have been nearly double what it was at the commencement of the 19th century. In 1831 it was found to amount to 7,784,539.

There is a table inserted in the Rev. Dr. Whitelaw's Essay on the Population of Dublin, shewing the decrease between 1798 and 1804, which I shall beg to extract as a further illustration of the causes which led to the erection of the fever hospital and house of recovery, and of the necessity there was of duly estimating them in the subsequent direction of that institution:—

The return of 1798, therefore, exceeds that of 1804, by ————	756	4,192
--	-----	-------

Indelible remains of the history of the six years embraced in the above table sufficiently manifest the miseries of civil war to have been the chief concurring causes of the depopulation of Dublin at that time; and without attempting to trace back to any preceding link, it is important to establish even this single one of connection between them, and the unprecedented and calamitous growth of epidemic diseases described in the next table, which took place since the open-

ing of the Cork-street hospital for the reception of patients, and was registered in the annals of that institution from 1803 to 1816 inclusive.

The following table is in many respects the counterpart of that inserted in another part of this sketch; both were constructed from my annual reports of the fever hospital and house of recovery, as to the admissions, deaths, average mortality, and successive changes in the causes and nature of the prevailing pestilence, as duly registered in that institution. Besides illustrations of the nature of pestilence, from 1817 to 1828, with a view to pathological and therapeutical information, this table, embracing the twelve years from 1803, when the Cork-street hospital was opened, to 1816, is intended for preparatory explanation of the succeeding observations on the management and abuses of that institution, which I made, in reply to the category sent me by the commissioners of the poor law inquiry. The comparative success of the Cork-street hospital in checking the growth of fever, which is exhibited in this table, whilst fevers were demonstratively contagious, will, I hope, assist at once to explain the signal failure afterwards of multiplied institutions of the same kind, to have mainly arisen from misdirection, and likewise to indicate those adaptations of the means both of prevention and cure, which other causes, and consequent changes in the nature of prevailing diseases, have made necessary. Moreover the infraction in the bye-laws, originally framed by the managing committee, not only to insure the right conduct of themselves and successors, when they undertook so responsible a trust, but the protection of all who co-operated with them, will be thus rendered more apparent; and likewise, how that infraction has been alike injurious to the public, and unjust to individuals, who, anxious to discharge the duties of their stations, looked to the bye-laws as their safe guides.*

This synoptical statement of the occasional increase and decline of contagious fever, and of the obvious causes of its desultory progress, under the preventive and curative means employed in the Cork-street fever hospital during the first twelve years of that institution, affords, I hope, some preparation, perhaps even apology, for the observations I have now to make on the management of that institution. They are made with a view to the more successful adaptation of the means of prevention and cure; an adaptation which I believe to have become necessary owing to the extraordinary increase and malignity of epidemic and pestilential diseases since 1816. To account also in some degree for the order of the subsequent remarks, I have to state, as already intimated, that it is the same as that of my replies to the commissioners of poor laws' inquiry, and of which they will chiefly consist.

There are many other fever institutions within its district (i. e.) in Dublin, beside the

* Efficacy of fever hospital manifest, and therefore extended over the entire city.

† Diminution of continued fever, but remarkable increase of ague.

‡ Ardent spirits cheap and of bad quality; fever more contagious and malignant.

§ Improved modes of prevention and cure, the cause of diminution of numbers affected, and of mortality.

|| The type of 1810 re-appears with the same causes; extension of fever hospital thus demanded.

¶ Fever of 1810 still continued to increase, but the mode of cure then founded on the distinctive characters of the blood, rendered the mortality less.

** Discriminate treatment of distinct forms of continued fever, preventive and curative, described. See Treatise on fever, London, 1814.

†† The same causes of increase of fever and less mortality continued.

‡‡ Though the harbinger of famine and pestilence this year, was remarkably healthy over Europe generally.

§§ Thus far the results of the operation of the Cork-street fever hospital are favourable even compared with similar institutions in Great Britain during the same period.

Cork-street hospital, which have been established since 1803, when that, the primitive one, was founded. They were erected to check the rise and growth of epidemic and pestilential diseases; but were constructed and multiplied in compliance with the opinion, (I think a fallacy) that the increase of disease depends mainly or wholly upon contagion. On this principle they appear to me to have been unnecessarily enlarged to provide for the emergencies of the occasionally alarming influxes on the more ordinary course of disease. In ordinary times, it is however, certain, that legitimate cases could not be found to occupy a sixth of the beds, and they must have remained vacant had not these hospitals been made asylums for the houseless and famishing poor, and for those labouring under disease often the consequence of misery alone, such as low fevers, dropsy, melancholy, and even mania. In the last three years, I know that many beds in the Cork-street hospital, not occupied in the manner just adverted to, have been kept empty, wholly in compliance with the opinion of the ultra-contagionists.

An experience of nearly forty years, as student and physician, in dispensary and fever hospital practice, enables me, without hesitation, to give it as my opinion, that the formation of medical districts, to each of which a fever hospital, dispensary, cowpock institution, with surgical beds to the number of six in each, would be a very great improvement; and I have no doubt, that under such an arrangement, one fever hospital on each side of the Liffey, with a dispensary and soup shop in each parish, would be found sufficient for the sick poor of Dublin during the fiercest outbreaks of epidemic diseases; and that after these extraordinary swells subside, the bedsteads in such hospital, whether surgical or medical, might be most advantageously occupied by those labouring under parturition, accidents, or chronic disease; or, if disengaged, accommodation should still remain, by the houseless and unemployed tradesman, predisposed by want to mental and bodily disease. As physician to the chief dispensaries of Dublin at the close of the last, and beginning of this century; to the Cork-street hospital from its foundation until July last, and as one of the officers of health in St. Peter's parish during the prevalence of the epidemic of 1817, 18, and 19, I have collected facts on this subject, from which alone these statements have been made.

In times of great emergency, as in 1818, 19, and 26, nearly 280 patients have been accommodated in the Cork-street fever hospital by the aid of tents, pitched on the enclosed grounds, but the wards themselves can accommodate from 240 to 280 patients. The apartments of the registrar, two apothecaries, two housekeepers, and head-nurse,

together with those of the nurses, take up perhaps a tenth of the whole. Great pains have been taken for the ventilation of the wards; there are both fixed and moveable baths. The out-buildings consist of a laundry, with a steam-engine and washing machine; of lodges for the porters, one at each gate; stables, and coach-houses. The latter are occupied by the servants engaged in the laundry, the porters, &c. The grounds are partly meadowing, and partly tilled for the use of the resident officers. All the above houses belong to the institution.

(To be continued.)

—o—

MANUAL OF OPERATIVE MEDICINE.

BY M. MALGAIGNE.

FREELY TRANSLATED AND CONDENSED

By GREVILLE JONES, Esq.,

Lecturer on Anatomy and Physiology.

CHAP. III.—Of Operations which are performed on the Teeth, or Dentists' Art.

WE shall treat, in succession, of operations the objects of which are to clean, file, cauterize, stop, extract, and luxate the teeth, or, lastly, to alter their situation. With respect to the proceedings had recourse to in fabricating and fixing artificial teeth, they belong to a particular business, and will not be treated of by us.

1. *Of Cleaning Teeth.*—The instruments employed consist of small rasps, variously shaped, square punches, &c. We may confine ourselves to the following:—1, A rasp, shaped like a carp's tongue, and which cuts on both sides; 2, a rasp in the form of a chisel; 3, a rasp hollowed out, or spoon-shaped; 4, a square punch cut aslant to a single point; 5, a square slanting rasp, bent at right angles; and, in addition, a small mirror, five inches long and one broad.

In the operation the patient is seated, the head resting against the back of the arm chair; a cloth is placed over the shoulders, for the purpose of wiping the instruments, and warm water is got ready to rinse the mouth with. The operator places himself before the patient, making use of the fingers of the left hand to separate the lips or keep the head fixed, or turn it gently, but never suffering his hand to rest on the person. The lower jaw is first operated upon. The tongue-shaped rasp is held in the right hand like a penknife, the upper lip raised, and each tooth, as it comes to be cleaned, supported by the right index finger; the tartar is to be removed from the front and right sides of the incisor teeth. For the lateral surfaces the rasp is held as a writing pen, and the *point d'appui* is made on the neighbouring teeth with the ring and little fingers. The chisel-shaped rasp is employed to clean the outer sides of the molar teeth, being

worked backwards or forwards, or upwards or downwards. Their interior is cleaned with the bent rasp; for the right side the *point d'appui* is made on the thumb of the left hand; for the left side and fore teeth the *appui* is made by resting the palm of the hand on the chin, previously covered with a corner of the cloth.

In operating on the incisors of the lower jaw, the dentist places himself behind the patient, and makes use of the tongue-shaped rasp in the manner before described. After having removed all he can he returns to the front, separates the lower lip with the left thumb covered with a cloth, supports the teeth, if they are not firm, with the left index-finger, and uses the rasp from below upwards.

The molars are cleaned like those of the upper jaw; the instruments are the same, also, for the inner surface of all the teeth.

The punch has two uses. It serves to remove all the tartar which exists in the intervals of the teeth; and when the layer of tartar is very thick, by driving the point of the instrument down to the tooth, and making a rotatory movement, we are enabled to break it off in scales. For this purpose the chisel-shaped rasp is also very useful. The spoon-shaped rasp serves to detach the tartar from the neck of the tooth by following the turns of the gum, without intruding upon them.

The general rules of action should be as follows:—1. Teeth that are loose should be carefully supported, and the tartar cut from each tooth in separate fragments, without succussion. 2. The instruments ought always to operate from the neck of the tooth towards its border, in order to avoid wounding the gum. 3. It must not be expected that we can render the canine teeth as white as the incisors, the former being always somewhat yellower. 4. We cannot expect to render every one's teeth equally white and brilliant. We must be contented to remove all sordes and tartar, without trenching on the layers of the enamel. 5. When we find the dental tissue softened or deprived of enamel, it is requisite to proceed with caution; indeed, it is often prudent to leave a little tartar. 6. The gums must never be divided or separated from the teeth.

The chief part of the operation being finished, the end of a pen is to be introduced between the teeth; they are to be rubbed with a little ball of cotton, or a root wetted and charged with some dentifrice powder; and we should examine, with the mirror, if anything has been left behind.

When the sordes are difficult of removal with the rasp, whether on account of their being near the necks, or because they occupy the fissures of the teeth, a pointed wooden stick, steeped in a solution of muriatic acid in five parts of water, may be used. The sordes, when rubbed with this,

are soon decomposed, and immediately all the parts should be copiously rinsed with warm water, to prevent the acid from acting any further.

2. *Of Filing Teeth.*—For this purpose the fine files used by clock-makers are employed: some of them cutting on one side, some on both. Fine saws are also of use in some cases. The files should be well-formed, and, with unbroken teeth, in order to avoid succussion, it is requisite to have small portions of file, which may be placed in a port-file, in order to operate on teeth deep in the mouth; otherwise the file which is fixed in a handle is firmer, and less liable to break. During the operation the patient is seated, the operator standing. Warm water is requisite to steep the files in, for cold water produces a disagreeable sensation. The operator is placed sometimes before, sometimes behind, according to convenience. He should take care to separate the lips with the fingers of the left hand, which will form a point of support to the right hand, and enable the file to act more solidly, and without violent motions; if it become fixed we should stop immediately, and endeavour to disengage it: the slightest force runs the risk of breaking the tooth or the instrument. The following rules are to be attended to, according as we use the file to destroy caries, asperities, or to shorten a tooth which is too long. 1. If the caries is shallow, we may remove it completely; if deep, it is enough to insulate the decayed tooth from the neighbouring ones. 2. When the teeth are filed on the sides a portion must be left untouched near the neck, in order to prevent the approximation of the neighbouring teeth. 3. If the operation be performed on the incisors, the file must be held obliquely, in order to save as much as as possible of their front surface. 4. If the teeth to be separated are both carious, a file must be employed which cuts on both sides; if one be sound, a simple one which cuts on one side will answer. 5. If it be required to remove asperities, or to shorten a tooth which is too long, a small saw will act with more rapidity than a file. In these cases, if it be impossible to direct the file or saw transversely, it may be directed obliquely in different directions, and thus that may be removed by several cuts which it would have been impossible to separate at once. 6. When the piece to be removed is very large, it is better to divide it by forming angles and projections than by filing uniformly: the operation is quicker. 7. When a tooth is very long it is prudent to file no more than half a line at once, and not to repeat the operation until some months have elapsed. By this precaution the tooth becomes gradually accustomed to external impressions, and is less subject to caries. 8. Sometimes a prolonged operation causes general irritation, vertigo, or nervous excitement—the operation must be

postponed for a few days. 9. Before filing very hollow teeth, especially the molars, when nothing but enamel is left, it is requisite to cut them off with strong scissors or good pincers.

3. *Of Breaking down the Nervous Pulp of the Teeth.*—We make use of a curved steel style, well pointed, with which the walls of the cavity are to be cleansed and scraped. Then we endeavour to introduce it into the canals of the roots of the teeth, and turn it about in different directions, in order to break up the nerve completely. If the style prove too large for the purpose, a fine needle, or even a hog's bristle may be introduced, and turned about until the nerve no longer suffers pain. This breaking up is very painful, and rarely succeeds: cauterization is preferable.

4. *Cauterizing the Nerves of the Teeth.*—A metallic stylet with a very sharp point is heated to redness in a candle, and introduced into the canal; or a piece of fine needle, heated in the same way, may be fixed in a portcrayon and used in the same manner. In order to succeed with this operation, the patient must be firm, and the introduction of the cautery rapid. Laforque, an Italian dentist, proposes to direct upon the dental pulp a current of inflamed hydrogen. He encloses the hydrogen in a bladder, and fixes to the neck of the bladder a pipe of Anel's syringe. Some push little balls of cotton impregnated with caustic into the hollows of the teeth; others the solid caustics covered with cotton; others drop from a writing pen a drop of concentrated acid into the tooth; but in none of these cases are we secure as to the quantity we employ. M. Turck, of Naney, makes use of a glass tube with very thin walls, about 8 lines in diameter, swelled into a globe at one extremity, and terminating at the other in a tube of capillary fineness, which is properly curved. By taking the globe in the palm of the hand the air is rarified by the warmth and partly expelled. If the capillary extremity be plunged into any liquid, by suffering the instrument to cool, part of that is absorbed. Nothing is easier than to graduate the quantity. The instrument charged in this manner is carried to the point we wish to cauterize, and by warming the globe a second time with the hand the liquid is expelled.

Cauterization of every kind is painful and dangerous, in consequence of its causing inflammation. It ought not, therefore, to be practised on those who have teeth very sensible to shocks or to heat and cold. The proceeding of M. Turck is the best for applying caustics, but it is applicable only to the under jaw; for the upper jaw the actual cautery is preferable.

5. *Of Stopping Teeth.*—Teeth are plugged in two ways—1, by metallic leaves; 2, by means of a fusible metal poured into them in grains. For the first method the requi-

site instruments are a curved stylet to clean the cavity of the tooth, one curved *fouloir*, with a sharp point, another blunt-pointed, a burnisher, carded cotton, and leaves of lead, silver, or gold. These leaves should be somewhat thicker than common gilding-leaf, and it should be refined, or otherwise Laforque says it falls into dust when melted.

We commence to clean the tooth by scraping its cavity, and removing all moisture from this by balls of cotton. If the cavity appears too smooth, a few inequalities may be formed, in order that the metal may be better retained. Desiring the patient to keep the mouth open lest any silver should again get into the hollow of the tooth, we form with the metallic leaf a ball three or four times as large as the cavity we have to fill. With the pointed *fouloir* the metal is to be pushed and pricked repeatedly in all directions, so as to force it into the deepest and narrowest anfractuositities of the cavity. The second *fouloir* is used to make more forcible pressure. When the hollow is perfectly filled, if any superfluous quantity of metal stands out of it, this may be cut with the rasp, or polished with the burnisher. The latter should be heated when we employ sheet lead. It is better to make the ball of metal too large than too small, as any leaf we may add never unites well with that first introduced. Teeth ought to be plugged when painful, and if the operation produces pain, the metal should be removed until that has subsided.

M. Delabarre modifies this operation by placing in the cavity over the nerve a small concave gold plate, and plugs over this. The method is designed to obviate pressure on the nerve, and pain, but is only practicable when the teeth are very much hollowed.

In stopping teeth by means of fusible metals, we may use nearly the same instruments, only as it is necessary to heat them to a sufficient degree, they ought to have at a distance from their extremity an enlargement capable of preserving the requisite caloric. The tooth cleansed and dried, a grain of metal is to be placed in its cavity with a pair of dissecting forceps. Upon the metal is applied the end of a cauterizer heated in the candle; the metal melts and fills the cavity. Superfluous metal may be removed with the same instrument, the heated burnisher, or, as in the other method, by the rasp. The plan succeeds very well in the lower jaw, but can seldom be applied to the upper. We may combine Delabarre's method with it.

6. *Of Extracting Teeth.*—Amongst the multitude of instruments invented for this operation, some are absolutely bad, and ought to be rejected, as *le pied de biche* (deer's hoof) and the *pelican*; others superfluous, or nearly useless, as the greater part of the modifications of the key or the forceps. We

shall describe only five, which may be substituted with advantage for all others.

1. *The Gum Lancet.*—An instrument ending in a small lamina, concave and cutting bluntly, and used to detach from the teeth the gums, when too firmly adherent.

2. *Garengot's Key modified.*—It is composed of a transverse handle, solidly fixed to the shaft; of a shaft twice bent on itself, in order that it may pass clear of the fore teeth, when applied to those deep in the mouth; of a "panneton" (a key-bit, iron pad, or quadrilateral plate) placed on the side and near the extremity of the shaft; and of claws, fixed by a moveable screw to the flattened head of the shaft. The claws ought to present such a curve that their extremity only can touch the tooth to be extracted; for when the middle of the claw rests on the crown of the tooth, we run the risk of breaking it. Hence the curved form given by Delabarre to his crotchets, appears preferable. It is convenient to have two or three of various sizes, one of middle size, terminating in a cutting point, and one shaped like a Z, for the last molares.

3. *The Tirtoir*—formed upon the principle of the key, with these differences, that the handle is continuous with the shaft, that the pad and claw are placed exactly at the end of the shaft.

4. *The Forceps.*—This is an instrument straight or curved, and various as to thickness. One only, with moderate sized claws, appears to us sufficient, because this instrument should only be used to take out teeth already loose. It is best to select a curved one, and one with its claws separated laterally, rather than from above downwards.

5. *The Lever* is composed of a shaft slightly bent, terminated by a sort of quadrangular pyramid, with two expanded surfaces. Instead of a termination in a point, we prefer leaving a nearly cutting edge, so that the instrument should nearly resemble a turn-screw. The handle may be transverse or continuous with the edge.

Operative Proceedings.—The patient is to be seated in a good light, in a chair against the back of which the head is to be supported, or otherwise an assistant, a wall, or a piece of furniture, will answer the same purpose. The dentist places himself in front or on one side, for the teeth of the lower jaw: for the teeth of the upper jaw, it is better he should be behind, when the patient should be seated on a low stool, or on the ground, with the head resting against the operator. But the operation may be performed in bed.

We should commence by examining if the diseased tooth be firm or loose. If loose, and the gum appears very adherent, it will be necessary to lance it first. In ordinary cases, and when these adhesions do not seem strong, the lancing, which prolongs the operation, and after all does not always prevent the laceration of the gum, may be omitted.

1. In *operating with the key*, after having armed it with a proper claw, and marked the points upon which it should act, the instrument is introduced with the right hand, the forefinger on the shaft, the middle finger holding the claw raised, or vice versa: then, by the aid of the left forefinger, the end of the claw is to be placed on the diseased tooth, below the crown, as near as possible to the alveolar process, care being taken that the middle of the claw does not touch the tooth. The point *d'appui* is made with the pad upon the gum of the other side. The claw must fall perpendicularly upon the tooth. The least obliquity endangers the breaking the crown of the tooth. The instrument being fixed, the handle is grasped with the right hand, the shaft passing between the middle and index fingers; with the left hand the side of the jaw upon which the operation is performed is to be firmly supported, and now a twisting motion is to be made, tending to turn the tooth over to the side of the pad. This movement ought to be gradual, until the tooth is forced to yield, when an upward movement should be communicated, which will throw it out of the socket, or even the mouth; though for this a considerable degree of practice is requisite.

In the operation these occurrences happen:—the adhesions between the tooth and the periosteum of the alveoli are destroyed, the dental nervous cord is torn, a small portion of the alveolar process, on the side to which the tooth was drawn, is broken: expertness consists in breaking as little of this as possible. Hence the use of the movement upwards. Sometimes, to avoid breaking the alveoli, it is attempted to make a partial dislocation of the tooth, leaving it to be afterwards extracted with the forceps.

2. *With the Tiroir*.—The instrument is to be seized firmly in the hand, the thumb and index as near as possible to its acting extremity, fixing at once the shaft, the pad, and the claw. The pad and the claw are applied like those of the key. The turning the tooth outwards is commenced by a gentle movement, and when that is found to yield, the pad is raised slightly on the gum; then the turning movement is recommended, so as to extract the tooth by these alternate motions. It is the best instrument, and the best method: unfortunately it can be employed only on the anterior teeth.

3. *With the Forceps*.—The tooth forcibly seized between the branches until the teeth descend to the alveoli, a slight rotatory motion is to be made, and then traction upwards. Many surgeons employ the forceps to all the fore teeth, but they run the risk of breaking them.

4. *With the Lever*.—The extremity of this instrument is to be glided between two teeth, either between a sound tooth, and one partially carious, or between a sound tooth and a stump, in such a way that the sound

one may serve as a point *d'appui*; or between a stump and its alveolus, taking then the *appui* from the index finger of the right hand or the left thumb. The instrument being fixed, it may be brought to act in two ways;—if it is between two teeth, a twisting motion may be made, which tends to remove them and overturn the diseased tooth; if a stump, it is to be acted upon as by a lever of the first kind. It is essential to fix the finger on the tooth of which the fulcrum of the lever is made, to take care that the instrument does not escape, and to repeat the attempt many times if it should not succeed at first.

Whatever be the instrument employed, when once the tooth is loosened from its attachments, its extraction is to be completed with the forceps; or if the gum adheres, the gum-lancet must be used. Then the gums are to be pressed together with the thumb and forefinger, and the mouth rinsed with vinegar and water, to stop the flow of blood.

The crown of the tooth must be somewhat solid when we use the three first instruments. When it has a large cavity, some advise that it should be previously plugged. It is much better, however, to have recourse to the lever. When a tooth has been broken to its roots, they are difficult of immediate extraction: it is better to wait some months, when their adhesions will be found weaker.

With regard to the mode of proceeding with respect to particular teeth.—1. The incisors, canine, and smaller molars: the forceps when they are loose, the tiroir when they are firm, are to be used, care being specially taken that the claws of either instrument are not so large as to intrude on the neighbouring teeth.

2. *The larger molars*.—In the upper jaw the direction of their roots, and the difficulty of otherwise finding a point of resistance, renders it a rule to draw them outwards. The operator places himself behind the patient, or on one side, in such a manner as to be always able to use the right hand. The point of resistance should never be taken on the inside, unless the opposite method should be impracticable: sometimes the pterygoid process is so near the second molar tooth, that it is very difficult, especially in full people, to make the point of resistance on the outside with the ordinary claws. Then a claw in the form of Z is to be made use of, and the pad rested against the first molar tooth; or it may be drawn inwards. For the lower jaw, the surgeon places himself in front. It is usual to extract the teeth outwards, but often opposite to the second tooth the oblique line of the bone is very protuberant, and gives so much thickness to the outer border of the alveolus that the pad is apt to slip, and the tooth to be broken. It is better in this case to extract inwards, taking the precaution to observe that the teeth are not so closely connected but that the outer surface (always larger than the

internal) may be brought inwards without loosening the neighbouring teeth. The first molar tooth may be extracted in the same way.

3. *The Wise Teeth.*—In the upper jaw the coronoid process is generally an inseparable obstacle to the use of the key on the outside; nor can a convenient point *d'appui* be found within. The Z shaped claw is therefore to be used, which allows the resistance to be made opposite the second molar tooth; or the lever may be passed between the two teeth, and the hinder one turned out in a direction backwards and a little inwards. The wise teeth of the lower jaw may be drawn inwards easily.

4. *Extraction of the Roots of the Teeth.*—The roots of the twenty anterior teeth should be extracted with the *tirtoir*; the others with the key and sharp claw, whenever enough of the neck remains to afford a little purchase. If they are loose, they will yield to the forceps: those which are not too strong nor too deeply imbedded in the alveoli, may be extracted with the lever.

5. *Of Teeth placed external or internal to the Alveolar Border.*—Those which are external, may be removed in the ordinary way. Those in the interior of the mouth, must be first loosened with the lever, and then extracted with the forceps.

6. *Extraction of the Milk Teeth* is generally more injurious than useful, and may usually be left to nature. If, however, it be resolved upon, it may be effected with the forceps, due regard being paid to the softness of the alveoli, and care must be taken to extract the whole of the root of the tooth.

Of Accidents.—Fracture of the teeth, of the alveoli, and bruising of the gums, are accidents which we cannot always help, and which admit of no remedies, when they occur. When the gum is torn up with a portion of the alveolar process, the tooth must be seized with the forceps, and extracted as quickly as possible. There is no danger. If a sound tooth be loosened, it will generally become firm again; should it be extracted, it is best to restore it instantly to its place. When *hæmorrhage* occurs, it may usually be stopped by an acidulous gargle, or the socket may be filled with wax, a little pad of charpie, or agaric, according to the obstinacy of the case.

7. *Of Luxating Teeth.*—The proceeding is the same as for extraction, only that the tooth is merely half drawn, and not removed entirely from the socket. It is replaced by pressure on the crown, and tied to the neighbouring teeth; or it may be covered with a little pad, which the patient may compress by keeping his jaws closed, and abstaining from mastication for three or four days. This operation is only practised on the twenty

front teeth, and in order to its success, the patient must be young, the gums sound, and the tooth but little decayed. As it is done for the purpose of entirely removing pain, it is requisite that the luxation should be sufficient to break the nervous thread completely which goes to the tooth.

8. *Transplantation of the Teeth.*—This consists in substituting for a tooth just extracted a tooth drawn from another person. Independently of the barbarity of the operation, the difference in the forms of the roots might be prejudicial to success.

9. *Of approximating Teeth.*—When the removal of a tooth leaves an ugly hiatus, particularly in the front of the mouth, the separated teeth should be drawn together with a moderately thick piece of silk, well waxed. It should be passed round their necks, and tied firmly. This should be repeated every third day, until the void is divided between these teeth and the neighbouring ones, which will occupy about a month. They should be held in this situation by a common thread, until the alveoli have become consolidated, which will be in about another month. The approximation of the teeth cannot be attempted with probable success except between the ages of ten and thirty-six. After the latter period, we merely loosen the teeth. Laforque calls this a sublime operation.

10. *Of restoring Teeth to their proper Situation.*—This operation has no probability of success after the age of thirty years.

It is hardly worth while to endeavour to replace a tooth in the row when there is no room for it; it is better to remove it as a useless deformity. Sometimes, however, there are cases in which a tooth which is in the row may be removed to make way for one that is not. Thus, we sacrifice the small molar to preserve the canine. And if there is not exactly room for it, but there is some interval between the tooth, we should apply the ligature in order to make a place. The operation is effected by means of a plate of gold or ivory, formed according to the situation, and pierced with holes for the passage of ligatures. If the tooth projects towards the inside, the plate is to be applied on the outside of the dental arch, and the neck of the misplaced tooth is to be surrounded by a strong silk cord, the two ends of which traverse the holes of the plate, and serve to draw the tooth towards it. Sometimes it is requisite to fix the plate to the neighbouring teeth by ligatures. When the tooth is misplaced exteriorly, the plate is put on the inside of the mouth.—It has been advised, to replace some teeth placed obliquely, to turn them round with the forceps, and retain them by means of the plate and ligatures. Laforque rejects this operation.

Observations on the Classifications, Etiology, Pathology, and Treatment of Diseases of the Skin, according to the most celebrated Authors of Ancient and Modern Times.

(Continued from page 528.)

On reviewing the whole of the classifications already described, it appears to me that M. Rayer's is the best, as it is founded on the pathological conditions of the tissues which enter into the composition of the tegumentary system. He should, however, in my opinion, have followed the example of his celebrated countryman, Baron Alibert, and prefixed a general, if not a minute account of the anatomy, physiology, and pathology of the skin, to his special descriptions of its diseases. The order of studying the structure, functions, derangements of the different parts which form the tegumentary system before their diseases, would be in strict accordance with the usages of the modern schools, and simplify the subject in a great degree to students. M. Rayer has followed Cullen's nosological arrangement, by dividing cutaneous diseases into, 1, inflammations; 2, hæmorrhages; 3, neuroses; 4, local alteration: and to these he added diseases of the nails and hair, as appendages to the skin. This arrangement is simple and physiological, and much more intelligible than the natural system of M. Alibert, and, I think, preferable. I cannot comprehend the possibility of classifying cutaneous diseases as naturalists have done plants, nor does the renowned author assign any reason why his first group should not be last, and *vice versa*. On perusing each of his groups, a reader unacquainted with the nature of cutaneous diseases could not possibly understand whether certain species were or were not inflammations, hæmorrhages, neuroses, or local complaints. This objection applies with equal force and justice to the classifications of Willan, Bateman, Plumbe, &c., to all quoted except those of M. Biett, M. Rayer, and Dr. Green. I feel convinced that students will sooner comprehend the pathology and scientific treatment of cutaneous diseases, by treating them in the manner of all other maladies, than by following the natural system already mentioned. I am convinced that it would be best to describe them in this manner; and endeavour to introduce a classical terminology wherever this is defective. The classification which I venture to propose is based on those of Willan, Bateman, Biett, Rayer, and Green, and is as follows:—

DEFINITIONS:—DERMATITES. INFLAMMATIONS OF THE SKIN.

1. *Exanthemata. Rashes*.—Circumscribed or diffused redness, red patches, with or without interspersed papulæ (pimples) or vesiculæ (small blisters), between which the skin is of a natural colour; terminating by resolution, delectescence (sudden disappear-

ance), desquamation or exfoliation of the cuticle.

This order comprises six genera—erythema, erysipelas, rubeola, scarlatina, urticaria, and roseola.

2. *Bullæ. Bles*.—Small aqueous tumours caused by an effusion of serosity between the epidermis and subjacent rete mucosum, succeeded by a crust, or sometimes by superficial ulceration.

The genera of this order are, vesicatoriæ, ampullæ, pemphigus, rupia, and zona.

3. *Vesiculæ. Vesicles*.—Small serous transparent elevations of the epidermis, or cuticle, becoming opaque or purulent, differing from bullæ, by their smaller dimensions. The effused serosity is deposited between the epidermis and subjacent reticulated body (rete mucosum). These small blisters may be absorbed or effused, if ruptured, on the surface of the skin; and they are sometimes succeeded by a small, thin, lamellated crust or exfoliation, or by superficial excoriations.

The genera of this order are the sudamina or miliary eruptions, herpes, psora or itch, and eczema*.

4. *Pustulæ. Pustules*.—Elevations of the cuticle, formed by the effusion of pus or matter, or a fluid not serous, between the cuticle and inflamed reticulated body (Rayer), or on the surface, or into the substance of the skin (Green). Pustules dry more slowly than vesicles, form hard, thick, crusts or scabs, which may be horny, friable or pulverulent, and frequently cover indurations, excoriations, or deep ulcerations. The varieties of pustules are:—

1. *Phlyzaci*um, or a pustule of considerable size, surrounded by a hard circular base of a bright red colour, and succeeded by a thick, dark scab, or incrustation.

2. *Psudracium*, or a small pustule, slightly elevated, surrounded by a pink efflorescence, its base often irregular, or but faintly marked, sometimes confluent and terminating in a thick laminated circular incrustation.

3. *Achor*, or a small acuminate pustule, filled with straw-coloured gelatinous fluid, surrounded by an irregular efflorescence, but marked between it and its base, by a faint interspace, usually confluent, terminating in a thin light brown irregular crust.

4. *Favus*, or an irregular pustule of a large size, scarcely elevated, containing a more viscid straw-coloured fluid, surrounded by a rose-coloured base, terminating in a yellow, semi-transparent, or cellular crust, and sometimes by superficial ulceration.

The genera of this order are variola, variella, vaccina, vaccinella, ecthyma, cuperosa,

* Willan includes in this order, variola (small pox), vaccina (cow pox), varicella (chicken pox); but Biett, Rayer, and Green much more properly place them among the pustulæ.

mentagra, impetigo or running tetter, tinea, porrigo, and acne or stone pox.

5. *Papulæ. Pimples.*—These are small, firm elevations of the cuticle, caused by an increased action of the papillæ, containing no fluid in their centre, with a base more or less inflamed, seldom suppurating, terminating usually in scurf, and attended with intense itching. They generally terminate by resolution or desquamation of the cuticle, and very rarely by ulcerations.

The genera of this order are, strophulus, or the red gum, white gum, and tooth rashes so called by nurses, lichen, and prurigo.

6. *Tubercula. Tubercles.*—These are small, hard, solid circumscribed tumours, larger than papulæ, with or without an inflamed base, permanent or persistent, imbedded in the skin, terminating in resolution, partial suppuration, or destructive ulceration.

The genera of this order are, lupus, cancer, elephantiasis of the Greeks, molluscum, and fambræsia.

7. *Furunculi. Boils.*—Solid tumours, larger than tubercles, caused by inflammation of the cellular processes or elongations, which enter into the areolæ of the derm or true skin.

The genera of this order are, furuncle or boil, anthrax or carbuncle, and hordeolum or sty.

8. *Squamæ. Scales.*—These are indurated, opaque, whitish or yellowish lamina or lamellæ of the cutis epidermis, caused by the inflamed reticular body, or are continually being detached from, and renewed on, the surface of the skin.

The genera are, lepra or leprosy, psoriasis or scaly tetter, pityriasis or dandriff, and, according to Willan, ichthyosis or fish skin disease. Biett, Rayer, Green, and other late writers, maintain that this disease is not caused by inflammation of the rete mucosum, derm, or true skin, but depends on an usual thickness of the cuticle. They object to its being placed among the inflammatory diseases of the skin. Nevertheless, it bears the closest resemblance to the other squamous or scaly diseases*.

* Two cases of this disease have lately fallen under my observation. The subjects were brother and sister, but they were not born consecutively. Both resembled the father in moral and physical constitution more than the mother. The girl was most affected on the knees, and anterior part of the legs. The boy was diseased on the trunk and superior extremities. The children born between them were free from disease. On inquiry, I learned that the father suffered from dandriff, and that his parent had laboured under ichthyosis. Both the boy and girl were cured by aperients, tonics, and the external application of hydriodate of potass in the proportion of one drachm to each ounce of prepared lard. My students observed these cases at the dispensary.

9. *Fissuræ. Fissures.*—These are lineal cracks of small depth, and seldom extend to the whole thickness of the skin.

10. *Maculæ. Spots.*—Discoloration of the whole or a part of the surface of the skin, generally congenital and permanent. They may or may not be accompanied by general disorder of the system. This is the eighth order of Willan, Bateman, Biett, Green, &c.: and its genera are—ephelis, sun spots or freckles; nævus or mother's marks, spilus or mole; and, according to Green, the albino state; vitiligo, or a partial degree of this state, cloasma or liver spot, and lentigo.

M. Rayer excludes this order, and describes the diseases referred to under the title, "Alterations in the Colour of the Skin." He describes these as follows:—

11. *Gangrene. Gangrehes.*—Malignant pustule, bubo of the plague.

Decoloration. Leucopathia—1, partial, 2, general chlorosis.

Accidental Colorations.—Ephelis, entigo, chloasma, meladermis, icterus, nævus maculosus; bronze tint, caused by the internal use of nitrate of silver, (lunar caustic).

12. *Multiformes. Multiform.*—Burns, frost-bite, syphilitic eruptions.

Ulcers are excluded from this classification, because they never constitute a primary alteration. "They always succeed subcutaneous abscess, viscidulous, pustulous, or tuberculous inflammations, &c. and the study of them cannot be separated from that of the different inflammations which produce them.

"All inflammations of the skin affect, more or less, the reticular body (rete mucosum) of this membrane; some affect the dermis itself, the sebaceous follicles, the bulbs of the hair, the interareolary cellular tissue of the dermis, and even the subcutaneous cellular tissue." (Rayer.) The various other tissues lately discovered by Breschet and Rousel, (1835) are of course equally liable to inflammation. (This description not received).

The functions of the different tissues may be deranged by inflammation; the transpiration or perspiration may be diminished, suppressed, or increased, the secretions of the sebaceous follicles and cuticle, the sense of touch, and there is no doubt but the hair and nails may suffer morbid alterations.

Cutaneous inflammations may be general or local; general, as when they affect the whole surface of the skin, as, scarlatina, rubeola, variola, &c.; local, or partial as tinea, mentagra, &c. acute or chronic and febrile, or non-febrile, and may cause congestion, effusion, inflammation, or suppuration in the head, chest, abdomen, or joints, or their sudden repression may induce apoplexy, paralysis, asthma, &c. &c.

CLASS II.—*Dermatorrhagia, Cutaneous, Hæmorrhages, and Subcutaneous Congestions.*

When blood is accumulated in the substance of the skin it is termed congestion.

When blood is effused on the surface, or

into the substance of the skin; it is termed dermatic hemorrhage.

The cause of either disease, is want of energy in the venous circulation. Thus, if a ligature is placed round a limb, the parts below it become red or livid, and swollen; and another familiar example is afforded by the tumefaction and redness of the soft parts under a cupping-glass. This state is also observed on the face and extremities in diseases of the heart, asphyxia of new-born infants, in pneumonia, &c. and on the face from vivid emotions. The causes may be temporary, intermittent or continued; but the diagnosis between congestions and exanthematous inflammations is very easily drawn.

Hæmorrhage from the skin, or dermatorrhagia is a rare disease, except when the epiderm is raised, congested, or ulcerated. A simple illustration is afforded by the application of a blister to a surface from which the cuticle has been already removed. In this instance, the blood will be effused on the surface of the skin in the same manner as on that of a wound. Cutaneous hemorrhage has sometimes occurred in the course of visceral inflammations, and in the last stage of inflammations which are about to terminate fatally. The disease is so rare, that little can be said of its cause or treatment. Some of the older writers have slightly alluded to bloody sweat as an idiopathic disease. Pournier cites two cases of it (*Art. Cases rares Dict. des Sciences Medicales.*) It is said to appear on new born infants, and that the blood may be seen issuing from the surface of the skin without any alteration in the appearance or tissue of this part. Bichat and others considered that the disease might be idiopathic. It often appears in confluent small pox, on extensive burns, eczema, pemphigus, &c. Rayer comprises, with reason, the following diseases under this head—ecchymoma (ecchymosis), sugillatio, petechia (febris petechialis), and purpura hæmorrhagica or hæmacelinose.

CLASS III.—*Dermatoneuroses—Neuroses of the Skin.*

The skin is the organ of palpation, or touch. "The skin," says Rayer, "is the organ of general and passive tactility, by which is recognized the presence of bodies, and their temperature—is the seat of a peculiar and active sensation (touch), at several points in which it is provided with numerous nerves and vessels. The function of the skin may be modified, or abolished, without its texture having undergone any appreciable alteration."

Nosographers describe neuroses of vision, audition, olfaction, and gustation, or in other words, of sight, hearing, smell, and taste, and why should there not be those of palpation or touch, or of the skin? Has not experience convinced every observant physician of the fact, that there may be excessive neuralgic

pain, or total insensibility in every part of the skin? Paralysis affords us a familiar illustration of partial or total insensibility of the skin. Every part of it may be affected with abnormal or disordered sensation, excessive pain, numbness, sense of cold, creeping, &c. &c.; and our foreign contemporaries designate these morbid conditions, the hallucinations of the sense of touch. In all the innumerable neuroses or nervous affections of the skin, there is no unnatural or diseased appearance of this tissue. This multifiform class of disorders are well known, for they are constantly observed; though their causes are as yet unintelligible. It is impossible to explain the causes of the numerous modifications or hallucinations of the sense of touch, or of the abnormal disorders of the skin. But their existence cannot be questioned or denied. In many visceral diseases, such as those of the liver, kidneys, uterus, &c. and in habitual constipation of the bowels, there may be great *exaltation of the sensibility of the skin* in some particular point: indeed, every part of the skin has at different times been in this condition, and unaccompanied by redness or any degree of inflammation, or of eruption.

In like manner, there may be *diminution or abolition of the sensibility of the skin* in any point of its surface. These disorders have been termed *anæsthesiæ* by the older nosologists; and may exist with, or without, paralysis of the subjacent muscles. The discoveries of Sir Charles Bell, of M. Magendie, and Sig. Bellinghieri, warrant the conclusion, that in cases without paralysis, the sensory, and not the motor filaments of the spinal nerves, in these cases, are affected. Numerous examples are also on record, of loss of sensibility of the arm or lower extremity, though the power of motion continued unaffected. Paralysis of the skin depends on affections of the nervous centres, which must be vigorously combatted to remove them.

CLASS IV.—*Dermatachromata—Achroa, Decolorations.*

Absence of colour of the skin, depending on the want of the pigmentary secretion, or usual colouring matter of the rete mucosum, skin and hair, leucopathia, leucæthiopia, albinism, general whiteness, and chlorosis. (Rayer.) This disease may be general or partial, congenital, or accidental.

When there is a partial colourless state of the skin, it is termed vitiligo.

CLASS V.—*Dermatodyschromata—Dischroa, Maladermia Discolorations.*

Discolorations of the skin are caused by different modifications of the pigmentary or colouring matter, as in epheles, sunburn, lentigo, freckle, chloasma, or pityriasis versicolor, of Willan, or maculæ hepaticæ, or dandriff of others. They are also produced by the introduction of extraneous matters into the tissue of the skin, as in jaundice,

artificial colorations, such as those induced by a long use of the nitrate of silver (lunar caustic); and lastly, the skin may be greatly discoloured, as in melanosis, and nævus, or mother's marks. Many of the last are more analogous to sanguineous tumours, such as the vascular and subcutaneous nævi, than to alterations of the colour of the skin.

CLASS VI.—*Dermatohydroa—Sudor—Diaphoresis—Perspiration.*

The morbid secretions of the skin are termed *ephidroses generales et locales, sudamina, miliaria, papule, sudorales et sudosæ and hydronos, hydronosus, hydropyretus, sudor Anglicus, or sweating sickness*. Haller well observed that there is disease of the perspiration: "*estque sudor morbi genus.*" There may be chronic sweat, partial or general, on the feet, hands, neck, shoulders, breast, and about the groins, pudenda, and anus. The sweat may acquire a sour, rancid, fœtid odour, and one somewhat similar to that of musk. It may be changed in colour, and cases of black, green, blue, &c. sweat have been cited.—*Sauvages' Nosol. Method. Art. Ephidroses, Ephem. Curios. Dec. 3, an. 7, 8, &c. Dec. 11, an. 4.*

CLASS VII.—*Dermatocryptoncoses.*

Morbid tumours caused by secretions of the cutaneous cryptæ or follicles, including acne, of a ceruminous or waxy layer, somewhat similar to the white unctuous coating on new-born infants, vermiform bodies (grubs) folliculous tumours, (A. Cooper and B. Travers), which have been denominated lipoma, meliceris, atheroma, and steatoma.

CLASS VIII.—*Adermata.*

Congenital absence and defects of conformation and texture of the skin—cutaneous and subcutaneous vascular vegetations and tumours, erectile tumours, moluscum, atheroma, steatoma wen, verrucæ, porri, or warts; mamellated excrescences, cornua, horny growths, clavi, gemursa, corns, cicatrix, scar, seam, healing of a wound or burn.

DISEASES OF THE APPENDAGES OF THE SKIN.

Onychosenology—Description of Diseases of the Nails.

GENERA I.—Onyxis, onychia, whitlow.

II.—Onychohæmorrhagia, onychensarcia, the nail growing into the flesh, sublingual ecchymosis.

III.—Onychophthoria; morbid alterations of the nails. Abonychia; absence of the nails.

IV.—Onychoptosis; fall of the nails.

V.—Polyonychia; supernumerary nails.

VI.—Onychophyma; tumefaction, or enlargement of the nails.

VII.—Onychogryptosis; curvature of the nails.

VIII.—Onychodyschroa; accidental coloration of the nails.

These terms are new, and perhaps will be objected to by the superficially informed;

but the erudite, whose opinions are valuable, will not repudiate them. There are many who object to the use of the Greek language, but they do not know, and cannot appreciate its brevity and expressiveness. The learned of all nations employ it constantly; and I see no reason why we should not imitate their example.

TRICHOMANOSOLOGY.

Description of Diseases of the Hair.

GENERA I.—Trichomatanoses; diseases of the hair.

II.—Trichomatitis; inflammation of the hair.—Plica polonica; also, matting of the hair.

III.—Canities; hoariness.

IV.—Trichomatadischroa; decoloration of the hair.

V.—Alopecia phalacrotes; baldness.

VI.—Atrichomata; absence of hair. Calvities senile; fall of the hair.

VII.—Polytrichomata; supernumerary hairs. Trichiasis; vicious direction of the hair.

Anomalous Diseases connected with the Hair and Skin.

Phtheriasis; morbus pedicularis.

Pediculi.

Pulex.

Acarus scabiei, sarcoptes; flesh worms; itch insects.

Œstrus, astromus.

Elephantiasis, lepra; Barbadoes leg; Cochin leg.

Some will censure this arrangement of diseases of the skin and its appendages; more, I hope and trust, will approve it; and all, I flatter myself, will admit, that if it do no good, it can inflict no evil; I submit it to the world, with all its imperfections on its head. I am disposed to imagine, that it is as perfect as other classifications of the diseases of the skin, but in this I may, and most probably am mistaken; nevertheless, I submit it to the profession in all countries.

Foreign Medicine.

—
Morey.

We hasten to publish the following communication, addressed to us by M. Scipion Pinel:—

It was on the fifteenth of this month, writes this physician, that I was called to attend Morey, in concert with Messrs. Barras and Bonnet, medical attendants of the prison. After the reports which had been spread by the journals, I expected to find a man resolute, haughty, peremptory, and determined to die of hunger. What was my surprise at seeing a mild old man, an-

swering with earnestness the questions put to him about his health, complaining bitterly of a sleeplessness which harassed him, and especially of an insurmountable disgust at food. "I am very desirous of eating," said he, "but the smallest quantity of food causes acute pain in the stomach, and aggravates my fever. I have a bitter taste in the mouth, with frequent nausea. I have now passed fifty-seven nights without sleep, and this is the thirty-fifth day since I took any nourishment."

I examined him attentively. The tongue was red and dry; the breath bilious; the epigastrium painful to the touch; the skin covered with sweat; the pulse quick. I retired with the director, who shewed me a report drawn up by six physicians, stating that Morey was tormented by a deep-rooted moral disease; that he had neurosis of the stomach; that he had taken a fatal resolution not to eat; and that he ought to be supported by nourishing enemata, to which should be added a few grains of the sulphate of quinine. Foreseeing that I should differ in opinion from my colleagues, I requested they would assemble on the morrow at ten o'clock in the morning. After a new examination, four of these gentlemen persisted in their opinion, and composed a bulletin, in which they stated that the remedies hitherto employed were the best they could advise.

After an animated discussion, I thought myself obliged, in consequence of their opinion, to express my own in precise terms, declaring that Morey was labouring under intense gastric irritation, which was the cause of his ill health and of his resolutions; and that it was necessary to resort to different treatment in order to arrest the progress of the mischief. In the evening I returned to the Conciergerie, and recommended for the night two ounces of syrup of gum, with the same quantity of distilled lettuce water, to be taken by spoonfuls every quarter of an hour. Morey having tasted the first spoonfuls, drank all the rest at once. He had a little fever in the night. On the morrow, which was Saturday, he took a mutton cutlet, and shaved. I found him much better. In consequence of the diversity in our opinions, a grand consultation of ten physicians was appointed by the President of the Chamber of Peers for Sunday. Having

received my summons too late, I could not attend, but had seen Morey in the morning: he was a little better, but much disposed to complain. It was decided in the grand consultation that he had chronic gastritis, that he ought to be removed to a *maison de santé*, and that the treatment ought to be adapted to the new indications. Various means were proposed for fulfilling them.

On Monday the condition of Morey was much improved; but the more sensible was the amelioration he obtained, the more he seemed to take pleasure in complaining. Next day his lodging was changed; from the low and gloomy room where he was first placed, he was removed to a wainscotted chamber on the first floor, well lighted, and looking into the inner court. This change of residence gave him evident pleasure. He got up for two hours in the day, but he always expressed disgust at food, and especially at meat and broths.

I felt it right, in the bulletin of this day, to insist on the continual tendency of the patient to believe and represent himself worse than he really was—whether his conviction was sincere, or whether it was from artifice. From the state of the tongue, the skin, the urine, and the epigastrium, however, I considered that the affection of his stomach was greatly amended.

On Wednesday, Morey was pretty well. In the evening, as he felt sick, he asked for a little brandy from one of his attendants, who gave him a spoonful. In drinking it, he felt as if it had been fire; but the imprudence was not followed by any important result. Next day, Thursday, he was in his ordinary state—calm and resigned; always repeating that he should never get well, and that this was the last disease he should have to encounter; but still declaring that he would eat with pleasure as often as he wanted food. His wish for strong drink last night, induced us to give him this evening some sweetened gruel, to which had been added a small spoonful of rum*.—*La Lancette Francaise*.

* This case does more honour to the diagnostic accuracy of M. Scipion Pinel, than to his therapeutic activity. The treatment adopted would have done just as well for "neurosis of the stomach," as "gastritis." In reading the *Clinique Medicale*, and other continental works, the conclusion irresistibly

Lithotrity.

It is well known with what eagerness, ever since the discovery of lithotrity, it has been sought to deprive France of the credit, and to bestow it gratuitously on strangers; who have even generously declined the honour attempted to be thrust upon them. They ransacked the oldest libraries; they disinterred ancient volumes which had not seen the light for many a day; they quoted,—they commented—they tortured passages—they copied the representations of instruments—they thought they met with lithotrity everywhere.

It might have been expected that this ardour for rummaging old libraries had worn itself out; but here we have the keeper of records in one of the Sardinian States, attributing the invention of lithotrity to one of his countrymen. He has exhumed an old parchment, in which are depicted the very instruments employed by M. Civiale.

Several journals, and especially the *Gazette de Turin* (No. 127, October 23, 1834), have in fact given out, on the faith of M. Baggiolini, keeper of the records in the city of Verceil, that in the precious manuscripts deposited in the archives of that place, an ancient parchment had been found, giving a design of an operation for lithotrity. M. Baggiolini, induced by a spirit of nationality, which does more honour to his patriotism than his intelligence, has pretended to demonstrate that the instrument represented in the parchment resembled M. Civiale's apparatus; and that its invention belonged to Jean de Romanis, of Verceil (others say of Cremona). This Jean de Romanis, whom we have Frenchified by calling *Jean des Romains*, was certainly a clever man. The invention of lithotomy, by which is called the apparatus major, is attributed to him. Marianus Sanctus, his scholar, improved that method, and published the first description of it in a work printed at Venice in 1535. This work, intitled *De Lapide Vesicæ per Incisionem Extrahendo*, is more remarkable for its matter than its manner; for it is written in a style very far from attractive. What proves that our keeper of the records

has not read it, is that in his notice printed at Verceil, he confounds the method of cutting for the stone, invented by the author in question, with that of Celsus; of which latter method, according to him, Jean de Romanis was the promoter. On the contrary, there is a great difference between the method of Celsus (*De Medicina*, lib. 7, cap. 26), and that of Marianus, or Jean de Romanis*.

However this may lie, the apparatus major has been employed by the greatest surgeons for nearly two centuries; and this is the extent of the obligation under which those affected with calculus be to the genius of its inventor. His title to the discovery of lithotrity is not so well established as M. Baggiolini would have us to believe. Our readers may judge of this by the following communication on the subject from M. le *President de Gregory*; who, occupied with the history of letters and arts among the Verceillese, was induced to write to M. Poggio, secretary of the city. The following is the Secretary's reply.

"December 17, 1834. Signor Baggiolini, who was charged with the duty of arranging the records of the city (Verceil), committed a great error in his memoir, which was printed here by Cerutti. He has proved either that he did not know how to read the parchment in question, or that he expected that his word would be taken as decisive of the matter in question. I have in my hands the parchment referred to, and find no mention in it either of the surgeon Jean de Romanis, or of lithotrity, or of a curative method. The figure delineated is simply that of a sound or syphon (*siringna*). The chapter from which Baggiolini has drawn his observations, speaks of a method of drawing off the urine, when the urethra is narrowed by strictures, or an abscess, or a stone impacted in its course. The parchment in question is a detached leaf of an old treatise on surgery, written in semi-gothic characters, and without the name of the author. It has been much used, and served as a cover to a volume of acts in our archives. Attempts have been made to correct this document; but the council and syndic of the city obliged Baggiolini to return it; and we preserve it with care for the honour of truth."

forced on the mind is, that since physicians think they have done all when they have accurately determined the nature and extent of the disease, the treatment is only of consequence to the patient.

* The plan adopted by Celsus has been called the apparatus minor. See *Cooper's Surgical Dictionary*, article *Lithotomy*.

The letter we have just transcribed, reduces to their just value the pretensions of M. Baggiolini. This honest keeper of records somewhat resembles the librarian of Florence, satirized by P. L. Courier; and who, after having passed six years in commenting on a precious manuscript, had forgotten to read it. Every body knows the tricks which were laid to the charge of our learned countryman, on account of a spot of ink which he had the misfortune to make on a page of this manuscript. This accident has not happened to the parchment of Verceil, which remains in a perfect state, an authentic monument of the strange mistakes of M. Baggiolini.—*La Lancette Francaise*.

M. Souberbielle gave the following reply to the report which M. Double had made at the last meeting but one, on a work by M. Civiale, entitled *Statistical Details on Calculous Affections*.

This academician has reproduced, without criticising them, the manifestly erroneous figures by which M. Civiale expresses the results which he has obtained by lithotrity. It was said, that out of two hundred and fifty-seven cases of lithotrity, only eight patients had perished. This was very surprising, considering that in a report which M. Double made in 1833, respecting calculous patients in the Necker Hospital, he had stated that M. Civiale had lost ten patients out of forty-three that he had submitted to the operation; and in a report made in 1831, by M. Larrey, on another series of calculous patients in the same hospital, five patients had died out of eighteen. Thus, according to MM. Larrey and Double, fifteen calculous patients out of sixty-one died at the Necker hospital; and I cannot explain how the honourable reporter should have confined himself to stating the proportional mortality indicated by M. Civiale; that is to say, six out of two hundred and fifty-seven; while at the same time his own investigations had revealed to him a much higher proportion; that is to say, ten out of forty-three, or fifteen out of sixty-one, if we add together the numbers of the two reports.

This contradiction cannot be attributed to the deviations of M. Civiale, for M. Dou-

ble has retracted nothing of his former report, which, besides, offers all the guarantees of authenticity; and M. Larrey has lately declared publicly that M. Civiale was wrong in pretending to have corrected the errors of M. Larrey's report, for that work was rigorously exact, being founded on authentic documents lodged with the secretary of the institute; and that if he (M. Larrey) had not caused the report and the proofs to be printed, it was from a feeling of regard—a kind of indulgence.

It is against this flagrant error that I protested, in the letters which I have already addressed to the Academy on the subject of this same work by M. Civiale. The first of these letters is dated September 1, 1833, and is entitled, "Letter to the Academy of Sciences, on the Statistics of Calculous Affections." The second, dated the 29th of the same month, has for its title, "Communications, addressed to the Academy of Sciences, on some points of the Statistics, &c." Finally, in September, 1834, I addressed a note to the Academy on the same subject, entitled, "M. Civiale's Figures again."

I believed that I had, in these writings, proved, from my own personal experience, and from the reports of MM. Larrey and Double, the incorrectness of many of M. Civiale's assertions, and particularly the erroneous representation he gives of the mortality which has occurred in his practice; and I have therefore the greater right to be astonished that the honourable reporter has not cleared up so important a point in the discussion, and that he has allowed to remain between the two reports the striking inconsistency which I have exposed. This is the more surprising when we recollect that the arguments I insisted on in my papers have since been brought before the Academy of Medicine, by the members who advocated lithotomy, in the memorable discussion which recently took place. In this discussion the advantage certainly remained with the advocates of lithotomy.

I find I judged correctly of M. Civiale's work, in protesting against the disordered state of its contents, and in shewing the impossibility of reconciling them with each other; since the reporter states that the documents have not the necessary complete-

ness, particularity, and authenticity; and that to print these documents would be to consult neither the dignity of the Academy, nor the elucidation of the question.

I find, in the last work of M. Civiale, a new proof of the system, by the aid of which he wishes to extol lithotrixy; for while he collects the greatest possible number of *lithotomy* cases, why does he not do the same for *lithotrixy*? Why does he not cite the 257 cases of lithotrixy which occurred in his own practice; and why does he neglect those which have been performed by MM. Heurteloup, Leroi, Legalas, Bancal, Amussat, and others? Why does he not include the two hundred cases of lithotrixy which have occurred to various surgeons at Vienna, Munich, Bagdad, &c., of which cases M. Begris speaks, in his *Dictionnaire de Medecine et de Chirurgie Pratique*? In short, why has he not profited by the researches he made on the subject of *lithotomy*, by making a similar investigation on the subject of *lithotrixy*, so as to be able to state the actual condition of as great a number as possible of the individuals who have been submitted to the latter mode of operating. This, I hesitate not to affirm, is the only mode by which we can satisfactorily judge of *lithotrixy*.

I have no intention of criticising M. Civiale's work just now. My only object is to entreat the members of the Commission to notice the representations I have already made to the Academy, on the evidently erroneous calculations of M. Civiale, and that this surgeon may not obtain the suffrage of the Academy for the propagation of errors, to the advantage of *lithotrixy*, and for decrying the operation of *lithotomy*.—*La Lancette Francaise*.

Eels in Artesian Wells.

M. Arago presented to the Academy two little eels which had been thrown up with the water from one of the artesian wells at Elbenf. This fact, which has been verified by M. Girardin, a distinguished professor of chemistry at Rouen, is of great interest, inasmuch as it demands considerable modification of the ideas which have been generally entertained on the origin and course of subterranean water. Many people, even at the present day, think that the water col-

lects in conduits from the effect of gentle filtration; but this opinion can scarcely be reconciled with what is observed at Tours, where seeds and leaves have been ejected in great abundance from an artesian well. It is still farther shaken by the fact related above.

M. Dumeril declared that the animals presented were incontestibly true eels. They are both nearly of the length of those which are seen at certain seasons going up rivers in vast numbers, and which fishers call *the ascent*. These last, however, differ from those presented to the Academy, in being white, with black spots; while those from Elbenf have completely the colour of the adult.

Larva of the Common Fly living in the Skin of an Infant.

M. Isidore Geoffroy communicated, verbally, an observation made by Dr. Fourcault, respecting the larvæ of insects lodged in the skin of a child. A peasant going to work in the fields, had carried thither a infant, which she suckled; and at the end of eight days, perceived a little tumour at the breast, of a suspicious appearance. Dr. Fourcault, to whom she applied, perceived in the centre of the tumour two larvæ of insects, which he succeeded in extracting alive, and preserving, till their transformation took place. It was then found that the larvæ belonged to the common fly.

M. Dumeril inquired if it was well proved that the perfect insect was really a common fly. If it was so, since that kind of insect has no apparatus for piercing the skin, there would be reason for concluding that the tumour had been formed and opened before the parent fly had deposited her eggs there. It was not the same with other kinds of flies, the females of which can deposit their eggs in a perfectly sound skin; but they are furnished for this purpose with an instrument which, as was observed already, is completely wanting in the common fly.—*Gazette Medicale*.

Hospital of Geneva.—White Oxide of Antimony.

The white oxide of antimony, administered by Dr. Lombard in doses of one or two drachms daily, has never produced vo-

miting, or even nausea; which distinguishes its action from that of the other preparations of antimony. The same rule holds with respect to diarrhœa, which has only once followed the administration of the medicine; and even then the number of stools was not great, not exceeding three or four. Cough has been but little affected by the white oxide of antimony. In ten cases in which this symptom was noticed with care, it was found in one to have increased in frequency, to have diminished in four, and to have remained five times unaltered. The state of the skin has been sensibly influenced by the employment of the white oxide. In fact, out of eleven cases, we only found one in which the skin remained dry during the administration of the medicine; while five had the skin habitually moist and wet; and five had abundant perspiration during the whole course of the treatment. From this it would appear that the ancient appellation of *diaphoretic washed antimony*, agreed very well with the medical properties of the white oxide. We have seen that nausea, vomiting, or diarrhœa, scarcely ever attends its use; and the state of the tongue proves that it produces no symptom of irritation in the digestive passages. Out of ten patients in whom the state of the tongue was noticed, we found it white and moist in nine, and red and dry in one only; and even the last case, which terminated in death, presented, on examination, no lesion of the intestinal mucous membrane. This absence of irritation in the digestive canal, is one of the characteristic traits of the white oxide of antimony; since it furnishes us with the most essential indication for administering it. When, for instance, we meet with pneumonia in patients weakened by age or prior diseases, and whose strength might be too much depressed by the employment of bleeding and tartar emetic, the white oxide of antimony may overcome the disease without causing any risk to the patient.—*Gazette de Medecale*.

Tracheotomy. By M. Moreau.

Laryngitis, or laryngo-tracheitis, requires, at a certain stage, a surgical operation, which has been improperly termed *bronchotomy*—the bronchia not being the parts engaged. It is more correct to give to every

operation practised on the principal air-passage, a denomination which definitely points out the part concerned. We shall, therefore, speak of *tracheotomy*.

From the time of Asclepiades, of Bythinia, who may be regarded as the inventor of the ingenious proceeding of making an artificial passage for the air, the ancients were accustomed, in all cases of suffocation, to incise the integuments and the trachea transversely, between the third and fourth rings; thus (so to speak) cutting the patient's throat. At a later period, Deckers and Buchot, in order to avoid hæmorrhage, pierced the soft parts and subjacent trachea with a trocar armed with a canula; but they frequently made a contused wound, injured the vessels, and were exposed to the danger of piercing the trachea through and through, so as to enter the œsophagus, &c. Vicq d'Azyr, guided by anatomical considerations, incised the crico-thyroid membrane transverseley. Nevertheless, he gained by this means only a little opening, with a wound difficult to heal. Since his time, various modes of proceeding have been imagined, such as the *tracheotomy* of former times, the *thyrotoimy* of Desault, the *cricotracheotomy* of Boyer, and lastly, the *sub-hyoideal laryngotomy* of M. Malgaigne. Of all these methods, *tracheotomy* alone is in repute in the case of membranous croup.

In the *Gazette Medecale* for January 31, 1835, I described a bivalve canula, which is to be used in the operation which I now propose—*sub-cricoideal tracheotomy*. I shall not enter on a discussion of the various methods of procedure enumerated above. I shall confine myself to an examination of the parts on which we operate in *ordinary tracheotomy*, and of those concerned in *sub-cricoideal tracheotomy*. I designedly omit, therefore, *thyroidotomy* and *sub-hyoideal laryngotomy*, because these modes of operating are not employed, except in cases where foreign bodies have found their way into the air-passages. I omit, also, the *cricotracheotomy* of Boyer, for the section of the cricoid cartilage cannot in any degree assist in keeping the wound open; while the elasticity of that cartilage is such, that it is almost impossible to keep the lips of the wound apart, even with a dilator.

Ordinary Tracheotomy.—Proceeding from

above downwards, from the cricoid cartilage to the top of the sternum, and from the superficial to the deeper parts, we find the cervical aponeurosis, the sterno-hyoid and sterno-thyroid muscles, and the first rings of the trachea; then the isthmus of the thyroid gland, of variable size; next the thyroid plexus of veins, a layer of cellular tissue, and the trachea crossed inferiorly by the brachio-cephalic trunk. We have also to remember that all the soft parts may be infiltrated with serous fluid, or with gas, and the veins may be gorged with blood.

In performing the operation, which I shall only superficially describe, we divide successively (in the median line) the skin and aponeurosis, and thus come between the sterno-hyoid and sterno-thyroid muscles of each side. Then, starting from the thyroid body, we divide the thyroid plexus of veins, and the trachea is uncovered.

M. Trousseau has remarked, that the more embarrassed is the respiration, the larger are the thyroid veins, and the more blood do they yield. He therefore advises that, notwithstanding the hæmorrhage, the trachea should be opened immediately, for a ligature, if applied, would not always be sufficient to arrest the flow of blood. He also takes the precaution to place a small piece of sponge beneath the edge of the wound and over the mouths of the divided vessels, both to check the hæmorrhage, and to prevent the entrance of air into the veins, an accident which, according to Messrs. Larrey and Dupuytren, is instantly fatal. As soon as the trachea is opened, we ought to incline the patient forwards, so that the blood may flow outwards, and the respiration be freely established, which generally puts an end to the hæmorrhage. Sometimes, however, in spite of these precautions, the hæmorrhage persists; on which account M. Recamier advises us, whenever the state of the patient will permit, to wait twelve or twenty-four hours before opening the trachea; and for the same reason authors recommend that the patient, if able, should take a few deep inspirations, and to tie all the vessels which continue to bleed, before opening the trachea. It is with this view, lastly, that I propose *subcricoideal* tracheotomy, which has the following advantages over the proceeding described above. 1. It

finds the trachea less deeply situated. 2. It does not expose us to an encounter with the brachio-cephalic trunk. It is performed in parts sufficiently free from vessels not to yield much hæmorrhage.

Subcricoideal Tracheotomy.—Between the inferior border of the cricoid cartilage and the upper curvature of the isthmus of the thyroid gland, there is a space about a quarter of an inch long, entirely free from vessels. It is formed by the first rings of the trachea. Below is the thyroid isthmus, which is occupied by the venous plexus only in its two inferior thirds. Very rarely the thyroid arteries, which pass along each side of its superior border, anastomose in its middle portion. It is, therefore, on its anatomical peculiarities that subcricoideal tracheotomy is founded.

The instruments required for the operation are, a straight or convex bistoury, a tenaculum, waxed threads, fine sponges, tepid water, and linen. The patient ought to be placed in a sitting posture, or lying on his back, with his chest raised, and the hands placed behind him, so as to give free play to the respiratory organs. The head should be slightly turned back, and kept motionless by a sufficiently resisting pillow. The operator places himself at the right hand of the patient, in any position which is most convenient to himself, with the bistoury in his right hand, while he commands with his left the larynx, and the parts on which he is to operate. The skin is stretched by the left thumb and inner border of the left hand. He then cuts through the integuments in the median line, layer by layer, to the extent of an inch, or an inch and a half, from above downwards, beginning at the superior border of the cricoid cartilage. We then come to the cellular tissue which separates the sterno-hyoid and sterno-thyroid muscles of each side. This is divided, and the trachea is uncovered, as well as the isthmus of the thyroid gland. The operator then plunges the point of the bistoury immediately beneath the inferior border of the cricoid cartilage, and divides the trachea from above downwards, in the median line, to the extent of about half an inch; including in the incision the superior third of the thyroid isthmus. The wound is cleaned with a little bit of fine sponge, and the bi-

valve canula is introduced. The only difference now in the patient's respiration is, that it takes place through an artificial channel.

It should be noticed that this proceeding requires the application of the *bivalve* canula; an opening of half an inch not being sufficient to admit any other.—*Gazette Medicale**.

The London Medical

AND

Surgical Journal.

Saturday, November 28th, 1835.

THE MEDICAL REFORM ASSOCIATION—
THE PRIZES CARRIED OFF BY NO-
BODY—OUR BITTER DISAPPOINT-
MENT.

BEING as all the world knows stanch advocates of Medical Reform, we have for some time contemplated with much satisfaction the existence of a Medical Reform Association, but events of recent occurrence have cast a shadow on our happiness—*surgit amari aliquid*.

Prizes having been offered for the three best essays on Medical Reform, and essays having been forwarded to the Association from different parts of the world, it was natural to expect that each of the prizes would be awarded to *somebody*, and we have been feeding our imagination with the delusive hope, that all the prizes would, without question, be awarded to *us*, seeing that we are continually publishing transcendent essays on Medical Reform in the columns of this Journal. What happens think you? In walks Nobody—the emptiest fellow in the world—who, setting us and all our competitors aside “with the back of his hand, thus,” takes possession of the three prizes with the full approval of the Committee of Examination!

In the first bitterness of our chagrin we had like to have adopted the opinion that this same Nobody himself constituted the Committee of Examination—an hypothesis which

would have sufficiently accounted for his getting the prizes, and which derived support from the fact, that although we entreated all our acquaintance, with tears in our eyes, to tell us who the Committee were, we could get no sort of information on the subject; nay, a still more extensive process of nullification floated vaguely through our mind; the analogy of the Rosicrucian fraternity presented itself, and we need not tell the more learned of our readers, that strong doubts have been entertained whether that celebrated Association ever had any real being, and whether it did not owe its imaginary existence to the machinations of that waggish divine, the Rev. John Valentine Andrea, who made half the savans of Europe believe that they were members of it; the analogy was strengthened by etymology—the affairs of the Reform Association had evidently been conducted *sub rosa* and it was equally clear that we had been *crossed* in our expectation of getting the money.

But theorizing is of no use; we are practical men, and all we are certain of is, that Edward Harrison, M.D. John Epps, M.D. and Joe Hume, M.P. have, or fancy they have, something to do with this matter; that Dr. Harrison advanced one hundred pounds sterling, or imagined that he did; that Nobody got the prizes, or thought he got them; notwithstanding which, Joe Hume has, or conceives he has, the money in his pocket.

After all, we may admit the strong *probability* that the Association actually exists, that Nobody has got the prizes, and that Joe Hume has got the money. Supposing this to be the case, we would gravely remark, that the gentlemen who have competed for the prizes have a right to think themselves ill-used.

When a set of men start for a race, it is not essential to its being fairly won, that the fortunate individual shall have run very fast, but simply that he shall have run faster than any of the rest. The same principle

* See also the *Gazette Medicale*, Vol. 3, No. 5, January 31, 1835.

applies to literary competition; the inducement to take the trouble of writing for a prize is the chance of winning it, and if the parties concerned find, by the event, that no chance at all had existed for any of them, inasmuch as no prize is forthcoming, they must all naturally feel discontented at having been induced, by a fallacious expectation, to engage in a labour which turns out to have been from the commencement fruitless, and which not one of them would have engaged in, had he previously known that he was to "fight as one beating the air."

We would therefore recommend the Association to revoke their present sentence, and give the prizes to those most worthy of them; or, at all events, to let it be distinctly understood that, on the next occasion, the prizes are actually to be given: if this be not understood, we venture to predict that the next time there will either be no essays at all, or very bad ones; since no man endowed with much intelligence is likely to exert himself greatly to attain the distinction of being considered no worse than his neighbours.

—o—

THE NEW POOR LAW ACT.

To the Editor of the London Medical and Surgical Journal.

SIR—It has fallen in my way to see much of the operation of the new poor law; and, excellent as I am convinced that many of its provisions are, I am compelled to lift my voice against the manner in which it is made to bear against the interests, the rights, and the respectability of the medical profession. Compelled by the laws of our country to fit ourselves for the highly responsible situation which we fill in society, by undergoing a tedious, expensive, and laborious education, I cannot but maintain, that the same laws, instead of making us the dependant tools of those who are interested in oppressing us, and incapable of appreciating our services, ought rather to shield us from oppression, and protect us from debasement and injustice. But it is not so. Either through the new poor law itself, or through the manner in which that law is executed by the Board of Commissioners, the medical practitioner who has anything to do with the attendance of the poor is placed in the most humiliating, the most unfortunate

situation. Bad enough was the situation of the parish surgeon under the old poor laws. The writer of this letter has suffered but too deeply from the abominable contract and tender systems, which even then too generally prevailed, and from the wretched pitance with which even the most liberal parishes thought fit to reward his labours. Placed for more than thirty years in a district, one-half of the inhabitants of which were paupers, it has been his fate to labour on from youth to age, not "to earn the bitter bread of servile toil," but to see the bread which his toils and his talents have earned kept from himself and his children by the cupidity and illiberality of those in whose hands were placed the administration of the law. To prove how inadequately his exertions were remunerated he need go no farther than to record the following facts:—that in one parish, for the attendance of which he was paid an annual sum of ten guineas, he had in one year, at a distance of three or four miles from his home, to attend fifty-three cases of severe autumnal remittent; and that in another, he had the satisfaction of receiving his accustomed stipend of sixteen guineas for attending, amongst much other sickness, seventy-two cases of the worst kind of typhus fever; most of which ran on for three and even four weeks, and one of which actually held an uninterrupted course of twelve weeks before it terminated in death.

But if the old system was bad, the new one is a thousand times worse. A practitioner in the former case had to do with the officers of a few parishes only; persons well known to him, perhaps his patients and his friends. They had some terms to keep with him. Mean as even the most liberal of these men are in the management of parish affairs, there was a point of meanness beyond which they could not go; or if from ill will, extreme niggardliness, or any other cause, they were led to step beyond it, there was the parish vestry to apply to; and I have generally found an appeal to an open vestry productive of a favourable effect, where the attempt to talk into justice or liberality the one or two individuals who have made up their minds to act unfairly, has always unfortunately failed. But under the new law, we have not the officers of the parish to depend on; we have no longer a parish vestry to appeal to as a court of ultimate resort; but we have in their stead a body of guardians chosen out of the various parishes in the union, and with them all the resident magistrates, who, as proprietors, have a greater interest in lowering the parochial expenses than even the tenants themselves. A considerable portion, perhaps a large majority of this board, are comparatively strangers to the respective medical gentlemen in the different districts; they are naturally bent upon reducing the rates to the lowest possible point; each person is emboldened to make an illiberal

proposal, by the countenance he feels sure of receiving from others; the odium of a mean and unjust action rests not on the shoulders of one, but is shared amongst the whole of his compeers: the pleadings of one or two kindlier spirits are outvoiced by the acclamations of the rest, and thus, "armed with a little brief authority," from which there is no appeal, they

"Playsuch fantastic tricks before high heaven
As make the angels weep."

A board of guardians forms in truth, as at present constituted, and with its present powers, a combination of employers, legally, but unjustly authorised to force upon the employed whatever terms they may think proper, and furnished with every motive to make those terms as hard as possible.

Let us now see in what manner the working of the new poor law has inflicted upon our medical brethren so intolerable a grievance. In the first place, the abominable system of *hiring* by tender, has been universally adopted, though, strange to say, no others of the union officers have been subjected to the same disgraceful process. For the chaplains, the clerks, the auditors, and the relieving officers, a salary has been fixed, bearing, of course, some proportion to the duties which they have to perform, and that salary being announced in a public advertisement, the candidates have been called on to send in their names and testimonials; and from amongst these applicants the choice has been made with some show of fairness, if not with absolute impartiality. Not so, however, with the medical officer. An open announcement of the wretched pittance with which they generally think fit to reward his exertions would expose their conduct before the tribunal of public opinion in a manner which they would not relish. They are wise enough too to know that they can generally obtain the requisite services through the medium of a tender, for a smaller sum than that which they would dare to offer in a public advertisement. They know that the established practitioner will reduce his demand to the lowest possible pitch, from the fear of losing that practice of which he has been, perhaps very long possessed, and upon which, poorly as his labours have been rewarded, the support of his family in part depends; while an opponent, an enemy, or perhaps some young aspirant after practice, who has no family, who perhaps estimates his time as nothing, and his talents at a trifle, and may not be much out in either calculation, will be led, by the desire of superseding his rival, to offer his services for a sum of the most debasing description, reckless of the influence of so ill an example on his own future prospects, as well as on the prosperity and the respectability of his profession.

Another objection to the present operation of the law, is its perpetual and harassing interference with every man's established

practice, especially in rural districts. Under the present state of things, a practitioner will never know what he has got to depend on. The talents which have formed or enlarged, will not ensure the permanency of his connection; the humanity which may have won the hearts of his poor patients, will not preserve him from the chance of being dismissed from their attendance. In vain by his skill, his industry, and his attention, will he hope to command success and to defeat opposition. Built on a sandy foundation will be the home, which encouraged by these flattering hopes, he may have been induced to erect, and uncertain as the winds, the happiness and well doing of the family of whom, in the confidence of success, he may have become the husband and the father. The vote of a board of guardians may blast his fairest hopes. Their fiat may create opposition where it has never existed, or revive it where it has been for a time destroyed. The members of the profession will be kept in a constant ferment; every man will be set in array against his neighbour. Jealousy and strife are too proverbially the characteristics of the profession under all circumstances, and it is but natural that they should be so, when we consider that it is not worldly profit alone for which they contend, but that the love of fame, the pride of talent, the desire of excelling, the eager longing after victory, urge them on in their career. But that jealousy and strife of which we before had reason to complain must now be increased a hundred fold. Year after year the disgraceful struggle will be renewed, year after year the medical attendant of one district may be forced in among the patients of another; and thus will the peace, the prosperity, the character of the profession be destroyed, and a continual and illiberal competition be established among its members; not a competition in science, in talent, in attentiveness, in humanity, but a competition of the basest and most humiliating description, having for its object the acquisition of a wretched modicum of paltry pelf, at a woful expense of time, and of talent, and of character, and whose necessary end must be the infinite production of "envy, hatred, and malice, and all uncharitableness."

I have yet more to say upon this subject, and I have especially to describe the mode in which several unions whose proceedings have fallen under my observation, have conducted the appointments of their medical officers. These matters will form the subject of a second, and perhaps, of a third letter. In the meantime, I am, Sir,

Your obedient Servant,

CHARLES VERRAL.

Nov. 7, 1835.

THE PRESTON DISPENSARY MEDICAL OFFICERS.

To the Editor of the London Medical and Surgical Journal.

SIR—As you have always evinced a desire to rectify abuses in the medical profession, and to expose the depravity of public officers to that obloquy which it merits, we trust you will permit us to lay before the medical public, through your journal, an instance of intrigue and faithlessness, that is, perhaps, unique in the annals of our institutions.

The principal medical institution in Preston is a dispensary, which was established in 1809. At first, it was managed by two or three physicians and a house surgeon. In 1830, three surgeons were appointed to assist in the labours of the establishment. The two senior physicians then consigned over to their surgical colleagues, such operations as they had previously performed; but the junior physician, Dr. Moore, tenaciously clung to his share of the surgical cases, and continued to act as a general practitioner, at the same time that he laid claim to the honour and fees of a physician in private practice.

Thus the business of the dispensary continued to be managed, till the senior physicians withdrew, and junior ones were appointed. These gentlemen, imitating, it is supposed, their senior, took their station as general practitioners also. There was no division into medical and surgical practice, but each honorary officer took all cases indiscriminately, that were presented on his day for the reception of patients. There were ostensibly, three honorary physicians and three honorary surgeons attached to the institution; and so the rules enjoined, and the reports continually declared; but in reality there were six general practitioners. Notwithstanding this anomalous state of things, the greatest harmony seemed to prevail among the honorary officers up to December last. Then an alleged irregular attendance of some of the medical officers, induced the sub-committee (whose duty it was to see that the affairs of the institution were regularly conducted) to inquire into the cause of the neglect, and where the offence rested. Dr. Moore (whether to screen himself from censure or not, he best knows) went to the sub-committee clandestinely, and told them that they must "look to the doctors," and they need not fear if some of the medical officers were to resign, as their places could readily be supplied. The truth of this statement Dr. Moore afterwards chose to deny, notwithstanding the united testimony of several of the members of the sub-committee, alleging that he had merely directed the sub-committee to "look after the shop," meaning the dispensing of the medicine, (the doctor's phraseology frequently needs interpretation), but unfortunately for himself, he

had declared to a medical friend shortly after meeting the sub-committee, that he had been telling them "to look after the doctors;" after hearing the testimony of that friend, he reluctantly admitted that he had made use of such an expression, but that it was by way of a joke. Some people, however, have such an odd way of joking, that no person but themselves can conceive how their expressions could possibly be construed into a jest.

The gentlemen of the sub-committee thought the doctor was in earnest, and as they had not the candour or honesty to bring the charge against the offenders, (and they well knew who they were), they hit upon the expedient of procuring a book, in which they resolved that the medical men should enter their names, and the time of their attendance, whenever they came to the institution. In this they exceeded their powers, for their duties were defined to be simply, to observe and report to the general committee. The book was first presented to the surgeons, who, not aware of any neglect on their part, and knowing that the sub-committee had no authority to enact any regulation for their guidance, naturally felt indignant at what they regarded as an insult, and immediately entered into a protest in the book, against the measure. This protest, the physicians and Dr. Moore, with the others, afterwards signed. The sub-committee were greatly displeased at this resistance to their assumed authority, and not a little surprised to find that the instigator of the whole affair was arrayed against them. The general committee was called together, and the medical officers, as part of the committee, attended the meeting. An attempt was there made to force the obnoxious regulation, but meeting with more resistance than they seemed to anticipate, the authors of the measure, with a very bad grace, consented to modify it; obliging the house surgeon to be the inspector, instead of compelling the honorary officers to be self-inspectors. The treatment which the medical officers met with at that meeting, was such, that they thought they could no longer continue to serve the institution, and shortly afterwards they all sent their resignations to the secretary, offering, however, to fulfil the professional duties till successors were appointed. The committee accepted the resignations, but took no steps to fill up the vacancies. Repeated meetings of the medical officers took place, at the suggestions of Dr. Moore, and at his house. He several times expressed great pleasure at seeing the unanimity that pervaded the meetings, and frequently reminded his colleagues, in his peculiarly elegant language, that "*there must be no splitting,*" but "*all must pull together.*" He required a pledge from his colleagues, *that no opinion should be given to the committee, or subscribers, without a general consultation, and that all must go out, or remain in together;* adding, *if any question be put to*

me, I shall say, I can make no reply till I have first consulted my colleagues.

In May, a meeting of the subscribers to the dispensary was called, to consider the resignation of the medical officers, and make some "verbal alterations" in the rules of the institution. Dr. Moore drew up a memorial to be presented to the meeting, in which he gave a partial statement of the causes which led the medical officers to resign their appointments, and in which he declared the differences between them and the committee to be "irreconcilable." In deference to his opinion, four of his colleagues signed this address, and were thus prevented from being personally present at the meeting. When the subscribers met, they expressed no opinion of the cause of the resignation, but they confirmed all that the committee had done, and passed a rule to exclude four of the honorary medical officers from the committee; thus actually attempting to punish them for having resisted a most arbitrary and uncalled for measure. The appointment of successors was still not made. When two of the surgeons became acquainted with the result of the proceedings of the subscribers, they felt disposed immediately to withdraw their services; but as it had been previously agreed to act in concert, they were wishful first to ascertain the feelings and intentions of their supposed friends before they took any final step. Accordingly, they called upon Dr. Moore, who met them with a smile, and the salutation of "Well gentlemen, I know what you have come about, but I have made up my mind to stay, whoever goes out; and I have told one of the subscribers so." When charged with violating his pledge, he replied, "Well, perhaps I have acted imprudently, but so I have done;" and then he threw upon the table an old coin, making some observation upon it, with a view to change the subject of conversation. He had suddenly discovered that, as he said, "it would not do to quarrel with the whole body of subscribers; that the poor should not be made to suffer for the faults of the committee;" and made use of a variety of other sentimental expressions of humanity, which he had entirely forgotten or overlooked for five months, during which the affair had been pending. The surgeons afterwards found, to their surprise, that the other two physicians of the charity, Drs. Alexander and Norris, influenced by Dr. Moore's representations, had also come to the determination to sacrifice their honour and consistency, to what they conceived to be their interest. Thus was explained a previous declaration of Dr. Moore's, that he knew there were medical men who would serve the charity, if the number of officers was reduced.

After such an instance of perfidy and deception, the surgeons considered themselves bound, for the honour of their profession, to separate themselves entirely from the phy-

sicians, and to act independently of them. They accordingly withdrew from the institution, and left the physicians in peaceable possession, apparently to their great satisfaction; although they had received official intimation that the committee had accepted their resignations, they knew that no apology would be offered for the insults which had been given to them, and with the disgrace of having one of their number excluded from the committee, and an inspectorship appointed over them. We regret, sir, the necessity of this exposure, and disclaim all feelings of personal animosity, but we conceive that it is our duty to hold up to public disapprobation, conduct so unprofessional, and so inexplicably base as that which we have brought to light. We offer no comments upon the previous statements, nor attempt to ascribe motives to individuals, but rest satisfied with a simple declaration of the truth, assured that we shall have the sanction of every honourable man to the course which we have pursued, and that reprehension will be bestowed where it is due.

We have the honour to be,

Your obedient Servants,

ROBERT BROWN, } Late Honorary Sur-
RICHARD INMAN, } geons to the Pres-
JAMES HARRISON, } ton Dispensary.

Hospital Reports.

NORTH LONDON HOSPITAL.

Clinical Remarks on cases of Rheumatism, and Scabies complicated with Impetigo. By Dr. Elliotson.

GENTLEMEN—I have to speak to day, of four cases of rheumatism, three of them inflammatory, one of them of an opposite character; it is not a mere chance that three of them are inflammatory, for you will generally find a greater number of cases of this species of the disease than of the other. The cases we shall have to consider, all occurred in men; this is not accidental either, for men are much more exposed, from the nature of their employments, to the causes of rheumatism, than are the opposite sex.

The first case is that of Thomas Welsh, aged 18, who was admitted August the 1st. He states himself to be a hair-dresser, that a few days ago he received a blow on the left elbow, which produced an abscess; the left shoulder soon after became swollen and painful, and the right one soon became similarly affected. He has sweated a good deal since the commencement of these symptoms. Now, you will generally find the patients sweat in the beginning of rheumatism, if kept at all warm: sometimes it is very profuse; sometimes, however, there is only pain,

without sweating. The pain is neither aggravated or relieved by heat; pulse 96, sharp; the tongue white, and moist. You will generally find this sort of tongue in acute rheumatism—not a furred or red tongue, but more or less moist and white. The bowels are confined; urine high coloured; great thirst; skin hot; no pain in the head.

28th. He was bled to eighteen ounces, and a draught, containing 3 ss. of the vinum colchici, ten grains of the carbonate of magnesia, one drachm of the sulphate, and one ounce of water, given every six hours; and to open his bowels, eight grains of calomel given at bedtime. The blood was bled and cupped; this you will find is generally the case in acute rheumatism. The pain and tenderness in the shoulders were not much relieved, and on the 19th he was bled again, and five grains of calomel given every six hours. The report on the 1st of September states that he slept better last night; as his shoulders still continued painful, ten leeches were applied to each of them, which considerably relieved them; as the mouth was getting sore the mercury was omitted; the blood was bled and cupped.

8th. As the pain in the shoulders still continued severe, a quarter of a grain of the muriate of morphia, the usual dose, was given him every night: there is no objection to this medicine in inflammatory rheumatism, when you have abstracted blood, and given colchicum and mercury at first. Sometimes you will find the inflammation gives way when the mouth becomes tender; in some cases, however, it requires to be very sore before it has a decided effect on the disease. It is my plan always to leave it off when the mouth becomes affected, because, by continuing it afterwards, you cannot tell to what extent the soreness may go; if you find the soreness going off, without curing the disease, you can have recourse to the medicine again.

10. Still finding the pain and tenderness to be severe, six leeches were applied to each arm, and on the 12th, twelve more to the left shoulder, and five grains of the pil. hydrarg. were ordered three times a day; the pain, which had been severe, was somewhat relieved by the last leeches; blisters were applied to the shoulders. On the 19th the pain is reported to be more severe during the day than at night; the mouth is not affected by the mercury; the morphia was increased to day to half grain doses, and the colchicum mixture given every six hours; fifteen leeches were also applied to each shoulder. On the 23rd, the shoulder joints were still very painful, but less so than at the last report. Now, a very unusual circumstance occurred in this case: the cellular membrane around the shoulders became inflamed and suppurated; now, in rheumatism of the inflammatory kind, there is generally swelling of the cellular membrane around the joint, as well as swelling of the bursæ, from too great

collection of synovia, but here the cellular membrane suppurated, and the matter had to be let out; we cannot, however, say that rheumatism produced the suppuration, for the cellular membrane is evidently not the seat of rheumatism—that disease is situated in the ligaments and aponeuroses, which do not suppurate in this manner; but phlegmonous erysipelas was excited in the surrounding cellular membrane, and it suppurated. The pulse fell immediately. Mr. Morton had given egress to the matter, a considerable quantity of which was discharged. From this time he continued to improve, and was discharged well, on the 27th of October.

The next case is that of D. L., aged 40, who was admitted on the 22nd of August. He states himself to be a pewterers' labourer; he was some time since in the hospital for palsy, the result of his employment being amongst lead; he left the hospital much relieved, but the palsy returned soon afterwards. He now complains of great pain in the hips and knees; the pain is much increased by heat; he has profuse cold, sour sweats, complains of weakness in the limbs; the arms are rather tremulous. You will frequently find that in the higher, as well as the lower classes, patients will complain of debility in the limbs, when there is no real weakness existing, but only pain on motion. His eyes were suffused and blood-shot, he feels giddy, and occasionally has pains in the head; pulse 94; tongue white, dry; bowels confined; urine high-coloured. We gave him a mixture like that in the last case, and his pains were much relieved. On the 17th, the report states he is much improved: as he is very weak, and has had a shivering fit, quinine was ordered him, and the colchicum omitted. On the 1st of September pain came on at the bend of each elbow; this was evidently rheumatic, but not of the inflammatory kind; I therefore, gave him four grains of the hydriodate of potash in solution, three times a day. This fact illustrates that an inflammatory species of a disease may and does often go into the opposite kind, and requires an opposite plan of treatment, so that you have to ring changes. On the 5th, the pain was still in the fingers, wrists, and elbows; a blister was therefore applied to the right arm. On the 18th, as the shivering continued, he was ordered to increase the quinine to ten-grain doses; which was still further increased on the 15th, to fifteen grains.

26th. No shivering fits since last report. He continued to improve until the 27th of October, when he was discharged well.

The third case is that of a young man, whose rheumatism was of an inflammatory kind; he did not require very active treatment: we cupped and purged him, and shortly afterwards he was discharged, well.

The next case is one of an entirely opposite character; you will see the difference

immediately. J. S.—, aged 40, was admitted on the 19th of September. Five years ago he caught cold, while riding on the outside of a Brighton coach on a cold wet night; a week afterwards he felt pain on the outer side of the left ankle, which soon extended up the leg and thigh in the course of the sciatic nerves, as high up as the great trochanter: he was under treatment for three months, when he recovered. He had a similar attack about two years since, and again, for the third time, about four weeks ago; he cannot assign any causes for the last two attacks. The pain has continued to increase since the commencement of the attack until now. The present symptoms are severe pain along the course of the sciatic nerve, popliteal and external cutaneous nerves of the left leg, from the great trochanter to the external malleolus; there is tenderness on pressure over these nerves, and pain on each side of the knee, on attempting fully to extend the leg. The pain is more severe when in bed at night, and he gets little sleep; it did not, however, appear that it was the warmth of the bed that affected him, for the pain was relieved by the warmth of the fire. There is great weakness, and frequent tremor of the limbs, no redness or swelling; the left upper arm is sometimes slightly affected; tongue white; little appetite; some thirst; pulse 80. Mr. Taylor made an accurate diagnosis in this case; he ordered the patient to have half a drachm of the volatile tincture of guaiacum; this was a very proper dose for a man; it might be well, in case your patient was a delicate female, to commence with ten drops for a dose, and to gradually increase it, until it is effective; the effect of an over-dose is to produce sickness, feverishness, or purging, or even all of them combined: it is, however, common for it to produce purging when given in proper doses. On the 21st, the medicine not warming him, or producing sickness, the dose was increased to a drachm; on the 24th, to a drachm and a half, and on the 28th, to two drachms; and he was ordered a warm bath. On the 30th, he used a liniment of olive oil and turpentine, applied to the affected parts. The bath gives him relief for three or four hours after using it. On the 1st of October, the dose of the medicine was increased to three drachms.

On the 5th, he is reported better and the medicine has rather purged him.

On the 9th, he had less pain, the medicine warms him, but he don't know for how long after taking it, the warmth continues; the leg is warmer than it was. Now, I have had to give a large dose of this medicine, as much as two drachms and a half, or three drachm doses to old people before I could warm them. As I have said before, increasing this medicine, by degrees is much better than giving large doses at first, if sickness is produced by it. Hydrocyanic acid is not likely to relieve it, from the stimulating character of the medicine. Now, had this patient gone on

with half-drachm doses of this medicine, it is likely it would have done him no good; you will hear people say they have taken this medicine, and that for a length of time without experiencing any benefit from it; it is often so with this medicine, but the question arises, How did you take it? in what doses? and for what length of time?

Now, when your patient gets to be warmed by this medicine, you may reduce the dose—sometimes they are warmed, at first, for an hour or two, then for three or four hours, and so on, until they are always warm. Our patient had a little diarrhœa come on, but this was stopped by one or two doses of opium; he continued to improve and was discharged on the 3rd of November, well.

Now this patient I am sure would not be relieved by colchicum; mercury might have relieved him, for it is effective, both in cold and warm rheumatism; the hydriodate of potash might also have done good.

Sir Gilbert Blane states that this medicine is useful in active inflammatory rheumatism, when it occurs in scrofulous people, but I should fear it would be too stimulating; I should fear it less for its purging than for its stimulating effects.

Scabies with Impetigo.

M. N. was admitted, Oct. 13. About a fortnight since, she observed an eruption about her ankles, and the dorsum of her feet; soon after, it appeared in front of her legs, and back of her hands and wrists; lastly, on her arms, chest, and side of the neck. It was attended with a sensation of heat and itching on the foot and about the wrists; a few small phlyzaceous pustules presented themselves on the arms, legs, and neck; the eruption is in the form of vesicles, congregated together, and attended with inflammation, much heat, and itching; her general health is good; she was bled to twelve ounces, and used the warm bath; the sulphur ointment was rubbed in; the next day the blood was bled and cupped; the eruption is better; there is less heat and itching: as the bowels were confined, she had a purgative given her. On the 24th, the eruption on the feet and hands had much declined; that on the arms and legs remained the same; she complained of heat and smarting in those places, from the application of the ointment, which was ordered to be omitted. On the 31st, the eruption on her feet and hands had almost disappeared; that on the arms, legs, and neck, was paler, and discharges a little. On the 10th, she went out well.

Now, we have had several cases like this since the hospital opened; patients have had the itch cured with the sulphur ointment, but the itch was complicated with another cutaneous disease, which was made worse by the ointment; these sort of facts sometimes puzzle people. I soon found at St. Thomas's, that in itch the skin is sometimes very irri-

table, and as long as the sulphur ointment is used, the irritation goes on; one part of the skin being irritated, irritates the other by sympathy, until the whole limb becomes in a state of inflammation, and is red and rough; sometimes eczema takes place, and sometimes even impetigo: it was so in one case. It is useful to bleed in these cases, not to cure the itch, but to relieve the irritation of the skin; we also kept her bowels open for the same purpose. Specific inflammatory cutaneous diseases, though somewhat relieved by antiphlogistic treatment, must have a specific remedy for their perfect cure.

Cases of Dyspepsia, Scrofula, and Phthisis, with Clinical Remarks, by Dr. Elliotson.

Creosote in Phthisis.—The first case, gentlemen, I have to speak about is a very unsatisfactory one, from the treatment being incomplete, the patient leaving the hospital before he was cured. He was, however, greatly relieved by the plan we pursued, and, had he stayed, would, no doubt, have received still further benefit from the medicines he was taking. It was a case of severe dyspepsia, in which a vast quantity of acid was generated; sometimes in this disease you will find there is no increase of the acid, beyond the usual quantity in health, the fluids being neither acid nor alkaline; in other cases the acid is so strong that it would corrode the stomach and throat, were not the mucous membrane lining those parts so well protected. The case is that of P. E. who was admitted on the 8th of September. The report states that he had had syphilis, which was treated with mercury; a node formed on the tibia, succeeded by an abscess, which was opened; the bone is now exposed to an extent of three or four inches, quite black and moveable. On his admission, he complained of burning pain in the stomach on taking food; he relieved himself of this pain by inducing vomiting, which he accomplished by putting his finger down his throat. Now, I have had this burning pain when ill with other diseases, and I relieved myself by vomiting induced in the same way. Water and oysters are the only things which do not give him pain on being taken into the stomach. When he vomits, the fluid ejected burns the throat and mouth, and is intensely acid. He has been within these three weeks in St. George's Hospital, under Dr. Macleod, who gave him complete relief by giving him hydrocyanic acid; but when he was transferred to the surgeons, and discontinued its use, the disease immediately returned. He has had rheumatism in the upper extremities, but as he got stronger, from the bark which was given him while under treatment for the dyspepsia, the pains left him. At present there is tenderness on pressure over the epigastrium, but otherwise no pain except when he takes food. His appetite is good, but he retains nothing on his stomach. He has insatiable thirst,

which soda-water relieves more effectually than anything else. He loses a good deal of blood from piles; he says he has had as much as a cupful come away at once; the quantity, however, is generally much less. His countenance is pale; lips and gums less red than usual; tongue pale, moist, and clean; bowels open; motions natural. Now, the anemia was from want of blood—from loss of blood—he was a good instance of great anemia. Great thirst is not an uncommon thing with persons who have too little blood—they often complain of thirst; but the acid coming up would in this case itself have caused thirst. I thought this a good case for the administration of creosote, and therefore ordered him two grain doses: from this he did not receive any benefit, but the pain was rather increased. His was not common vomiting; the acid being present, came up without the effort that attends vomiting. This was an instance in which creosote did not agree; where there is a little inflammation, the administration of creosote does harm—such is the case, probably, where there is a raw surface. The stomachs of some persons will not, however, bear the smallest quantity of creosote. It appears that it did not suit our patient; but he had an aversion to it, and he might have said it increased the pain because he disliked it. It is, however, wrong to disguise any fact; for though I believe creosote to be an admirable medicine in these sort of cases, still I know that it is not infallible, and there are cases in which the employment of creosote is proper for the disease, but it does not suit the individual. We subsequently gave him carbonate of iron for the anemia, and small doses of the hydrocyanic acid and creosote, which seemed to agree with him. Under this treatment he became much improved, gained strength and colour, but it would have required at least two months longer of the treatment to have cured him. It is probable the discharge from the rectum had continued too long to be entirely removed, and he would still have been kept with a deficient quantity of blood. The treatment, I have said, was imperfect; had he stayed in the hospital I should not have altered the plan of treatment, but continued with the same remedies. He went away a few days since.

LECTURE XXV.

*General and Partial Chronic Gastritis, or
Indigestion.*

CHRONIC inflammation of the stomach may be either partial or general. When general, the rest of the digestive canal being sound, or nearly so, there is sensibility of the gastric region, and the stomach prevents digestion; in which case one of two things occurs—there is either inappetence and impossibility of swallowing food, which is seen in the highest shade of it, or the patient swallows, but afterwards vomits. In both cases there is inability to bear a sufficient quantity of alimentary matters to sustain nutrition and prevent emaciation of the body. The sensibility varies with individuals; some are exceedingly tender about the pit of the stomach, others not at all so; some are pained by the introduction of slightly irritating matters, but bear mild and fresh alimentary matters: in some mild substances give as much pain as those that are irritating: some experience great pain over the whole chest, or at least in the lower half: these, when they swallow anything irritating, experience the feeling of having received a blow in that spot, or as if the skin were lacerated or burnt—for the sensation is just as referable to the skin of the thorax as to the stomach.

When this inflammation is intense, without, however, proceeding to a febrile degree—for then we should fall into the shade of cholera morbus, and there only needs an untimely administered stimulant to bring it to that shade—when, I say, this inflammation is vivid, the patients experience sensations of lassitude, of fatigue and prostration of the powers; they are of necessity downcast and become thinned; they are thirsty, but, as they are unable to swallow with comfort, they drink but little, and pass scarcely any urine, the consequences of

which are inflammations of the urinary passages, dry skin, deep redness of the apertures of the mucous membranes, sunken eyes, red conjunctiva, red and rigid tongue, with enlarged follicles at its root. Some of these symptoms attach to the preceding shade; but in that the belly is more retracted, there is some evacuation, with diarrhœa, pain, &c.; whereas in that now under consideration there is no evacuation whatever. There is only a step from this disease to the other: it cannot even long remain in this condition, it must either rise to the acute state, or diminish and pass into the intestines, leaving the stomach at liberty to digest, or it must become partial in that organ—and this last is the more frequent case.

The signs that announce the acute stage are easily recognised—fever supervenes, the tongue becomes dry and burning, and ataxic phenomena, or those of cholera morbus, come on.

The signs that announce the generalization of the disease in the digestive canal are heat of skin, tumefaction of the belly, thirst, ability to drink, inappetence, renewal of the absorbing faculty, and typhoid symptoms.

The signs that announce the cessation of the disease in the stomach, and its transfer to the intestines, are the possibility of drinking without pain, tumefaction of the belly, meteorismus, little or no fever (without which sign it would be an acute gastro-enteritis), ingestion of food without pain of the stomach, provided the food is not too exciting, but return of pain when the aliments have passed down into the intestines.

The signs that announce the dissipation of the disease in the stomach, without transfer to the intestines, are the return of health and the re-establishment of the digestion. But there almost always remains a marked irritation in some point of the stomach, in the great sac, the cardia (upper orifice), or the pylorus (lower orifice), and then the signs of partial chronic gastro-enteritis come on. These partial gastritis are perhaps the most interesting, because they are misunderstood by persons who have not made a particular study of the affections of the digestive canal. They have given rise to a host of errors and false assertions, especially when they are of long continuance.

They are ordinarily seen in persons that have had repeated attacks of acute gastritis, who are no longer subject to it, who have not been completely cured, who have relapsed into them by too early stimulation, by mental affections, or by bad regimen, and who have conducted themselves intemperately before the phlegmasia was past. They are common among individuals who have been treated according to the old method, and they frequently end in the neuropathic or nervous state. Once established they may pass through numerous changes: sometimes they augment, extend in the viscus, and render the patient unable to eat: they have recourse to emollients, to which they are forced to adhere until the irritation is calmed in the once sound portion: the appetite then returns, they begin to eat, at first with success, during a few days or weeks, but subsequently they become unable to support nourishment, and are obliged to return to strict diet: and this routine occurs three, four, or more times successively. In this manner they pass the greater part of their lives with this partial gastritis, invading, from time to time, the sound regions of the organ, and then retiring into its former limits, until it rises to the acute condition, which disorganizes the stomach, or a scirrhus degeneration takes place in the part where it predominated, or it passes into other diseases, such as peritonitis, pulmonary consumption, apoplexy, &c. A vast number of individuals live on with this complaint. In it the employment of stimulants in chronic affections of the stomach found a support; they appeared to effect a cure, especially if the patients had been kept on low diet; but relapses took place, of which no account was taken, or which were attributed to different events with which they had no connexion. These phlegmasiæ have made the fortunes of some physicians into whose hands patients fell who had been treated too severely or too conscientiously by physiological physicians, and to whom the latter had been too tardy in allowing food, desiring, as they did, to wait a few days longer; meanwhile a stimulator came in, who worked a cure for a time, if the partial gastritis was not entirely cured, and definitely if it was.

Chronic partial gastritis have three principal points of existence, the cardia, the great sac, and the pylorus. Persons attacked with gastritis of the cardiac orifice suffer pain in deglutition; when the substance enters the stomach it seems to pass through a painful ring, and belchings, and convulsive movements of the stomach, with a burning feeling, supervene. If the disease is not excessive, they are able to ingest, and the ingestion over, they digest; but towards the close of digestion, when the chymic pulp has become somewhat strong, the pain of the cardia recommences, or is felt at the left side of the breast bone, behind the left

breast, or it strikes to the back, beneath the shoulder blade, in the left shoulder. This partial gastritis readily acts upon the heart, if the persons have that organ very sensible or enlarged, and produces palpitations. It is accompanied with a sense of ardor of the pharynx, which is sometimes inflamed and red, and always hotter in this variety than in the others. Patients have in the morning a great flow of acrid and acid saliva, which sometimes injures the teeth; in short, a powerful influence is excited by this phlegmasia over the throat, the salivary glands, the arch of the palate, and the pharynx. There is frequently great dryness of the back of the mouth, so much so that a thick and tenacious mucus collects about it, until the patient cannot clear his throat without having efforts at vomiting. When the disease has arrived at the highest degree it produces vomiting: this, however, is rare, because at such a degree it becomes general in the stomach, and is confounded with general gastritis.

It may end in a state of scirrhus; but it is difficult to ascertain this, and it can only be perceived from certain data, for instance, from a scrofulous disposition manifested by swollen glands of the throat, by a pale complexion and lymphatic constitution, or by taking cognizance of the scrofulous or scirrhus state that may have existed in the nearest relatives of the patient, in which they have sunk. Percussion cannot throw much light upon it, because to render the sound dull the scirrhus must have become enormous, in which case the patient would have perished: besides which the vicinity of the heart would prevent an accurate distinction of the dull sound of the scirrhus.

When inflammation predominates in the great sac, the patients swallow without pain; but after the entrance of the aliments into the stomach, instead of experiencing the pleasing sensation which they do whose great sac is sound, they have a disagreeable feeling. If the aliments are exciting they feel an acrid heat, as if a painful girdle were pressed round the bottom of the chest, and hiccough supervenes. The pain augments towards the close of digestion, as in the preceding case, that is about three hours after the meal, when the chyme is formed and ready to pass the pylorus.

Each of these partial gastritis develops in a manner peculiar to itself. The last named is discovered by a deep seated pain in the region of the spleen, underneath the left hypochondrium: it shoots to the back, but less than the preceding, and does not act on the heart unless it radiates upwards to the cardia. The pain that accompanies it is exceedingly harassing for several hours, and more violent as the aliments are entering into the advanced stage of digestion. The affection is, by ignorant medical men, mistaken for an affection of the spleen, the more as when it has endured for a long time

the spleen becomes swelled, as you may readily imagine from the vascular connexions between it and the stomach. The great sac of that organ being in a continued state of irritation and habitual engorgement, the spleen also becomes irritated and contracts adhesions to it: it is in such instances that we behold hemorrhagies, the material for which is supplied by the spleen, and which are particularly common in gastritis of the great sac: these hemorrhages go by the name of *melæna*.

The progress of this affection varies as the preceding did. If it has been badly treated it may end in ulceration: the spleen is applied to the stomach by the contraction of the cellular tissue that unites the two organs; they become adherent to each other, and the ulceration may go on to the establishment of a communication between them: the inflammation may then extend and pass into the state of general gastritis or gastro-enteritis, in which the patients perish. All these phlegmasiæ tend to the acute stage, and to kill the patients with typhoid symptoms; or else they become thin, and after being for a long time able to eat, they lose all such power, the alteration of the great sac being consummated, and the stomach no longer fit for the execution of its functions, they then die in a state of marasmus, and with horrible vomitings.

Nor is the scirrhus condition of the great sac cognizable, on account of the spleen and colic epiploon, which, when the affection is vivid, contracts and closes along the arch of the colon, where it forms a tumour that may be mistaken for the stomach. Facts of this kind authorize us to say that neither nosological classifications, nor the therapeia can be grounded on the different modes of alteration in the organs: we can only be guided by the seat and the degree of the irritation. In this case, moreover, the pancreas and cellular tissue may become swollen, tumefy, and give rise to mistakes.

Partial gastritis of the pyloric region is, perhaps, more common than the others. The signs of it are as follows: no pain is felt in deglutition, nor towards the heart, nor the back, as in the preceding cases; the ingestion of food is pleasant, and the appetite even sharp; but towards the second or third hour of digestion the mischief begins: the patients have pains of the right hypochondrium, that shoot up to the shoulder, just as those of the cardia do, only that they have no effect on the heart. If the affection is extended to the small arch of the stomach, painful sensations proceed from it to the tonsils, when they resemble the prickings of a lancet. The third hour of digestion arrived, these pains increase; belchings, and sometimes rumination come on: the food is rejected by gushes. At the beginning, all the aliments are not rendered, and in some individuals nothing but glairy mucosities are at first thrown up; but as the disease

augments, the patients reject all food that has not agreed with their stomachs, such as milk, farinaceous, or spoiled and insipid substances; but they retain meat. Other patients do not vomit at all, but suffer considerably during the time the stomach is being emptied. I have opened a woman who died of scirrhus, occupying the whole extent of the pylorus and duodenum, and in whom a small canal was seen passing through the thickness of the lardaceous induration, through which it would have been impossible to transmit a crowquill. This woman had never vomited: no food had ever risen in the month; but she was twenty-four or thirty-six hours in effecting digestion, suffering, meantime, all imaginable tortures—*anxiety*, great *malaise*, burning of the stomach, lancinating pains of the chest, shoulder, and clavicle, simulating mischief of the lungs, and tenderness about the liver, which deceived several medical men, and made them affirm that that organ was disordered. Indeed, it is a common error to attribute pains and dragging sensations of the right shoulder to the liver alone; for they may proceed from the pylorus, the duodenum, and the liver, seeing that the same system of nerves is common to all those parts. I have seen them in the liver in cases of penetrating wounds of that viscus: they are daily seen in duodenitis, without any disease of the liver: and may be even observed in chronically-affected pylorus.

When the disease has continued for a long time, we usually say that vomitings supervene; but previous to that, the inflammation may become generalized, and the patient be led into a typhoid condition that puts an end to him. The disorganization is then laid to the account of the acute state, because it is very difficult in autopsies of acute gastro-enteritis (typhus, putrid, and adynamic fevers, dothientery, &c.), to distinguish what appertains to the chronic state, from that which is the sole effect of acute inflammation. If the patient dies not thus, he undergoes the fate reserved for him in the preceding cases; he becomes emaciated, falls into marasmus, has a host of neuropathic symptoms, and sinks. Occasionally the stomach dilates sufficiently to hold several pails-full of solid and fluid matters, and the patient does not vomit them until his belly is enormously swelled. At other times the patient becomes incapable of vomiting, and he dies in inexpressible torture: this occurs when the great sac is softened, its mucous and muscular membranes destroyed by the inflammation, and the stomach is unable to contract. Sometimes the coats of the stomach give way at the points where they are most softened. Again, the incapability of vomiting may proceed from the absorption of the muscular fibres, and the deposition in their place of scirrhus and lardaceous tissues, in which case there is generalization of an affection that was in

the first instance partial in the organ. Such are the partial chronic inflammations of the stomach.

Scirrhus is more readily ascertained in the pyloric than in the other regions, because it is then more accessible, and less liable to be confounded with the neighbouring organs. If in a patient who has had the symptoms of partial gastritis of the pylorus, we find an ovoid induration behind the right false ribs; if pressure on it is felt in the stomach, provokes nausea, and brings on sympathetic pains; if, at the same time, the liver is confined to its normal position, and does not project beyond the ribs, so as to render any tumefaction of it distinct from that which we are diagnosing, there is a probability, and even a certainty of the existence of scirrhus of the pylorus. I am unwilling to say *complete* certainty, because a lymphatic tumour may exist in the laminae of the cellular tissue surrounding the pylorus; there may be a considerable tubercle situated on the exterior of the stomachal parietes, and produce the same effect on pressure, as an engorgement of the pylorus; the gall-bladder with contained gall-stones may produce the same effect; and lastly, the stomach may be upraised, for not uncommonly there are displacements of the viscera, in persons who have been long sufferers with similar affections. It may, therefore, be sometimes difficult to determine with accuracy the seat of a tumour, and the tissue to which it belongs. For the rest, the remaining probabilities are drawn from the circumstances of which I spoke, when on the subject of scirrhus of the cardia.

Chronic Duodenitis.—I proceed to this phlegmasia before giving the treatment of the preceding, because pretty nearly the same treatment applies to all, and repetitions are thus avoided.

When inflammation predominates in the duodenum, it has considerable resemblance to that of the pylorus: from that, however, it is possible to distinguish it. The pain that is felt towards the close of digestion, and which is common to gastritis of the pylorus and duodenitis is not, in the latter, necessarily accompanied with belchings and tendency to vomiting: there is also a propagation of pain towards the shoulder: the patients have a feeling of heat across the part immediately below the stomach, at the time when the aliments are passing along the duodenum. This heat may be mistaken for that of the stomach; but by attentive examination the error may be avoided: you are aware, that when stimulating aliments have been taken, a sensation of heat is felt in the stomach, which, however, soon passes; but in three or four hours after this heat, without the ingestion of anything in the interim, another heat supervenes, which appears also to be a heat of the stomach, and is accompanied with pains and prickings in the right hypochondrium:—this is peculiar

to duodenitis. In the best health something analogous is experienced at the close of the stomachal digestion: a slight transitory pain is felt, connected with a sensation of cold and yawning: it is this heat, in a morbid degree, that exists when the duodenum is chronically affected.

Duodenitis being prolonged in this state, tumefaction and painfulness of the liver and of the whole right side of the trunk comes on, more particularly recognizable by pressure, and sometimes propagated to the lungs and kidney of the same side. But as the passage of aliments by the duodenum is only transitory, as the secretions in it are copious, and as it possesses great facility of excretion, as the bile flows thither, the mucosities produced by the irritation are evacuated, and the stools are abundant: all this process of secretion and evacuation puts a stop to the suffering, and the patient feels quite well after the termination of digestion: he is neither subject to flatulence, nor risings in the throat, nor to the unceasing uneasiness that is observed in gastritis of the pylorus: he only suffers more or less in the right side during the second part of digestion, after which he is at ease. This irritation would even seem frequently to cause an increase of digestive activity: the patient makes blood, becomes fat and subject to piles. This is also owing to the fact that duodenitis is often the effect of excesses of the table, and especially of the more substantial and stimulating aliments. There are very few men of easy circumstances, and who live as they please, who escape attacks of this affection between their fortieth and fiftieth year, and frequently as early as their thirtieth; notwithstanding which they seem to be in tolerably good health, except that from time to time they have bilious attacks, now and then vomiting, colicky pains, occasional bilious stools, and attacks of jaundice: a tenderness of the right hypochondrium rouses their attention; they apply to medical men, who purge them; the purgatives relieve them, and the disease is palliated. It returns once or twice during the year. Patients of this kind, huge feeders as they are, making as they do double the quantity of blood that is requisite for the regular maintenance of their functions, are in a constant state of hyperemia and hypersarcosis, and become subject to hemorrhages, affections of the kidney, rushes of blood to the head, apoplexy, &c. If to all this there is added—as there frequently is—enlargement of the heart, the latter favours the congestion of blood about the right hypochondrium, and they have pains there, with difficulty of breathing.

This disease is described by authors under a host of different names. It may continue for a long time without causing serious mischief, because the continued evacuations that go on prevent its rapid progress. Still it *does* make progress, and many possibilities

present during its course. The inflammation may become general in the apparatus of digestion, and pass to the state of acute gastro-enteritis, an affection that is then of great import, and seriously implicates the brain: it may not extend, but only predominate in the lower parts of the bowels; a peritonitis may ensue upon it, for this too is one of the not-uncommon chances of gastro-intestinal inflammation. Generally speaking, not more than two or three attacks of acute gastro-enteritis occur in the course of a life: after these attacks, it passes to the chronic condition, not because it is a speciality, but because it is man's nature rarely to pass through frequent onsets of the same acute disease. This is a truth that has not been much suspected, and it constitutes one of the principal dogmata of the physiological doctrine: almost all men who die in the middle period of life are killed by a chronic phlegmasia that has become acute; and such is frequently the fate of persons labouring under chronic duodenitis.

After repeated disturbances of the stomach, repeated hemorrhoidal crises, attacks of vomiting, threatenings of various congestions, seizures of gout or nephritic affection, all more or less completely cured, the scene changes; constipation, invincible constipation, comes on, bile ceases to flow, the liver no longer secretes, becomes altered in structure, fatty, tumefied, or scirrhus: sometimes gall-stones form in the gall-bladder, or in the biliary ducts, and add to the sufferings of the patient, who now begins to lose all colour; the appetite fails; he is no longer moved without the aid of purgatives, into the habit of taking which he falls, and by which he, for some time, prolongs his existence. But at length the effect of purgatives wears out, the fluid secreted by the liver is no longer recognizable as bile, and the organ itself becomes of a waxy whiteness: the belly tumefies; the patient has incessant belchings: the digestion of the food is long and painful, and finally the latter ceases to pass out of the stomach at all. Then comes dropsy of the belly: the swollen liver is pressed on by the effused fluid: the patient never regains health, but lives a varied period in this condition, with a yellow skin, a face-like wax, feeble, dropsical, and languishing, until an effort of acute inflammation is made, and carries him off.

This termination is common among drunkards that have abused spiritous fluids through a long period of time. Such fluids have been regarded as exerting a debilitating power peculiar to themselves: this, however, is not the case, for the debility is preceded by a long continued irritation, and the organs lose the capability of exercising their functions only in consequence of having been irritated. In this case the affection of the liver is almost always consecutive on that of the duodenum, and it becomes fatal

if treatment be not applied before the mucous membrane has been deteriorated in structure, and unfit for action.

CASES WITH CLINICAL REMARKS, BY DR. ELLIOTSON.

—

Gout—New Remedy—Gastrodynia, and Chronic Gastritis—Sub-Phrenitis—Hepatitis, Autopsy, Softening of the internal Organs.

GOUT.

GENTLEMEN—I have to notice a case today, not generally met with in hospitals—gout, *podagra*, as it is called—but that term would imply a disease affecting the feet, but gout is called so wherever it appears. It has also been termed *arthritis*, which would lead us to suppose the disease was confined to the joints, but we find it in other parts though it generally does affect the joints. *Podagra* is a generic term as applied to the disease; we use it in this case in the correct sense—a disease affecting the feet.

W. P., aged 60, was admitted, Oct. 20; he describes himself as a coachmaker, he is a strong muscular man, and has, generally, enjoyed good health. He represents himself as a man of very moderate habits, never addicted to gin-drinking, but making porter his principal beverage. About fifteen years ago, being in the service of a wine-merchant, he was in the habit of drinking wine, but not immoderately. His father had never been affected with rheumatism, but his mother had been often troubled with that complaint. He had a rheumatic attack three years ago in the feet, and had experienced several slighter attacks since. Last Friday-week he was seized suddenly in bed, between the hours of 10 p. m. and 5 a. m. with pain in the hands and elbows, which extended afterwards to the knees and feet. He has had no medical advice for the complaint, but took some antibilious pills from a chemists shop, which did not give him relief, though they had the effect of opening his bowels. He now complains of pain in the elbows and hands, particularly in the right one, and also in the knees and ankles. The joints of the ring finger of the right hand, the ball of the great toe of the left foot, and the internal malleolus of the right are inflamed and tender on pressure. The pain intermits, being most severe at night; it is of a shooting, darting, gnawing character. His appetite is good, his tongue clear, he has no thirst—bowels not very open; he voids a good quantity of urine, which does not deposit any sediment. Now, I inquired of this patient where the disease originally affected him, and he said, "in the ball of the great toe." I asked him, to ascertain if the disease he was labouring under was gout; the attack came on in the night, the joints became sud-

denly swollen, red, and shining; he had had frequent attacks of the kind before—there could be no doubt he was suffering from gout. Now, gout seldom attacks persons before the age of fifty, but if the causes of it are applied, or if there be a strong hereditary predisposition to it, it may occur even in childhood; I have seen cases which happened before puberty. Now, we do not know whether the disease in this case was hereditary, but his mother had often attacks of rheumatism, was frequently crippled with that disease; she might, however, have been a sufferer from gout. His make was that which we generally find in gouty persons. Now, I do not think that gout is produced by drinking ardent spirits, on the contrary, I believe it frequently prevents it. I have seen cases in point. It is not so, however, with wine; our patient drank wine fifteen years ago, which might in him have been a predisposing cause of the disease, being as he is of the gouty make; particularly if he had hereditary predisposition to it. We immediately gave him a draught containing the colchicum wine half a drachm, one scruple of the carbonate, and one drachm of the sulphate of magnesia every six hours, in some peppermint water, for the benefit of his stomach. On the 21st he was much better, the pain in the affected parts being considerably diminished; the bowels had not been opened by the colchicum—you will find the symptoms sometimes give way before the colchicum produces purging, but they generally give way much better when the bowels are purged. He went on very well, under the treatment, till the 30th of October, when he was attacked with a very acute pain in the left knee. Now, a short time since a Swiss physician sent a letter to me which he had received from a French gentleman at Nantes, which states that the writer had discovered as certain a cure for gout, as quinine is for ague; he offered me a supply—the medicine is in the form of a liniment, which is to be applied to the external surface of the body. It produces no sensible effect, but removes the disease. Now, it could do no harm—it was not to be taken internally—but as I have said, only to be applied to the surface of the body four times a day; I do not know its nature, but it smells like camphor. I did not see any objection to the use of it; I therefore ordered our patient to be rubbed with it on the 30th. On Nov. 2nd, the report states that he feels pretty well, but is not able to stand on the left foot. On the 6th, he had pain in the whole of the left arm, but his feet were relieved. On the 9th, he was free from pain and was shortly afterwards discharged, well. Now, I cannot say, whether this liniment did good or not; gout, we know, does not last forever, and I, therefore, cannot say what effect it might have had in this case; however, I have twenty-four bottles, I believe, of this lini-

ment; any gentleman having the gout, or a friend afflicted with the disease, I shall be happy to give a bottle to, but, I must confess I am rather sceptical on the subject that rubbing a liniment on the surface of the body can have any effect on an attack of acute gout. This case, certainly, cannot speak much in its favour, for the patient had a severe attack a few days after commencing the use of the remedy. The gentleman who sent me the medicine, states that he had just applied it in the case of an ambassador of the Great Powers who was suffering from a severe fit of this disease—he got well in two days. He does not say whether any other medicines were used.

Gastrodynia—Chronic Gastritis.

I proceed now to speak of two cases which illustrate the necessity of opposite plans of treatment where the symptoms are somewhat similar; they are both cases of affection of the stomach. The first case is that of C. M., aged 21, who was admitted, Oct. 20; he is a tall, slim young man, by trade a tailor; has generally enjoyed good health, except about four years ago, when he suffered from an attack of pleurisy, from which he entirely recovered; he states himself as a moderate man not addicted to drink; this is a very rare circumstance indeed among tailors, for they generally are very intemperate. He has led a very sedentary life, working sometimes 18 or 19 hours a day, and seldom taking exercise. This is great confinement you will say, but I can assure you the poor milliner girls work harder and are more confined; they lead most horrid lives; slavery in the West Indies, or the sufferings in our manufacturing counties are really nothing in comparison to what they go through, working often all night and on Sunday, in ill-ventilated crowded rooms, ill-fed, and ill-treated, in order that our fashionable ladies may have their dresses by a certain time. This plan is pursued in most London houses, but there are, I am happy to say, some exceptions; it is hardly possible to conceive any thing so bad as the treatment of these poor milliner girls could exist in a civilized city. To return to the report, about a year ago, a slight pain came on in the side, which made him apprehend a return of the pulmonary disease; he applied to a medical man, who gave him some ointment to apply to the precordial region, and some medicine to take; from this treatment he found relief. Within the last three months the pain in the side has returned and has been gradually getting worse ever since. He has been till lately an out-patient; has taken medicine, applied leeches, lived low, and employed other means, but without much benefit. He has never had rheumatism. He now complains of pain at the inferior region of the chest on the left side, with palpitation of the heart, increased by any mental emotion or bodily

exertion. The pain is sometimes burning, sometimes it seems as though a stream of water passed along the heart from above downwards; the pain, he says, is confined to a spot which might be covered with a crown-piece. The left hypochondrium is not painful or tender on pressure. When a boy he had frequent fainting fits, but of late years only experiences a feeling of faintness without actual deliquium. His breathing is perfectly free, and he has no pain in any part except the region above mentioned. He complains of great weakness and dimness of sight. His appetite has become impaired during the last fortnight; he complains of a burning in the mouth, which is relieved by drinking cold water. He sleeps pretty well, has no unpleasant feeling at the chest, and is not obliged to lie with his head raised. Auscultation detects no morbid sound of the heart, but there is great palpitation. Bowels open, pulse 100, full and regular. Now, from all these symptoms and the history of the case, I had no doubt it was pain in the stomach without inflammation, but attended with great weakness; the heart was affected with great weakness and irritability. In gastrodynia, or when the stomach is in any way affected, the heart is liable to be affected with palpitations; there were no symptoms in this case of any organic disease. The burning heat you will observe was not constant; from the general weakness, from the absence of all inflammation and organic disease of the heart, I gave him tonics; had I given him narcotics, they would have done no good, the weakness was so excessive. I ordered him half-drachm doses of the tinct. ferri muriat. which was increased to two scruples, then to a drachm, and afterwards to four scruples; this last dose appeared to stimulate too much, his head began to ache, he was giddy, and his eyes felt heavy; we then diminished the dose to a drachm, which he took until a few days since, when he was discharged well.

I shall now refer to the case of a young female, who, like the foregoing patient, had pain in the region of the stomach, but a pain of a very different kind. L. M. was admitted on the 27th of October; has been subject for the last nine months to pain in the epigastrium, attended with a sensation of heat in the stomach, extending up the throat; these symptoms were always increased after taking food; she had urgent thirst also; the pain was much augmented by taking warm or stimulating fluids. She had frequent attacks of headach, accompanied with giddiness and dimness of sight; no appetite; her strength has gradually declined. She has menstruated regularly, until the last period. About a fortnight since, the pain began to be more severe, and has continued so to the present time; it is increased by pressure, and is accompanied with a sensation of heat in the stomach and throat;

there is great thirst, tongue red, dry, bowels open, pulse 70, weak. Now you will observe the difference in the two cases: this patient had thirst, the man had none; her pain was increased by stimulants, but a strong stimulant like the tincture ferri muriat. did not affect him. Now, in this girl's case, from the great heat in the throat and stomach, increased by stimulating food, the pain on pressure, and the thirst, there could be no doubt that inflammation existed. Her tongue, too, was red and dry, a general attendant on inflammation; the man's I should have told you was white. It would have been improper to give tonics in this case—it was decidedly of a chronic inflammatory nature. I therefore ordered eight leeches to be applied to the epigastrium, and two minims of hydrocyanic acid every six hours. This medicine may be used in cases like the present, when using the leeches in order to lessen the tendency to spasm. She felt relief from the leeches; up to the 19th of November, the pain had become less and less, but on that day she was taken with a sudden pain in the stomach, evidently spasm. She went out well on the 17th, having been on low diet all the time. This form of chronic gastritis is very common among young women, I know not why. It will be well for you to put the cases together, to see the success of opposite treatment in opposite cases.

Sub-Phrenitis.

I have another case of an inflammatory kind to speak about, requiring the same plan of treatment as the foregoing, only the disease was situated in a different part of the body. S. P., aged 40, was admitted October 30; she is a cook, has had some trouble lately, and has suffered much from great anxiety of mind, which brought on watchfulness, and she passed three nights in succession without sleep. After this she began to complain of some pain in the head, which felt very hot. She had tinnitus aurium and dimness of sight, and her mental faculties became impaired; she had vomiting, her skin was hot, and she had urgent thirst; no appetite; there was great lassitude. On her admission she was sensible, but previously had been violently delirious; she was affected in the same way, two years since, from a similar cause; she has always menstruated regularly. This woman was a cook; now cooks are very subject to pain in the head, arising from their being obliged to be so much near a fire. Cooks, too, in high families suffer much from charcoal, which is frequently used in cooking; the heat makes them thirsty, and a great many of them drink gin, which practice only increases the thirst, and the liability to headach. We do not know that this woman was intemperate, but nothing tends to induce inflammation of the brain and its membranes so much as in-

tense watching; and there was sufficient cause in this case in the fact of her mind being affected—she was immediately bled to sixteen ounces, her head was shaved, and a large blister applied, and we gave her five grains of the pil. hydrarg. three times a-day. I should say she had vomiting, which I suppose was sympathetic. On the 2nd of November, she complained of much tinnitus aurium and dimness of sight, but has no pain in the head; he was delirious last night. On the third, she is much the same as yesterday; on the 10th, the tinnitus aurium has left her, and she has no dimness of sight, but she is troubled with *muscæ volitantes*. She gradually improved to the 24th, when she was discharged well. This case was decidedly inflammatory, and antiphlogistic remedies were proper; perhaps the disease, though styled on the card “pleuritis,” might be properly called sub-phrenitis.

Hepatitis—Softening of the Viscera.

The next case is that of Thomas King, who was admitted Nov. 17. He is a tall thin man, of irregular habits, accustomed to drink wine at one period of his life, sometimes as much as two bottles a-day; has generally enjoyed good health, except occasional attacks of dyspnoea within the last twelve months. He had, however, the appearance of a worn-out man, having a bloated countenance; and the peculiar injected net-work appearance of the minute vessels on the face, which indicates visceral disease. About three weeks since, the difficulty of breathing, and the pain in the chest, became augmented, with wandering pains in the loins and thighs, and general feeling of uneasiness and languor. He however continued in the discharge of his duty, that of a door-porter, until this day, the 17th of November, when he was admitted into the hospital. He now complains of pain, and soreness at the scrobiculus cordis, extending to the right and left hypochondriac regions, but the pain, he says, is most severe in the right; the pain is very much aggravated on pressure, both at the regions above named, and over the whole abdomen, though in a slighter degree. He sometimes feels sick, but does not vomit; the sclerotic coat of the eye has a yellow tinge, which is also observed in a slight degree in the face; the capillary vessels on the cheeks are red, and minutely injected; the bowels open once a-day, little appetite, considerable thirst, tongue moist and furred, bitter taste in the mouth, no sleep, urine very scanty and high coloured; pulse 120, small and fluttering. Now, looking at all these symptoms, it was evidently a case of hepatitis; the whole liver was undoubtedly in a state of great tension; he was so weak we could not bleed him generally; his constitution was worn out—his pulse 120, small and fluttering; we could not be more active than to apply eight leeches to the side,

afterwards a large blister, and give him five grains of the blue pill three times a-day. On the 18th he felt rather easier, from the leeches and blister. On the 20th, he is still troubled with frequent attacks of dyspnoea, but he feels, on the whole, better than on his admission. On the 23rd he was attacked with a violent fit of shivering, to which he says he is subject; his mouth, hands, and feet, have a bluish red and livid appearance, but they felt of the natural temperature; he had no difficulty in breathing: his pulse was very small. Bowels open, the stools of a dirty whitish colour; passed a very restless night; he has frequent attacks of dyspnoea, and often got out of bed, arranged the bed clothes, went to bed again, and displayed other symptoms of restlessness and uneasiness. He died on the following day, whilst on the close-stool.

Autopsy.—The body appeared stout—I should say not exactly so—it would scarcely be called a stout body; there were no signs of emaciation—the neck and head were blue and livid—the hands and feet were of the natural colour; but the veins over the whole surface of the body were distended with blood, presenting an arborescent appearance. On opening the chest, the lungs were found to be healthy, but there was a quantity of serous fluid in the cavities of both pleuræ. The lungs were very much congested, and a few tubercles were found sprinkled in their substance. The heart was large and flabby; there was fluid blood in the right ventricle. The liver was of the ordinary size, but friable, and much congested. Spleen small, friable, and congested; kidneys also congested. The stomach presented a dark livid colour at the cardiac orifice: the same discoloured appearance was observed in the large intestines. The brain was soft, the arachnoid membranes opaque and congested.

Now the appearance given by the veins of this patient was like that presented in bodies that have been dead some months—not opened in this way, twelve hours after death. I presume the vessels lost their power, and the blood was no longer driven on; the same change takes place after death. It appeared that the softening of the different parts took place just before death, and proceeded rapidly. I have seen cases like this before; the pulse is generally quick and low. In these cases putrefaction takes place rapidly. In persons of bad constitutions, the structures of organs sometimes suddenly change during life—congestion appearing, as in this case, after death.

In the next lecture I shall speak of a case of phlebitis resulting from venesection; pus was found in the veins—here are some of the points—but I will speak of it more fully at our next meeting.

A Sketch of the Medical and Statistical History of Epidemic Diseases in Ireland, from 1798 to 1835, with the Method of Prevention and Cure, as practised in the Fever Hospital, Cork Street, Dublin. By William Stoker, M.D., Hon. Fellow of the King and Queen's College of Physicians in Ireland, &c. &c.

(Concluded from page 554.)

WITH respect to the effects of contagion amongst the medical officers to fever hospitals, and their longevity, it may be stated that of the three physicians and surgeon first elected to the Cork-street fever hospital, all are still living, except Dr. Mills, who died of chronic disease long after he had resigned his office in Cork-street, and which he did not hold more than two years; Dr. Barker was attached to the hospital from its beginning, for twenty years; Dr. A. B. Colles, the surgeon, about three years; and myself thirty-one years. All the medical officers, however, attached, or subsequently added to the Cork-street fever hospital, before 1823, or at the first opening for the reception of patients, were attacked more or less severely after the commencement of their duties there, or of their attendance at the houses of the sick poor. It was in this way that Dr. Lee and Dr. Lynch contracted the malignant typhoid disease, of which both died a few weeks after their election; they were the only physicians in the Cork-street fever hospital who died of disease so contracted. Dr. George Hagan died, I think, of chronic disease, which was the result of long-continued exertion, as physician to it, but I believe that effect was aggravated by the baneful influence of a contagious atmosphere in the dwellings of the sick poor. It is moreover very remarkable, and a fact highly instructive on the subject of contagion, that none of the junior physicians have been attacked with the prevailing disease since the unprecedented revolution towards malignity, which occurred in 1823. And, though many have been added, and some of them were transferred to cholera hospitals since 1832, I have not heard of any of those being attacked with symptoms of the epidemic.

From the annual reports of the average number of days each patient remained in the hospital, it appears it was nearly the same in 1831, and in the preceding year, as in the years 1823, 4, 5, when, as may be seen by reference to the reports published of these three years, that the pestilence, with many of the characteristics of that which prevailed in the year 1831, and each succeeding year since. The correspondence, however, between the average mortality in these several years of pestilence, is more remarkable than the length of time the patients remained in the hospital. (See report for the year 1828, page 8.) That mortality, as 307 deaths to 3317 recoveries, or 1 to 10 147-307ths, exceeds

that of any other year from the opening of the hospital, and is nearly the same as happened in the three years, 1823, 4, and 5, when pestilence of the same characteristics as already intimated, prevailed. The average number of admissions into the Cork-street hospital, during the three years 1823, 4, and 5, likewise, as may be seen by the general retrospect at the 8th page of the report of 1828, was nearly the same as in the year 1831. This parallel is of great importance, as will appear more manifest when the symptoms of the epidemic of 1831, even as they are detailed in the report for 1831, are compared with those of the epidemic of 1823, and with those of every succeeding year since. (See 2nd section, page 35.)

The medical report for 1831, quoted in the 2nd section, though it was written avowedly to show that no extraordinary epidemic then prevailed, yet detailed decided symptoms of malignant cholera; of late more properly designated malignant diarrhoea.

In the same report, too may be seen, not only proofs of the existence of the malignity of the epidemic which afterwards ravaged the country so dreadfully, but also the very same arguments which I employed in addressing the committee, to urge them to investigate its nature, and which I did chiefly with a view to induce them to relax those restrictions which retarded immediate admission into the hospital; and owing to which restrictions, I am ready to show, several patients died of malignant cholera, in 1831, 2, 3, and 4; but on the other hand many, in the incipient stage, were saved by speedy admission*.

The average number of admissions into the Cork street hospital, and deaths during the three years, 1823, 4, and 5, as may be seen by consulting the synoptical table at the 8th page of the report for 1828, already referred to, were nearly the same as in the year 1831. That parallel, too, is of great importance in determining the vital question, whether or not the epidemic of 1832, was or was not in the Cork-street hospital in 1831.

The number of patients annually received into the Cork-street fever hospital is daily entered in the registry, but the disease of each patient is not particularized, an omission greatly to be deplored at all times, but especially in the last five years. At all times such statistical information would have been a valuable desideratum to practical physicians, and medical annalists. It would have acquainted them with the most general form of endemic and epidemic disease, in antecedent years, and with the adventitious circumstances and symptoms, which gave to it a designatory epithet, (e. g.) when small-pox, measles, scarlet fever, influenza, cholera, &c. prevailed. This, I suggested to the managing committee of the fever hospital many years ago, and in

* See my comparative view of Cholera. Dublin, January 1832, pp. 16, 17, 18, and 19.

September, 1834, at the instance of the able and, I believe, truly humane chairman of the committee of the House of Commons, (Mr. Warburton, by whom it was proposed when I was examined by him,) that a column should be in the registry, on which the name of the disease should be inserted, opposite that of the patient. This would have prevented in a great measure, or wholly, the public embarrassment that ensued, first, by showing that the epidemic then, though more malignant than at later periods, had occurred much earlier, and, secondly, though previously under a milder degree than in the last five years, in most cases still, that by them studying it much valuable pathological and therapeutical instruction might be derived, and have been applied subsequently with great advantages to the prevention and cure of the more malignant kinds. This injurious omission in the registry of the Cork-street hospital should be immediately rectified, to prevent further evil consequences.

None but those who require gratuitous relief obtain assistance from this institution. The sick person sends notice to the hospital, which is served on one of the physicians on extern duty, who visits the applicant, and gives an order for admission if it is not opposed to any mandate of the managing committee. The order for admission must be signed by the visiting physician, at the residence of the patient. But this regulation, though intended originally for the exclusion of persons not labouring under infectious fevers, yet from the acknowledged difficulty of distinguishing, at least at the commencement of fever, between those produced by contagion and by other exciting causes, has wholly failed in that respect; moreover, it has become a very injurious regulation in many instances, by rejecting those who seek admission at the hospital gate, or lie in the neighbouring streets, who are often ejected from their lodgings for either non-payment or from being thought sources of contagion. Such events I have known to happen every year in the last ten, and many patients to have died neglected and unsheltered, whilst numerous beds in the hospital from which they were turned away were vacant. This abuse should be immediately corrected to prevent further mischief arising from it. Besides, although there is, literally, no limitation in the rules and regulations of the hospital to the admission of the objects of charity, the sufferer living within the Circular-road (i. e.) in Dublin, yet these objects of the charity were wholly lost sight of since malignant cholera prevailed, and in a greater or less degree supervened upon almost all contemporaneous diseases. Whatever appeared to the theory or the alarm of the visitor to be Asiatic cholera, was of course rejected, in obedience to the mandate of the managing committee, and at a time when the hospital was most needed was it most inoperative. This appears to

me a serious abuse, and directly at variance with the principles of the institution. The limitation of admission to patients whose residence is within the Circular-road, also requires to be reconsidered, because it has been fatal to many who were rejected after being removed from the country to seek admission.

The Cork-street fever hospital makes no provision for extern patients. If a dispensary and cheap provision store were connected, great advantages to the poor might be thus derived, more especially in those outbreaks of epidemics, obviously produced by famine, such as occurred in 1817, 18, 19, and 20. During the prevalence of famine and succeeding pestilence in 1817, 18, 19, I saw in Peter's parish very great advantages from supplying the sick at their own houses with the necessities of life, and administering such remedies as actual disease demanded*. The fever hospital does not receive any case which may not come under the head of "febrile disease;" (according to the opinions of the Committee, which unfortunately they have not been able to define with any degree of accuracy, and as may be seen in the preceding part of this sketch,) if the principle of this restriction had been acted upon since 1823, by any one well acquainted with the real state of the case, the worst cases of the sick poor labouring under epidemic and pestilential disease, not being fever, must have been rejected, as happened with respect to malignant cholera, for 1832, 3, and 4.

There also appears from the facts already stated in the second section, to have been a gradual change in disease towards that called Asiatic cholera, produced in my opinion, by changes, however subtle, in the constitution of the air, assisted in their operation by the local miseries of the country.

Generally speaking, potatoes, and potatoes without anything else, are the food of the Irish poor, and even these are most deficient in quantity, and often of a coarse quality. I do not think the full grown potato unfit for food at any season of the year, at least till it has been exhausted by its vegetation, which commences in the spring. The unripe potato, or the exhausted potato, which happen about the same period, I believe to be a common cause of disease among the poor. I am sure the use of them at such periods has been a fruitful cause of disease at all times, but more especially since our epidemics have assumed the characteristics of malignant cholera. That a potato in its perfect state is a wholesome food for the human species as any other article either animal or vegetable, I am induced to believe; but being taken alone by perhaps 7-10ths of the poor of Ireland through the entire year, it predisposes, or actually excites disease,

* See my reports for the years 1820, 1821, and 1823.

especially in the season of its immaturity or decay, to a greater extent than in any other country so dieted. The greater prevalence of cholera, common and malignant, and of other diseases of debility, is chiefly referable, I think, to that cause. And whether the greater prevalence of such pestilential disease in Ireland, is rightly to be considered the cause of dropsy to a greater extent amongst all ages in Ireland than in England, or should be traced back to the causes of these pestilential diseases themselves, it cannot be denied that whilst dropsy in England is confined either to the intemperate or the aged, numbers of young persons, living entirely on potatoes, and without the means either of over-eating or drunkenness, the frequent cause of dropsy, sink every day, by that mortal disease, in Ireland, into their graves*.

In the famine of 1817, 18, and 19, the poor were driven to the use of all green vegetables they found within their reach, and the succeeding epidemic, greatly enhanced as it had been by that circumstance, assumed forms of peculiar virulence; particularly diarrhoea, and other forms of bowel complaints, from the use of some of them more noxious than the rest. A mixture of fresh animal and vegetable food in generous allowance, appears now, I think, by the universal consent of medical practitioners, and writers of reports on the epidemics of this country, to have been not only preventive but curative, when judiciously administered. In the epidemic of the last four years, fruits, and some vegetables, especially the potato in its exhausted or unripe state have been found to predispose to an attack, and were often deemed the chief causes of fatal ones. The most general causes of actual disease amongst the poor of Ireland, is, I believe, want of sufficient sustenance and of remunerative labour; likewise the use of noxious ingesta, whether bad food, or ardent spirits, to which they often resort, to blunt the feelings of hunger and of misery.

The extensive use of ardent spirits still prevails, but happily seems on the decrease. Lunacy and idiocy are often the result of the abuse of spirituous liquors; but the disease denominated *Delirium Tremens*, the well known consequence of that abuse, is becoming more frequent. Spirituous liquors seem, though they very frequently are not, the sole cause, as the quantity of ardent spirits drank is sometimes small in proportion to the quantity of beer or porter. *Delirium tremens* is often fatal, sometimes terminating in paralysis, of body, or mind, or of both. Whether these cases of idiocy or palsy, are directly or indirectly produced by the use of ardent and fermented liquors, I cannot say;

but the habitual excess which leads to them is very generally incurable. Fermented liquors, even the abuse of them, are certainly less pernicious than ardent spirits; but a substitution for both in the beverage of the poor must be I think, a great desideratum in ameliorating the condition of the Irish poor. I have no doubt that ardent spirits are frequently resorted to by the poor, (according to their own well-known phrase) "to drown grief," or in other words to gain, by inebriation, a respite from the painful sense of the want of everything. I do not doubt that it would also much conduce to the health of the poorer classes, if beer could be substituted for spirits; but until the condition of the poor shall be ameliorated, I fear, for the reasons already intimated, that the possibility of such substitution would be very doubtful.

Although I think that the cold and damp of the climate, and the ardent character of the Irish, along with the wretchedness of the poorer classes, have produced a common and excessive use of ardent spirits, which it would be extremely difficult to check, yet I feel certain that the production of any cheering and nutritious beverage, within the means of the poor, would be most desirable; and that very many who now leave their reason, with their pence in the whiskey shop, would gladly mend their ways, if they could bring home a comfortable supper for themselves and their families. But, I greatly fear that it would be scarcely possible to reduce the price of tea, coffee, or cocoa, so very low as to bring it within the reach of the Irish poor. It is, therefore, with infinite pleasure I suggest a preparation of dandelion, which, in appearance and flavour, is very like coffee, and which might be produced so cheaply that even the most wretched could easily procure it. Of the benefit of the root of the *red-stemmed dandelion* (*Taraxacum*), prepared as it may be very cheaply for the poor, in the greatest abundance in autumn, to provide against the periodical famine of the succeeding year, I can now speak with full confidence, from very extensive experience of its use under the form of coffee, both for preventing and curing many other stomach and bowel complaints besides cholera, which in the seasons of famine are the harbingers of dropsy and marasmus, to an extent unknown in England, or any other country, where such constant misery and frequent visitations of famine do not occur. I may add that I have been recently informed by some eminent physicians that they have employed dandelion coffee in their own cases with the greatest benefit, and have since more fully proved its efficacy amongst their patients. Further particulars of its preparation may be seen in my *Pathological Observations*, part 2, Dublin, 1829; and part 3, 1830. As to its general utility both in diet and medicine, see Dr. Paris's *Pharmacologia*.

The want of work causes much more

* See my observations on dropsy. Part I, Dublin, 1823, page 48 to 108; also Part II, Dublin, 1829, page 209 to 238.

mental and corporeal disease amongst the poor operatives of Dublin, than the manner or materials in which they have been employed. This has been always evident in the rise and growth of all our epidemical and pestilential diseases, and found to be almost as deleterious as even deficiency of food, or of other necessities of life, which are besides intimately connected with dearth of employment. The famine fever A. D. 1827, was clearly* the result of want of employment, the prevailing sickness being then obviously excited by it, especially amongst the English and Scotch operatives, who were forced of necessity to work on the roads for food; and who in leaving their looms and other modes of manufacture, relinquished with them all their previous hopes and habits. The rise and growth of pestilence in Dublin for the last thirty-seven years is, I believe, mainly attributable to similar causes. There is, I am sure, much less ground of complaint upon the subject of filth and imperfection of the pavement of lanes, stagnant water, &c., than the public has been generally led to suppose.

Neither clergy nor laity of any persuasion have interfered, unsought for, with the patients during their illness, in the Cork-street hospital; neither have theological or controversial tracts, of any description been circulated there of late years; but the want of having chaplains of the leading persuasions and sects, attached to the institution is a great injury to it, inasmuch that I have often seen the tranquillity of patients destroyed, and their recovery materially interrupted, by not having their own clergyman, at times when they anxiously wished for him. This want should be provided for. I stated this orally to some of the managing committee many years ago, but it is still in existence.

All the medical officers are graduates of the colleges after which they are respectively denominated; but, I believe, they are not all licentiates. The medical duty is extern and intern, (i. e.) visiting the applicants at their abodes, to see if they are proper objects for admission, and attending the patients when received into the wards of the hospital. Of the physicians, three attend at the dwellings of the applicants, and three attend at the wards of the hospital. The intern and extern duty is alternated every two months in succession. The hours of attendance is 11 A. M. and 7 P. M., and, I think, sufficient time is generally allowed. I am not aware of any complaint having been made by the poor to the controlling power. A nurse-tender is always in attendance, and administers the medicines to the patients; the apothecary dispenses them.

For how many years after the opening of the Cork-street fever hospital, no salary was allowed to the physicians, I cannot recollect; but a salary has since been given to them. At first it was 20*l.* per annum. This, how-

ever, has since been gradually increased to 100*l.* late Irish currency, and has been the maximum, at which it has stood for several years. This is the only allowance to the physicians. The Grand Jury has never exercised any control, neither does it appear that its members have any; but I believe such a control is vested in the government; through whom, and by whose sufferance alone the presentments pass for those parliamentary grants, on which the institution mainly depends for support.

The medical and all other officers are appointed by the committee, consisting of the trustees and six other persons, elected annually by the managers themselves. When a vacancy occurs it is made known through the newspapers. It would be highly desirable that these appointments should be subject to the approval of the Lord Lieutenant and College of Physicians. It is necessary that the candidate physicians should be Doctors, or Bachelors of Medicine; a diploma from the College of Surgeons is required from the surgeon; a diploma from a School of Midwifery is required from the accoucheur; and letters testimonial from the Apothecaries' Hall, from the apothecaries or dispensers. There is not any limitation as to the officers' age—there is not any retiring allowance.

The Cork-street hospital, one of the largest fever hospitals perhaps in Europe, if under a more liberal direction, might, with the greatest advantage to the immediate objects of the institution, be made a most effective school for medical and surgical instruction. The extreme wretchedness and poverty of the district in which the hospital is situated, always produce in its wards an abundant source of every variety of the prevailing epidemic. Few are the cases which would not afford abundant subject matter for an instructive clinical lecture; and, I may add, that very many are the cases to be met with in that hospital, for which a more watchful and intelligent attendant than the common hospital nurse-tender must be required. Nor would the advantage to the immediate objects of the institution, by the admission of students, stop even here; for it is my conviction that the pupils would give to the physicians, as in the Meath hospital, Stevens's, Mercer's, Sir P. Dunn's, very much more than an equivalent for the salary they now receive. Thus a very important saving would be effected, or, in other words, a new fund would be created for extending the benefits of the institution. I have repeatedly sought those advantages, for my pupils and for the hospital, as well as on my own account, but have been as often refused*.

* When lecturing on the practice of physic, in some of the private schools of Dublin, (e. g.) in the Peter-street or Eccles-street School, the advantage to my pupils

The patients in the Cork-street fever hospital are invited by placards through the wards to prefer any complaint for ill-treatment by the medical officers, to the managing committee, or monthly visitors; but I am not aware of any such complaint having been made; neither am I of any secret influence or circumstances to deter them from giving such information.

The medical officers of the Cork-street hospital are not bound to give vaccine matter gratis; I think a dispensary for such a purpose might be advantageously attached to such hospitals, which should contain two or three beds for patients, or accidents requiring particular attention. The medical officer has not been in the habit of inoculating for the small-pox. My opinion of vaccination, and how far preventive of small-pox, is the same which I expressed in my observations on the varioloid disease, published, Dublin, A.D. 1820; and as it accorded very generally with the candid and intelligent reports of several respectable medical observers, published at that time throughout the kingdom, I shall quote it here in the same words, viz. — "Small-pox appears after vaccination in but small proportion to the number that enjoy perfect immunity from that antidote, and even in this small proportion the supervening disease is so mitigated as in general to cause slight sickness only, on the 7th or 9th day, and very rarely consecutive fever." My objects, however, in that pamphlet were to show, by experiments I had made, that cases of eruption after vaccination, which had been confounded with chicken-pock, swine-pock, &c., were genuine cases of small-pox; an opinion which has since been fully corroborated. Small-pox after vaccination having been urgent in many cases, some of them fatal, the efficacy of the antidote was questioned by the families who had thus suffered. I believe the confidence of the public in the efficacy of vaccination is rather increasing than diminishing. But as to how far it would be advisable to prevent those who still doubt its efficacy, from inoculating with small-pox, I do not feel authorised to express an opinion.

Wine is given on the order of the physicians. For the last five years the quantity ordered by me has been very small, owing to my substitution of dandelion coffee for it. This may be seen by comparing my diet tables in corresponding months in which I employed dandelion coffee in lieu of wine. Not only was the mortality diminished in my wards in those months when dandelion coffee was prepared according to my directions, and whilst it was given in lieu of wine, but it was relished by the patients. Moreover, as stated

in my publications 1829, 30, and 32, it relieved nausea and vomiting after all other means had failed*.

There is a regular dietary divided into low, middle, and full diet, but there is none for particular diseases; the managing committee having, in this instance also, acted under the fallacious opinion that contagious fever was the only disease to be found in the wards of the Cork-street hospital; a fallacy which they, as well as the physicians, might have detected. Some extra comforts, however, are allowed, such as a wet nurse, or arrow-root, which I suggested for the new-born children of mothers affected with bad fevers, or pestilential disease, the suck in such cases being either deficient or depraved, and I had often found it to be fatal to the infant. But there are other extra comforts, however, which I also suggested, such as tea, dandelion coffee, and sugar, which are not allowed; and I have known numerous cases in which they were urgently required.

There are monthly reports as to admissions, discharges, deaths, which are printed, and known to the public in general. But the minutes even on medical subjects, have been kept secret from the physicians; a circumstance which must be at all times detrimental to the reports. Moreover these reports are subjected to alterations by the managing committee, who are obviously disqualified for such censorship. The clergy, of all persuasions, medical men, gentry, &c. might be formed into a Board of Health in every district. They would, I think, be qualified and willing to assist in a more minute investigation of the wants of the poor.

I believe the future support of the Cork street fever hospital will depend, as it ought chiefly, on good faith in keeping the original rules and regulations, as on that the private bequests and public grants have been hitherto made.

In concluding this hurried sketch, I feel most sensibly how very much its numerous defects need apology. The importance of the subject, whilst claiming the highest order of medical knowledge, I could scarcely hope my utmost efforts adequate to its perfect development; and in attempting to compress it within the narrow limits prescribed to papers offered to the College of Physicians, or to the sections of the British Association, it must have been further injured. Still the kind indulgence which this view of a subject so generally interesting requires, will not, I am persuaded, be denied to an attempt, however imperfect, to discharge a bounden duty.

Although I may fail as to other objects, perhaps too ambitiously entertained, yet if I shall realise the leading one, namely, parliamentary investigation, in the course of the

of attending the wards of the fever hospital would have been great. The injury done by the refusal was, therefore, very material.

* See third part of my Pathology, Dublin, 1830; and Comparative View of Dublin, July, 1832.

next session, of the subject of medical statistics in Ireland, and of the mischievous abuses arising out of the neglect of them, I shall consider any labours of mine fully remunerated.

Hitherto my memorials to the Irish government, the College of Physicians, and the managing committee of the fever hospital and house of recovery, Cork-street, were dictated by my anxious desire for rigorous and impartial investigation of the questions to which they referred. On all those occasions that investigation was denied, and public injury and private injustice were allowed to escape the test of truth. To bring them to that test has led me to persevere, and, relying on its efficacy, I do not despair of ultimate success.

P.S.—The appendix notified in drawing up this sketch is postponed, in expectation of freer access to the annals of the Cork street hospital, from which it will be taken, and of the replies also of a category for rural districts, with which, at their request, I furnished the Commissioners of Poor Law Inquiry. In the meantime, my dissertation on the Institutes of Medicine, published in 1826, and my Comparative View, January, 1832, will be substituted for that appendix; both these publications being intimately connected with the leading subjects of this sketch.

LECTURES ON THE DISEASES OF THE NERVOUS CENTRES,

NOW BEING DELIVERED IN PARIS.

BY M. ANDRAL.

LECTURE I.

Generalities of the Nervous System.

THE study of diseases of the nervous system is difficult on account of the multitude of facts which we are obliged to collect, because they are scattered in various works and periodicals. There is at present no work which embraces a full account of nervous disorders. The difficulty of this study is further augmented by the diversity of opinions deduced by each observer from the facts which he studies, and from which he is to make his selection. In commencing this laborious study, we find the science is really in state altogether provisional. It is still very far from being so completed as that of the diseases of the other systems.

We shall commence some details, which will demonstrate more clearly what we have advanced. In all diseases, we are necessarily obliged to study the causes, the symptoms, the anatomical lesions, of which the symptoms are often the effect, and, lastly, the treatment. But when we investigate the diseases of the nervous system, we find cir-

cumstances which make the study of these diseases, of their symptoms, of their anatomical characters, of their treatment, offer difficulties which are not encountered in the diseases of other organs.

We shall pass in review the different orders of difficulties, and first consider the causes.

Here, as in other maladies, we find the causes. 1st. In the internal organs. 2nd. In the reciprocal action of the organs on each other. 3rd. In the mode of the performance and the nature of the functions of the diseased organ. The nervous system is not influenced in a very remarkable manner by external agents. There is not, for example, any comparison between its relation and those of the respiratory system or digestive apparatus.

The second order of causes shews itself in the most powerful manner, in the production of the diseases of the nervous system. Every organ disordered in its action, reacts upon the nerves. There is no disease in which they are not affected; sometimes in a secondary manner, but deserving to be placed in the first order. It is then that certain primitive states of the liver, lungs, and intestines are afterwards accompanied by nervous phenomena, which give them a special form.

As to the third order of causes, all organs in the nature and performance of their functions, are subject to diseases.

But to the nervous system belong the intellectual and moral phenomena, which are a peculiar cause of numerous perturbations; and as the intellectual and moral phenomena are not the same in different individuals, and according to the different states of society, the different ages, professions, religious ideas, &c., &c., it will follow, that there will be great difference in the aspect of the same diseases. In cities, for example, and in hospitals, individuals exert their brains very differently, and, as the ideas of every age have their peculiarities, as for example, the religious ideas carried to excess in the middle ages, have gradually given place to ideas of a different kind, we should not be surprised that certain maladies which were developed under the influence of such fanaticism, are not observed in our times; thus, the epidemic, St. Vitus's dance, religious extacies, &c. are not now prevalent, whilst there are others of common occurrence in these days; and which were not then observed.

Symptoms.—Here we meet with formidable difficulties, which do not present in diseases of the other organs. 1. Our senses cannot be employed here, for example, as in diseases of the chest and abdomen, in which the diagnosis can be drawn with so much precision. We frequently can only recognize the diseases of the nervous system by induction; the relative difficulty is then very great.

2. Premature theories have thrown other

difficulties in the study of these diseases. The theory which refers all the affections of this system to augmentation or diminution of excitability, is inadmissible. There are numerous and various other disorders of a perversion of function.

3. Different lesions may produce similar symptoms; thus the same phenomena often manifest themselves in two individuals, one attacked with congestion, the other with cerebral anemia, in such a manner, that it is more by the antecedent symptoms, than by those present, that we establish a diagnosis. On the contrary, there are lesions of the same kind which cause different symptoms; and this may depend on the seat, on the slow or rapid formation of the lesion, on the extent &c.: thus the diseases would vary according as the cerebellum, brain, &c. &c., were affected.

The brain may be considered as a multi-form tissue, formed by the aggregation of organs having different functions: but the localizations which some attempt to make are premature. I do not believe that they can know the precise state of intelligence, of speech, of motion, of feeling, &c. This question remains to be determined, and in admitting this diversity of organs, it must be understood, that there is a chain which forms the unity of a vital principle.

All the rest of these difficulties may be appreciated and submitted to these laws; but there is another which must not be neglected, for it is a fact; I mean *idiosyncrasy*, by which the same action produces in two individuals such different results. This idiosyncrasy exerts an important influence in diseases of the nervous system.

4. But this is not all. Sympathetic reaction becomes, in the subject of which we are investigating the source of enormous difficulties. We know not sometimes if the symptoms we observe, have their origin in the nervous system, or in some other organ; for example in the cerebral fever of infants, &c.

The symptoms of diseases of the nervous centres present remarkable differences according to the different ages; so that if two good observers, one placed in an hospital for adults and aged persons, the other in an hospital for children, their monographs will be quite different, and, nevertheless, the facts will be perfectly correct: because they have observed individuals of different ages.

These are very great difficulties, which do not exist in diseases of the other organs.

When we have determined the nature and the seat of a disease, all is not finished; we must study the anatomical lesions. Pathological anatomy has, undoubtedly, within a few years, discovered alterations in the nervous centres, which were previously unknown. Thus *ramollissement* was scarcely glanced at by Morgagni and has been the object of the valuable researches of MM. Lallemand, Rostan, &c.

Cases in which after death we discover by the scalpel some changes are, common in the other organs, but this is directly the reverse in the nervous system; the cases in which lesions are met with, are very rare, and this fact will appear a paradox, if we only pay attention to three or four diseases observed in hospitals; for it often happens that we pass over slight nervous affections and do not notice except the most formidable, which derange sensibility, intelligence, &c. In these last cases we sometimes fail to discover any morbid appearance, or those that we detect have no relation with the phenomena observed. Is it to be said that they do not exist? It is true, that nothing can be seen; but it is probable that there is organic lesion, since there is deranged action.

We have not yet arrived at the end of our anatomical discoveries: let us wait with hope. It has been said, some years since, that disorders of the understanding were connected with alterations of the grey substance of the brain. The fact has been contested, but may be perhaps hereafter definitely established in science.

There are other researches to be made besides those which we owe to the scalpel. Thus, various disorders may be connected with the difference of chemical elements, dependant on different circumstances. Thus in these latter times, it is found that from infancy to old age, there is a diminution of the aqueous element, and an augmentation of the albuminous. Phosphorus is at its maximum of quantity in adults, &c.; but these questions are for future investigators, for the facts are not as yet perfectly established.

We have seen the difficulties relative to the study of the causes, symptoms, and anatomical characters; there are others which are furnished by the treatment. In all others, when signs of irritation or of excitation are observed, we deduce the just conclusion, that there is phlogosis, requiring the use of antiphlogistics; but it is different in the nervous system, in many cases. Thus, signs of excitement exist; you bleed, and the symptoms become aggravated, according as the individual is debilitated; and these morbid states, which are exasperated by bleeding, may increase with other diseases, that may require sanguineous evacuations, however contra-indicated; for the state of the brain after the bleeding will be more serious than the inflammation of the lungs, intestines, or even the peritoneum. By a remarkable coincidence, the condition that will not require bleeding, is often occasioned by the too abundant loss of blood; and it will disappear under the influence of chalybeates and antispasmodics, and harmony is restored by these means, where bleeding would certainly have increased the disorder.

There are other means from which we may derive very great advantage, such as

those that act on the imagination. Certain diseases are produced in all cases by the influence of a strong passion, or of an energetic faith, &c.; and these diseases may be cured by means analogous to those that have produced them. I must remark, that not only simple nervousness, but diseases tending to become organic, have yielded to this treatment. In this way, cures are effected by a strong faith, from Mesmer's tub, and the juggling of magnetism, to the infinitesimal fractions of homœopathy, which have a great effect on the imagination: from this fact immense advantage may be drawn.

It has been observed, that in proportion to the advance of the sciences, they have always met at a certain elevation. When we investigate diseases of the nervous system, we perceive the possibility of enlightening this study by other branches of knowledge.

It is necessary to have recourse to the most minute dissections: thus, a certain number of diseases of the cerebellum produce blindness in children. What relations have these with the optic nerves? It is this that we have to investigate. It is true that there is a connexion between the cerebellum and the corpora quadrigemina by the cerebellic process ad testes, from which the second or ophthalmic pair of nerves take their origin.

In certain cases the motion has continued in the inferior extremities, though the half was almost completely interrupted, a small, very thin thread being the only means of communication between the two ends, or there may be only a small quantity of liquid interposed; and it is asked, how then is it that the functions were not totally suspended? Comparative anatomy comes to our assistance, and shews us, that in cases in which the spinal marrow is no longer an organ of feeling, it is of a very small volume. It has moreover shewn, in certain fishes, that the nerves separated from the marrow by a liquid, are nevertheless able to transmit motion.

To these splendid results experimental physiology has added its facts, and has rendered immense service to pathology. It is thus that certain paralyses of motion in the face, the feeling remaining uninjured, and vice versâ, have been well explained by Sir Charles Bell; and M. Magendie has put beyond doubt that the lesions of the posterior cords of the marrow give rise to lesions of feeling, and those of the anterior cords to disorders of motion.

There have been cases where a man became blind, deaf, and lost his sense of smell, without any alteration in the specific senses, the eye, ear, or nasal fossæ, nor in the optic, acoustic, or olfactory nerves, &c., and these facts are among those on which pathological anatomy can give no information. It has, however, been proved, at the present time, that the fifth pair is, in man, accessory to the functions of sight, smell, and, hearing;

and in certain species of animals comparative anatomy shews us this same pair, as the principal nerve of these specific senses.

Guided by these facts, it has been tried in certain cases of alteration of the sight, hearing, and smell, if there was not some lesion of the fifth pair, and sometimes it was only to be found in them.

But pathology restores what it receives; if it receives light from other sciences, it is in itself a fruitful source whence the anatomist and physiologist may draw to elucidate a multitude of the points of their sciences. It may, then, with truth be said, that according as the sciences advance they meet at a certain eminence.

The order that we shall follow will be the same we usually lay down. Thus we should study—

1. Diseases of the nervous centres.
2. Disease of the cords.
3. Those of the great sympathetic.

The other subdivisions shall be also the same.

Lesions of circulation.

Lesions of secretion (few in number, however, we shall have to treat here of cerebral œdema).

Lesions of augmented nutrition.

Lesions of diminished nutrition.

Lesions of perverted nutrition.

Lesions of innervation, that is to say, of functions (intelligence, feeling, motion).

Lesions of innervation of organic functions (digestion, generation, secretions, &c.).

Lesions of the power which directs and regulates in the economy the laws of organism, and which produce vital power (hypersthenic, asthenic, and ataxic states).

In this course we shall study the facts that have been demonstrated, others that are not demonstrated, but which are very similar. We shall not reject facts supposed to be false and inexact, as many such have been re-established. We shall examine theories, as these supply facts, but we shall reject all hypotheses. We shall steer a middle course between excessive scepticism, which destroys everything, and too much credulity; though it must be admitted that scepticism is necessary to science, and to those who cultivate it.

—o—

Foreign Medicine.

Dental Exostosis. By M. Lobstein.

THE exostosis of the teeth are very small tumours, sometimes situated at their neck, and sometimes at their root. Those, which I have had an opportunity of examining, did not exceed the size of a large pin's head. They were perfectly round, and of a very hard consistence. Those which were situated at the neck, or at the base of the crown, had almost the nature of enamel, being

equally polished and shining. Those placed at the root of the molar teeth, were usually found at the angle of bifurcation.

Dental *osteophytes* constitute little osseous processes, resembling stalactites, and adhering to the membrane which lines the cavity of the tooth. They are generally met with in the cavity of the *molares*; but they have been found in the *incisores* of the ox; and are sometimes free (like the almond in its shell), and sometimes intimately adherent to the walls of the cavity. The fact that these osseous concretions are always accompanied by morbid alterations of the teeth in which they are found (such as caries and decay), has led M. Duval to the opinion that they result from an effort of nature to replace that which had been destroyed by disease.—*Gazette Medicale*.

Pelvic Exostosis. By Dr. Rognetta.

In 1820, M. J. Cloquet presented to the Society of the Faculty of Medicine at Paris, an anatomical preparation exhibiting an exostosis of the posterior surface of the pubis. This exostosis, after having pierced the anterior wall of the bladder, projected into that organ. Had its existence been ascertained during life, it might have been mistaken for a calculus in the bladder.

M. Duret, a naval surgeon at Brest, has been obliged to practise the Cæsarian operation on a woman who could not be delivered on account of a considerable exostosis in the hollow of the sacrum, entirely filling up the inferior outlet of the pelvis. It is remarkable that seven years previously this woman had been delivered through the natural passages.

In the museum of the Faculty of Paris, may be seen a preparation analogous to the case last mentioned. I am not certain, indeed, whether it is not the pelvis of the woman operated on by M. Duret. It has the appearance of a little amorphous rock, evidently parasitical, resembling pretty closely a piece of pumice stone, of the size of an infant's head at the full term, and attached as it were accidentally to the concave face of the sacrum. This case closely resembles one related by M. Nagele. Ruleau has also given us the history of an exostosis the size of a nut, growing at the inferior part of the pelvis, in consequence of a fall

upon the buttocks five years before. This exostosis projected into the vagina, and was an obstacle to natural delivery. I might produce fifty cases of a similar description. As to *extra-pelvic* exostosis, I have met with only one well authenticated example—a case related by Professor Regnoli.—*Gazette Medicale*.

Destruction of Sequestra by Sulphuric Acid.

In the year 1816, a patient presented himself at the Clinic of M. Delpech, suffering under necrosis of the tibia, almost the whole extent of which was occupied by a sequestrum. Caustic potash was applied to the superior part of the leg, so as to produce a circular eschar. This was detached, leaving the bone exposed. A pledget of lint, dipped in diluted sulphuric acid, was immediately applied, and renewed every five or six hours. Two or three dressings rendered the bone sufficiently soft to be destroyed with common dressing forceps. When this had been accomplished, two other applications of the caustic potash and the sulphuric acid were successively made, below the former, so that the sequestrum was exposed to the extent of five or six inches in length, and an inch and a half in breadth, and could be extracted with the greatest facility. It formed almost two-thirds of the cylinder, being more than six inches long. During the whole process, the patient might be said to feel no pain, and left the hospital perfectly cured, a month after he had entered it.—*Gazette Medicale*.

Angina Pectoris. By Dr. Gintrac.

Believing that the explanations hitherto given of the nature and seat of *Angina Pectoris*, cannot stand the ordeal of a rigorous examination, Dr. Gintrac gives one, which he conceives approaches more nearly to the truth. The situation of the pain, and the force of the pulsations, had already led him, in 1825, to imagine that the disease is an expression of suffering originating in the aorta. Since that period, attentive consideration, and numerous researches, have confirmed him in his opinion. In examining the cases which have been collected, he has generally found an alteration, either of the aorta itself, or of the semi-lunar valve or of the cardiac vessels. These parts, though

apparently different, nevertheless form, by their development, only one organ, of which one point or another may be affected, without the difference in the seat of this affection sensibly modifying the consequences of the lesion.

The author declares he has collected thirty cases of this disease, in which the aorta was either thickened or dilated, or cartilaginous or ossified; while he has met with only ten or twelve, in which that organ had undergone no alteration; and among the latter cases, he adds, there was not one which bore the character of a case incontestably belonging to the disease, or of an observation accurately made, with the necessary attention and detail. Allowing that among the cases of inflammation of the aorta, published by authors, there are some, in which the characteristic pain of angina pectoris has not been mentioned, Dr. Gintac thinks this depends on the fact, that the history of inflammation in the large vascular trunks has been scarcely sketched; and that greater part of the observations have been made on patients labouring at the same time under other affections.—*Gazette Médicale*.

The Influence of Day and Night upon Births.
By M. Guiette.

Struck with the influence which day and night exert on the functions of the economy, M. Guiette imagined it might extend to the birth of children. He therefore ascertained, at the *Maternité* of Brussels, what had been the number of births for every hour of the day, during a period of eleven years; namely, from 1812 to 1822. Let us attend to the results of this table. If we divide the twenty-four hours into four periods of six hours each, we shall find the births thus disposed:—

	Day.	Night.
From one to six o'clock,	674	799
From six to twelve o'clock,	616	693
	1290	1492

Here we see that considerably more infants are born during the night than during the day. It is from eleven o'clock at night to two o'clock in the morning, that the greatest number are born. Thus, the first of these hours numbers two hundred and

twenty-four births, and the second, one hundred and seventy-two. It must, however, be remarked (and the observation has not escaped our author), that only four of these 2782 births are said to have occurred at midnight. There is an evident inexactitude, arising, no doubt, from the births which took place at that hour having been set down to the previous or the following one, in order to avoid all dispute as to the legal day of the birth. At the same time, the hour of noon furnished only forty-eight births, and during three years, it did not furnish one; while the hour which (after that) gave the smallest number, still reckoned eighty-eight. It would be very curious to ascertain whether the *sage-femmes* on duty at mid-day did not neglect their patients a little, at the provincial hour of dinner.

The author, who was connected with the *Maternité* from 1827 to 1834, collected, during those eight years, other cases, of which the accuracy is still more to be relied on. The following was the distribution of 2766 births:—

	Day.	Night.
From one to six o'clock	632	750
From six to twelve o'clock	677	707
	1309	1457

Here, also, we perceive it is the night that furnishes the greatest number of births; and during the night the period from one to six o'clock in the morning. The period which furnishes the least, on the other hand, is from one to six o'clock in the evening. The most favourable hours are eleven at night, and two or three in the morning; the numbers for them being 134, 132, and 140. The hours least burdened are seven in the morning, and three in the afternoon; their numbers being 102 and 97. Noon and midnight present higher numbers. Combining the two tables we find that out of 5548 births, 2949 belong to the night, and 2599 to the day.—*Gazette Médicale*.

Absence of the Anus.

M. Velpeau was called to a child which came into the world without any trace of the anus. The surgeon made an incision at the place where the anus should have been, and in the direction of the rectum,

and arrived at a cavity whence he felt assured he saw meconium escape. Nevertheless, the symptoms continued unmitigated, and the patient died. On examination the *cul-de-sac* of the rectum was found on a level with the fundus of the bladder, but without having any communication with that organ. The bladder filled the whole pelvis, so that it was almost inevitably wounded in the operation.—*Gazette Medicale*.

—
Anasarca following Scarlatina. By M. Baudelocque.

Antonie Deschamps, aged twelve years, of a lymphatic temperament, felt towards the middle of September, pain in the throat, with general febrile uneasiness. These symptoms were accompanied for two or three days with redness of the skin of the inferior extremities. He did not keep his bed, but was obliged to give up his employment, which, however, he resumed at the end of a few days. Towards the 25th, after the patient had experienced various alterations of heat and cold (from being obliged to descend into a cellar, several times a day) the face became infiltrated, and œdema attacked the scrotum and limbs, so that on the 29th (the day of his admission into the *Hopital des Enfants Malades*) the infiltration was general. A small quantity of blood was taken from the arm.

The following was his state next day: considerable swelling of the face, and especially of the eye-lids, which the patient could not open without difficulty. The thoracic and abdominal walls as well as the inferior limbs were infiltrated. The scrotum nearly equalled the size of a full-grown fetus. The upper extremities were untouched. The skin was dry and moderately warm. In many parts it was the seat of desquamation in large spots. Pulse 112, small and regular. Respiration but little accelerated, and its murmur strong and clear. Auscultation revealed no unusual sound in the region of the heart; tongue moist; no effusion into the peritoneal cavity: bowels opened daily; his understanding was perfect, and all the sensorial functions were unaffected.

Dropsy of the subcutaneous cellular tissue, occupied in this case a very great ex-

tent. But in the state to which medical science has now advanced, we ought not to confine ourselves to stating the existence of anasarca; we ought to ascend through it to the morbid affection from which it has sprung. The heart and its appendages appeared altogether free from alteration; for auscultation and percussion gave only negative signs. Thus the central organ of the circulation had nothing to do with the dropsy with which this patient was affected. Beside, the progress of the œdema had not been such as we observe in affections of the heart; for it was not in the lower extremities that the swelling began. We ought then to direct our attention to the organs which secrete the urine; since they sometimes undergo an alteration of which general dropsy is an attendant.

The examination of the urine was conducted with great care. It was submitted to the action of heat, and was tested with nitric acid, but without detecting the smallest quantity of albumen. It was not then in the kidneys that we could find the cause of the dropsy. The desquamation of the skin led us to suspect an antecedent scarlatina; and although the patient at first denied it, we afterwards came to the knowledge of the facts stated in the commencement of the case.

On the 2nd of November the fever had disappeared; the pulse had fallen to eighty; the temperature of the skin was natural. The infiltration occupied the same extent as before. The urine was scanty, cloudy, and of a brownish tint, throwing down a sediment of the same colour. The digestive apparatus was in good order. Two basins of broth were allowed, and one of decoction of dog-grass, with two grains of nitrate of potash. The quantity of the latter was increased next day to fifteen grains, and on the following to twenty-four. The urine became a little more abundant and limpid. Pulse seventy-two. On the 5th, thirty-six grains of nitre were given; and the quantity of urine was double that at the commencement. Pulse fifty-six.

On the 6th, in addition to the previous remedies, decoction of *cahinea* was administered, in the dose of a drachm in an ounce of liquid. This treatment was continued till the 12th, increasing the dose of *cahinea* to

two drachms. The anasarca underwent but very slight diminution, although the urinary secretion was a little augmented. On the 12th, the employment of vapour baths was commenced, and the nitre and *cahinca* were suspended. From the second bath a notable amelioration took place; the scrotum became less in volume, as did also the eyelids. Six other vapour baths, taken from the 13th to the 18th of October, made the anasarca completely disappear. The patient quitted the hospital entirely cured on the 25th.

In this case the bleeding from the arm practised at the beginning triumphed over the fever, but caused no modification in the anasarca. The same may be said of the nitrate of potash and dog-grass. To these was then added *cahinca*, which, though taken at first with great repugnance, was afterwards administered regularly, but appeared to be without any effect, physiological or therapeutic. The action of the vapour baths, on the other hand, was very manifest. Seven or eight baths were sufficient to triumph completely over the disease.—*Lancette Francaise*.

—o—

ON THE NEW POOR-LAW ACT.

Mr. VERRAL having been requested to bring this subject before the Western Medical Association, began by reading the letter which appeared in our last Journal, and then proceeded as follows:—

GENTLEMEN—Before I proceed with the history of the conduct of the guardians towards their medical officers, it seems necessary that I should guard myself against a charge of inconsistency, which may, perhaps, be urged against me. It will be said, that while I have described the contention to be as eager as if it were for a prize of great value, I have affirmed the existing ratio of remuneration to be a pittance utterly unworthy of a struggle. Now, it happens, that both these statements are true, and that there is not in them any real ground for the charge of inconsistency. The real question, unhappily with many a practitioner is, not whether he shall be fairly compensated for his services, but whether, without the proffered compensation, wretched as it may be, he be able to obtain the means of decently supporting his family. Such is the alternative offered to the medical practitioner. The sum which his parish practice may procure him, may, perhaps, be less than one shilling a head upon the numbers he is called on to

attend, (a calculation which I know to be no unfair one:)—it may be a most wretched compensation for his medicines, his time, and his talents—for his many sleepless nights and toilsome days—for his exertions, both of mind and body—for the fatigues, the anxieties, and the dangers which he may be compelled to undergo. But, strip him of that poor sum, of that paltry and insulting compensation, strip him of that, and the balance that remains to him may be found inadequate to his support. Nor is the loss of this miserable stipend the only evil which he has to dread. He knows that if another, by under-bidding him, obtain the parish attendance of his district, he will be placed in a situation to interfere with the rest of his practice, and to win from him others, and perhaps, more important patients. The knowledge of this fact, and it is well known to those cunning gentlemen who are accustomed to the management of parish affairs, is frequently used to the injury of the medical practitioner, and I know has been held out in terrorem by many of the boards of guardians. A man will do in his official what he would be ashamed of doing in his private capacity; and to save a few pence in their respective poor-rates, the guardians have frequently insulted the parish surgeon by employing against him such an ungenerous threat. I have said, I trust, enough to prove that the wretchedness of the compensation must not be held to be inconsistent with the struggle that is made to obtain it.

One more observation and I have done with this part of my subject. I have heard it said by the farmers, that as they are suffering from the low rate of agricultural produce, that they cannot afford to pay the doctor as they ought, and that he must, therefore, be compelled to bear a share of their privations. Now, this, Sirs, is a matter that they ought to settle with their landlords. The poor-law question is one altogether between their landlords and themselves. The higher the poor-rates, the lower should be their rents. If they have cause to complain, then to these landlords let their complaints be made; but let them not seek to compensate their own losses by the robbery, (I can call it by no better name) of those who, labouring in their service, are worthy of their hire. They will say that they force no one to accept their illiberal terms; I maintain, that although there is no physical, there is a moral compulsion acting on the mind of the practitioner; that the wretched alternative between a shamefully inadequate salary and absolute ruin, compels him frequently to submit to the acceptance of terms derogatory to his talents, humiliating to his pride, and injurious to his interests; and I maintain, again, that the law which insists upon the possession of talent and the cultivation of knowledge, and which enforces a vast sacrifice of time and of money for the development of the one, and the ac-

quisition of the other, ought in common justice to protect us afterwards against the cruel oppressions at present inflicted upon us. We must not be consigned over to the tender mercies of the boards of guardians; we must not be held by these hard taskmasters in an almost Egyptian bondage; they must be deprived of the arbitrary power which they at present exercise over our fortunes; our practice must not be regulated, our interests unsettled, our prospects blasted, by their ignorant or illiberal decisions. There are, doubtless, amongst them many well-informed, and liberal, and kind-hearted men, but taking them as a body they know us not; they cannot appreciate our merits, they cannot estimate our services, they cannot even calculate our necessary expenses; but having heard the standing joke of elevenpence three-farthings profit out of a shilling, they chuckle over it as a witty answer to all our complaints, and make their calculations upon it as if they religiously believed it to be true. Ruinous to the profession it must be, ruinous alike to its peace, to its interests, and its character, if it be left thus to the mercy of those who care so little for its prosperity, and know so little of its worth. I have said nothing of the temptation which these miserable stipends must hold out for the substitution of cheap and inefficient medicines, for the more efficient and more expensive ones. I would fain hope there are few of us capable of so acting; but the people of England should know, that if any one be capable of so cruel and disgraceful a part, it is he who dishonourably supplants his more respectable neighbour by under-bidding him in his contract.

I proceed now to describe the mode in which the new law has been administered in relation to the medical officers, and in the first place I have to complain of the board of commissioners themselves, whose business it is to issue orders and regulations for the guidance of the board of guardians. Many very excellent orders these gentlemen have certainly issued: they had indeed a voluminous and well digested body of reports by which to direct their conduct. But those reports gave them no information, or none that was worthy of the name, upon the subject of medical attendance. The commissioners of inquiry, indeed, do not appear to have directed their attention to this part of the question, so that the board of commissioners seem to have entered on the subject without any information whatsoever, and playing, as it were, a game of happy-go-lucky, they instituted a series of experiments considerably similar in their effect to those which are said to have been made by certain unruly urchins upon a pondful of unfortunate frogs; and in the words of the latter we may fairly address them, saying, "Gentlemen, it may be sport to you, but it is death to us." The consequence of all

this has been, that instead of one consistent set of rules, the agreements are directed to be made with us in every possible variety of form. In one place every thing—medicine, surgery, midwifery, non-parishioners, &c. &c., were all to be included under one general contract; in another place, midwifery was to form an extra charge; in another, broken bones, or perhaps, surgery in general, or small-pox, or vaccination, were admitted as exceptions, while in many districts, the attendance of non-parishioners was to be contracted for at so much a head. All this "confusion worse confounded" is exceedingly improper, and towards the profession operates very unfairly, and that most especially in those places where nothing, or where the fewest things are allowed to form exceptions to the contract; for so ignorant, so uncalculating, or so unreasonable are the majority of the boards of guardians, that they either allow nothing for the things included, or not near so much as they would produce if admitted among the exceptions.

The first specific case that I shall mention to you, is that of the union of which I happened to be elected one of the guardians. The first proceeding was a considerate and very proper one, the union being divided into such districts as accommodated the medical gentlemen who had been accustomed to attend the different parishes. The next thing was to advertise for sealed proposals for the attendance of the several districts, including, as the commissioners had directed, every thing in one general contract. I must just observe, that in the course of the previous conversation, it was admitted by the guardians of the two principal parishes, one of whom was the chairman himself, that their medical attendants had hitherto been underpaid. Well, on the appointed day, the tenders were examined. No proposals had been sent in, save by those who, if I may be allowed the expression, were the natural attendants of the districts. The offers in the aggregate amounted to about 360*l.*, which the guardians, without calculation, refused at once to give. A repetition of the advertisement was then resolved upon, and, in the mean time the different parishes were required to produce returns of the sums paid to their medical attendants during the preceding three years. The appointed day again arrived, but with it there came no new tenders. There was no opposition on the part of their medical neighbours to those gentlemen who had previously offered themselves. Foiled in this attempt, the guardians exclaimed that there was a combination of the medical men in order to raise their prices. A combination! In the name of Heaven, gentlemen, what were they themselves? what but a combination of landlords and tenants, armed with irresponsible power, and resolved upon having their work done without paying for it? A combination,

taking advantage of the power which the law had unhappily given them, and acting in despite of reason, in despite of justice, in despite of the scriptural command, which says, "Thou shalt not muzzle the ox that treadeth out the corn." But being foiled in this attempt to excite opposition in the neighbourhood, they next examined the parish returns, which showed an aggregate annual expenditure of 311*l*. But then observe, first, that two of the surgeons had been confessedly underpaid; by this, I do not mean that any had been paid enough, for I know there was not one of them who had not been grossly injured in that respect—I mean then, that there were two of them especially underpaid, and that openly stated by the guardians of the parishes they attended. Secondly, that although the parish officers could make returns of their own medical payments, they could make no calculation of the sums which other parishes had paid for the attendance of paupers of theirs residing within this district. I was, however, prepared with such a calculation, which, though considerably imperfect, showed an average expense of more than 40*l*. This added to 311*l*, made 351*l*, and 9*l* more, shared between the two underpaid gentlemen, would have made up the exact 360*l*, which the tenders had amounted to. In vain, however, did I call on my brother guardians to adopt this fair and reasonable calculation. The majority of them would listen to nothing I had to say, and there was amongst them a young magistrate, a man of education, of considerable wealth, of gentlemanly manners—one from whom better things might have been expected, who was, if possible, more unbending, more unreasonable, more illiberal than the rest. I was accordingly completely cried down. They would listen to no calculations. They would have nothing to do with the non-parishioners; 300*l*. would be an ample remuneration for the whole, and at 300*l*. a year they stuck, threatening to advertise for one person to attend the whole of the union for that sum—for one person to attend 4000 paupers, midwifery, surgery, and all; and these scattered over a district sixteen miles in length. In vain did I expose the preposterousness of such an attempt, and the impossibility of carrying it into execution. In vain did I show, that the necessary expenses of assistants, horses, rents, &c. &c., would devour the whole sum, leaving nothing to the contractor himself. They would listen to nothing, or to nothing but the pleadings of their own pockets; and at length, after a deal of stormy discussion, the matter was settled for a time, by dividing 311*l*. among the respective medical attendants; thus allowing nothing for the attendance of non-parishioners, and not an additional halfpenny for those gentlemen who, as they confessed themselves, had not been sufficiently paid; and is it for this, gentlemen, that you have

undertaken the duties of a painful and laborious profession? Is it for this you have submitted to the drudgery of a five years' apprenticeship, and now at a distance from your homes and from your friends, are passing the better, or at least the gayer portion of your days in those deep and unceasing studies which alone will enable you to fulfil your future destinations in life? "Verily I say unto you ye shall have your reward;" but if these things are to continue, that reward must be looked for, not in the good things of this world, but in the silent approbation of your own hearts—in the proud consciousness of a conscientious discharge of your duties; and if this species of reward afford but a slender support to those who may hereafter look to you as their only stay, you must even compose yourself with the idea, that while you may after this life, be allowed, like Lazarus, to repose on Abraham's bosom, you will never be amongst the rich men who are to become inheritors of a less agreeable abode.

The next case that I have to relate, is that of a gentleman who was deprived of a parish which his father and he had attended for fifty years, and in which he had the earnest good wishes, and could have had the suffrages also of every inhabitant, whether rich or poor. A district was formed by the union of this parish with another of somewhat less extent. The gentleman I allude to, well knowing that he was likely to be opposed, and unwilling to let a stranger introduce himself into the midst of his practice, actually proposed to undertake the district for a sum scarcely exceeding that which he had been accustomed to receive for his own single parish. A young man who had just established himself in the neighbourhood, put in a much lower tender. The guardians of the larger parish warmly supported their former medical attendant, whose character was known and appreciated also by several other members of the board. But his opponent had his supporters also, some in consequence of the lowliness of the offer, and some from religious feelings, he and they being mutually dissenters. The question being put to the vote, the suffrages were found equal, but a gentleman who had just purchased an estate in the neighbourhood, who was a magistrate of but a few hours' standing, who never till that day had been qualified to sit at that board as an ex-officio guardian, and who was utterly unacquainted with all the parties and utterly ignorant of the merits of the case, most improperly, as I venture to think, gave his casting vote in favour of the lowest tender. The gentleman, thus deprived of a portion of his long-established practice, is one who is far from being rich—a husband—the father of a large family, whom a long course of incessant labour has scarcely enabled him to educate and support.

Nor is this the only loss which the same

gentleman has been doomed to sustain. In the town in which he resides he has for many years attended one, and on alternate years a second large and populous parish. So entirely have his services been approved of, that in the former parish, not more than eight months ago, an attempt having been made to supersede him, he was supported and triumphantly reappointed by a very large majority of the inhabitants; and in the latter it is not two years since he was solicited by an unanimous vote of the vestry to continue for a second year, though out of the usual course, that attendance which had given such universal satisfaction. The first thing the new poor law did was to set aside all these old arrangements. The town was divided into two districts, and one of these he was in great hope of obtaining. Will it be believed that politics here stepped in and deprived him of an appointment to which his character gave him so fair a claim. He had at the last election supported the two present liberal members of that, his native borough. Now there are residing in the town four ex-officio guardians in the shape of tory magistrates, and their number, added to a few of their creatures, whom they had been enabled to get elected as guardians, gives to their political party a majority of one. These gentlemen give themselves and the board little trouble when the ordinary business, that of relieving the poor, is the only order of the day, but when any of the officers are to be elected, or any job to be carried, they take good care to be present, even though they be dragged from their sick beds for the purpose. In this manner it was that the gentleman in question was thrown out, and a politician of the right stamp appointed in his stead.

I shall now just mention a case which will show you one evil arising from the arbitrary power at present vested in the guardians, and for brevity's sake I shall designate by the letters A. and B. two practitioners residing in two country towns exactly four miles apart. There are five adjoining or intervening parishes, three of which had long been attached to the practice of A., and two to that of B. The guardians threw the whole five into one district, and A., who obtained the contract, was thus forced into the midst of the practice of B., and became the attendant of persons some of whom lived four miles from his own house, and within a quarter of a mile from his opponent's very door. Thus were sown the seeds of strife between two persons who had hitherto been on friendly terms; and I would ask what possible right a board of guardians could have so to interfere with the interests of any practitioner, and so by their arbitrary decision to disturb the natural order of things? The sequel of this tale I relate with some degree of pride, in which I feel you will sympathize with me when I tell you that the successful competitor has

handsomely resigned to his neighbour the two parishes in question, and that he who has performed so worthy a part is connected with myself in the three characters of a successor, a pupil, and a friend.

Among the enormities which have resulted from the present system I have farther to mention the case of two respectable practitioners (partners) who have actually lost eleven parishes, the whole of which they have attended for a great many years, and have thus suffered an abatement of their professional income of some hundred pounds a year, because they would not degrade themselves by taking them upon such low terms as would have been destructive to their own interests and derogatory to the character of the profession. I grieve to add, that on terms so low, and so disgraceful, these and other parishes have been taken by two persons, also partners, the elder of whom is a man of considerable wealth, who is about to retire from practice, and who, we may reasonably presume, by thus adding to the nominal amount of his receipts, expects to obtain a higher price from the future purchaser of his share.

Had I searched farther a-field, I might doubtless have found many more, and many worse cases than these. In Kent, for instance, and in some other counties, the experiment has been tried of hiring one person to attend the whole of an extensive union, and a pretty scene of confusion has doubtless been produced by the experiment; and blessedly the sick poor must be attended to under such a system. But I have said enough to convince you—to convince any man of common sense and common liberality, of the gross impropriety and injustice of the present state of things. What, sirs, because the resident professional men refuse to give their time, to exercise their talents, to labour by night and by day, in sunshine and in storm, "in summer's heat and winter's cold," because they refuse to do this—not without an adequate compensation (for who expects to be adequately paid for the attendance of paupers?) but because they refuse to do it for a compensation most shamefully and notoriously inadequate, for a sum scarcely equal, in comparative amount, to the wages of a common mechanic; because they refuse to do it—not from uncharitable feelings towards the poor themselves, who often regard their regular medical attendant as almost their only friend, but because they refuse to do it to save the pockets of the mighty landlord, of the overgrown farmer, of the wealthy tradesman; and a combination of these men to meet, under the authority of the law, and by a tyrannical exercise of the almost despotic power which is vested in their hands, be permitted to disturb their peace, to blast their prospects, and deprive them of those advantages which their long years of study and attention, of labour and

successful practice, have fairly earned? Aye, and I may ask, are the poor themselves to be exposed to the misery of so violent and unnatural a change? Gentlemen, to youth and health I would grant but little relief; towards idleness and profligacy I would exercise but little forbearance; but in infirmity and in old age, "in the time of sickness and in the hour of death," I would not deprive the unfortunate sufferer of the consolation which the visits of a medical friend are so capable of bestowing; and in spite of the sneers of the cynic, and the contemptuous colourings of the satirist, I will fearlessly assert that there are thousands of our professional brethren who know how delightful it is to have the blessings of the poor; who know that second only to the power of restoring health is the charitable office of softening the terrors of despondency, of stilling the writhings of pain, of pouring oil on the ruffled waters of death. Again, then, I ask, are the suffering poor to be exposed to the misery of this violent and unnatural change. Are they to be subjected to the attendance, or, probably, the non-attendance, of an utter stranger? of one not connected with them by any ties of neighbourhood, of kindness, or of confidence? of one who has undertaken the task from the merest mercenary motives? who is, perhaps, not inspired with the most humane, as he certainly has not been actuated by the most honourable feelings, and who will, of course, be as sparing as possible, both of his time and of his trouble, aye, and of his drugs also; for that, we know is no inconsiderable part of the question, if we mean to administer such as the diseases of our patients require?

I burn with indignation, gentlemen, while I am asking these questions; I burn with indignation while I answer that such powers are placed in the hands of the guardians, and that they are often tyrannous enough, and illiberal enough, to exercise them in so oppressive a manner; nor is the indignation lessened, when I compare the wretched compensation awarded to the medical officer, with the salaries which are paid to some of the other officers of the unions. Take the chaplain, for instance, with his sixty or seventy pounds a year, for the performance of duties which demand not one tenth part of the time, one twentieth part of the labour, one fiftieth part of the study, or one hundredth part of the talent, which are demanded from the medical attendant of any one or two of the districts. Look too at the auditor, who has his fifteen or sixteen guineas for an occasional examination of the accounts, a task which may occupy him some six or eight days in the year, and which sum would be grudgingly given to the medical attendant of a parish containing two or three hundred paupers. But I could keep on thus till midnight, and then should have but half enumerated the evils of

which we have to complain. It were better therefore that I here conclude my address, with the length of which I fear you are already wearied. But before I conclude, permit me especially to express my feelings towards you, the younger portion of my hearers; the inheritors of our cares and of our toils, the inheritors of more than our knowledge, and I trust of more than our success.

Gentlemen, I address you not with the tongue of falsehood, nor do I wish to win you by the voice of flattery; but when I look on you, and the hundreds like you, who throng the schools of this mighty metropolis, when I see you, with all the ardour of youth, and all the sedateness of age, pursuing those abstruse and multifarious studies which alone will fit you for the stations you are about to fill; and, that ye may pursue those studies with effect, flying from, or sparingly sharing, the amusements and dissipations of this gay town; when I see you, hour by hour, listening with respectful attention to the lessons of your teachers, consuming the midnight oil in the perusal of works by which the information you have received in the day may be confirmed and enlarged; and digging after wisdom and knowledge in those dark and dreary mines in which they are best to be found—in those abodes of death, and disease, and decay, from which others would turn with disgust; and, when I compare with the lives you are leading, the idleness, the pleasures, the frivolities, the useless employments, the unintellectual pursuits of other young men of your age, your equals or superiors in fortune, your equals or superiors in rank; when I make, I say, a comparison so highly advantageous to yourselves, I cannot but ask, and feel assured, that your answer will be NO, whether you will tamely submit to return from hence to your homes, to have your destinies decided, your fortunes made or marred, your labours unrequited, and your talents set at nought, by men, in knowledge, in intellect, in industry, and in usefulness, so infinitely inferior to yourselves. Yet so it must be, if the poor law remain unaltered, and be administered as it now is. But the comparison I have drawn, has lighted up a bright ray of hope to break through the darkness that at present overclouds us. If, as we are told by Lord Bacon, "Knowledge is power," by whom, if not by yourselves, shall that power be possessed which knowledge has to bestow? Versed in all the sciences that bear upon your adopted profession, acquainted with the wonderful mechanism of the human frame, and accustomed to compare it with those of the other inhabitants of the earth, from the minutest insect, up to the elephant and the whale; instructed in the principles and operations of chemistry, with all its astounding results; conversant with the properties of metals and of the great

mineral kingdom, and accustomed to wield their powers, and to convert them to the use of man; versed in the history, the characters, and the virtues of plants, "from the cedar of Lebanon, to the pellitory that groweth against the wall;" daring even to dive into the most secret operations of the Creator, to investigate the mysteries of mind, to scan its powers, to watch its eccentricities, and to correct its aberrations—so enlightened, so endowed, what body of men is there to compete with yourselves in knowledge? Is it the clergy, with their Greek and Hebrew, their algebra and mathematics—learning which, adding, as they know, but little or nothing to their capability of performing their duties, is at first acquired from compulsion, and afterwards forgotten from neglect. Is it the lawyers, with their musty parchments, their legal fictions, their authorized chicanery, their studies of forms and precedents, or even with their occasional eloquence, the chief merit of which is "to make the worst appear the better side?" or is it the lordling, or the squire, or the gentleman farmer—those whose studies are the pedigree of a horse, or the staunchness of a pointer; whose only philosophical knowledge lies in the science of percussion, and whose only chemical compound is a mixture of sulphur and carbon, with nitrate of potass?

Gentlemen, if knowledge be power, the power of redressing your wrongs is placed in your own hands. But to obtain this desirable result, you must be firm, energetic, and, above all, united among yourselves. Be as the profession has hitherto been—a rope of sand—and you must continue to crouch beneath the iron rod of your oppressors; but let firmness and energy, and union of purpose, be superadded to your expansion of intellect, and your accumulation of knowledge, and you may then obtain the glory of gaining for your profession a more honourable rank, for yourselves a more independent station, and for your toils a more adequate reward.

The London Medical AND Surgical Journal.

Saturday, December 5th, 1835.

THE POOR LAW AMENDMENT ACT.

WHENEVER men whose opinions on most subjects are widely different or diametrically opposed, concur in an unqualified denunciation of any one thing, it is fair to infer that the thing in question is obviously and abominably bad. Now this is the case with respect to

the medical provisions of the new poor law act. With the general bearings of that piece of legislation we have nothing to do here; but in as far as it relates to the poor, who are the suffering party, and to the medical profession, who are the insulted party, we join most sincerely in the general expression of execration against this most flagitious and contemptible act. It is astonishing with what unanimity the medical profession in town and country exclaim against its cruelty, its insolence, and its absurdity. Every medical journal cries out against it; the *Lancet* pricks it, the *Lizard* gapes at it, and we pound it. For our own part we are overwhelmed with letters from the most respectable and experienced practitioners in all parts of his Majesty's dominions, all echoing the universal feeling: nay we are convinced that the dark recesses of Pall Mall, of Lincoln's Inn, and of Black-friars, are filled with stifled murmurs, and that if it were not for the fear of seeming to sympathize in anything with the mass of the profession, the *noodles*, the *curs*, and the *hags* would break forth in a "horrid harmony" against a measure so vile, that not even they can derive any advantage from it! What is the upshot of the matter? Long walks, neglect, and death, for the pauper—long rides, ridicule, and *half-a-crown per annum* for the doctor! We do hope that in this instance, if in no other, the profession will lay aside its wonted supineness. Every medical man who lends his aid directly or indirectly to this most iniquitous affair, is an enemy to his profession and to humanity; his conduct admits of no extenuation—selfishness offers no inducement, for there is nothing to be gained; poverty offers no excuse, for the half-crown pittance is insufficient to ward off starvation. Will nothing open the eyes of the profession? Do they not see that the tameness with which they have submitted to the tyranny of the medical oligarchs, is now beginning to

be perceived and acted on in every quarter? Do they not see that the *gratuitous humbug* which they have themselves assisted in setting up, is continually made a precedent for proposals, the parallel of which no one in his senses would ever dream of making to any class of men, professional or non-professional?

We should like to see how a baker would look, if he were asked to supply the paupers of a parish with loaves all the year round at half-a-crown a head; he would throw a loaf at the head of him who made the proposal, and he would do quite right. We adjure our brethren to consider this affair seriously. The indignities that have been heaped upon the medical profession have now arrived at their acme; the "heads of the profession" have long looked with scorn upon what they deem the tail of the profession—the *subordinates* to wit; the public have long since taken the hint, and regarded the said tail as a thing to be trodden on; and now, to crown all, the legislature has offered to the general practitioners of England terms which, setting aside all honorary considerations, and putting the matter on the common footing of *price for value received*, are beneath the acceptance of the lowest tradesman or the rudest mechanic! Let the general practitioners of England show on this occasion, that their long subservien-
cy to the medical oligarchs, (of which we pray their forgiveness for saying they ought to be most heartily ashamed) has not utterly divested them of the common feelings of Englishmen. Let them refuse, as one man, to have anything to do with the administration of this infamous system. But let not the poor suffer; let the practitioners of every district manage amongst them to attend the poor gratuitously, till the inhuman act has been fairly defeated by their joint and continued opposition, and let the gentry of every district co-operate with the medical men in this

good and charitable work. What! Do we, after all that we have said, advocate the *gratuitous humbug*? No, indeed! There is all the difference in the world between the man who, actuated by real humanity, gives his services to the poor who need them, and the man who, to answer his own selfish purposes, puts on the mask of charity, and, compromising both the interests and the honour of his profession, suffers himself to be made a dispensary drudge in the hope of one day reaping a golden reward for his hypocrisy.

—o—

DEATH CAUSED BY MORRISON'S PILLS.

WE learn from last week's papers, that another votary has fallen prostrate at the shrine of Hygeia—in other words, that another unfortunate individual has been killed by Morrison's pills. We wonder much that the wise men of the poor-law amendment act do not make application to Doctor Morrison; that gentleman, being a philanthropist, would, no doubt, supply them with a few thousand tons of pills at a very moderate rate, and if every pauper in England had a hatful of them for his weekly allowance, all further medical arrangements would be rendered superfluous, and, indeed, the whole system of the poor-laws might be embraced in an act "for the sufficient supply of universal vegetable pills to the poor of these realms, and for their decent interment when dead of the same."

—o—

BENEVOLENT DISPENSARY FOR THE RELIEF OF THE POOR AFFLICTED WITH FISTULA, PILES, AND OTHER DISEASES OF THE RECTUM, ALDERSGATE STREET.

OUR readers will perceive, by an advertisement in this day's number, that a dispensary is opened for the relief of a class of painful diseases which have been too long consigned to unprincipled empirics, because the profession had, until a recent period, neglected them.

The folly of excluding such diseases from the domain of pathology reflects no great credit on our hospital and dispensary functionaries. It is only within a recent period

that a worthy contemporary of ours lauded Mr. Martin Van Butchell, of advertising celebrity, as infinitely superior to the whole profession in the treatment of the maladies to which we have alluded! But every medical practitioner must hail the establishment of an institution having the surgical aid of a gentleman, a distinguished member of the profession, who has for many years devoted his whole attention to the investigation of the nature and cure of diseases of the rectum. Mr. Salmon has cultivated the study of rectal diseases more assiduously than any of his contemporaries. He has a collection of specimens of rectal and pelvic diseases more extensive than any in Europe. This has naturally excited the ire of certain hospital monopolists against that gentleman; but the voice of the profession is in his favour, and we know that he is consulted from all parts of the kingdom, and has patients sent him not only from distant parts of this empire, but that he has been frequently called to France. Many of his preparations or specimens of disease may be seen at the new dispensary, and every member of the profession may inspect them on Tuesdays and Fridays, from one to two o'clock.

We enter into this statement for the purpose of attracting the attention of our readers to a valuable charity—one long wanted—and with the hope that they will send their poor patients to an institution in which they may obtain relief. In saying this we do not mean in the slightest degree to detract from the merits of our brethren, but as the advocates of humanity, we must state, *coute qui coute*, that there are not, in our opinion, five surgeons in this kingdom who understand diseases of the rectum, or whom we should consult, were we unfortunately the subject of such infirmities. The truth is, until Mr. Salmon and Dr. O'Beirne published their respective works, the subject was greatly neglected, and we do not name preceding or subsequent writers, because their productions were superficial and most imperfect. The reason of this was, that in autopsies the rectum was scarcely ever examined, nor is it even now in this country, in one case in a thousand, by the great majority of surgeons. It therefore follows, they can know nothing about them.

We feel convinced that in bringing the new charity before our readers, we shall benefit the poor afflicted with diseases, which it is intended to alleviate or remove.

—o—

MEDICO-BOTANICAL SOCIETY.

AFTER a congratulatory address was presented to Earl Stanhope, President of the Society, on his return to this country from his tour through Europe, Dr. Sigmond pronounced the following eulogium on the late Professor Burnett:—

I have now a melancholy task to fulfil, and which must materially check the feelings of pleasure usually attendant on the first meeting of the session. I have to announce the death of a highly gifted and much loved individual, who filled, with honour to himself and to the Society, the distinguished office of Professor of Botany—Gilbert Burnett. His career has been untimely stopped by the inscrutable decree of that Great Being, whose beauteous works he studied with delight, whose wondrous paths he loved to trace. At a period of life when few have even commenced the search of knowledge, he had, by his devotion to the sacred cause of science and of truth, attained the respect and the esteem of the wise and the good; and he was recognized as a highly accomplished teacher, from whose stores the rich harvest might safely and surely be diffused.

His delivering of a course of lectures at the Royal Institution of Great Britain, first attracted attention, as well from the classic learning, as from the intimate acquaintance with the nature and uses of the vegetable kingdom, that they displayed; the high character which he obtained, and the promise of future excellence which he thus held forth, induced our illustrious president to consider him as the fittest person to fill the then vacant office of professor of botany to this institution, and which he held to the day of his death. The zeal and ardour with which he attached himself to our interests, realised the sanguine expectation of our president, and called forth repeated testimonials of your approbation, and they are the best proof that you appreciated his labours. When a chair was established in the King's College, for a professor of botany, he was the individual upon whom, after mature deliberation, the choice fell, and the appointment was hailed with universal approbation. He felt, and he often expressed his conviction, that it was owing to the testimonials that your illustrious president gave, that his claims to the professorship were recognized. The next official station to which he was elevated, was one that was a source of great gratification to him, as it came from a body, determined scrupulously to weigh every consideration, before they appointed their pro-

fessor, and as the Society of Apothecaries had exhibited the greatest anxiety to forward botanical knowledge, their selection of Professor Burnett was a still further proof of the estimation in which he was held. He was, however, destined only to enjoy the honour which it conferred. Disease preyed upon his frame, and before he could fulfil the duties which devolved upon him, he was numbered amongst those who have been.

As a writer, his works have been highly estimated, and the popularity amongst students, of his *Elements of Botany*, is a proof that it is a practical guide to the study of plants; his edition of *Medical Botany* is replete with information, and displays his reading; his occasional lectures delivered in these walls, and also at the King's College, have been published, and have been admired; whilst upon the minds of those who heard them delivered, a lasting impression is left. His works will remain a memorial of his talents, his industry, and his knowledge.

As an editor of a distinguished medical periodical, he obtained the character of an impartial, acute, and honest critic; he praised wherever it was in his power; no unkind thought or expression ever issued from his pen, and where admonition was necessary, it was conveyed with a gentleness of spirit, and a mildness of feeling, that left behind no sting. He had the honour, during the last session, of filling the highly respectable station of President of the Westminster Medical Society; his firm and temperate manner conciliated for him the respect and esteem of all. I cannot but look back with pleasure to the circumstance, that it was my good fortune, as a member of that Society, to propose him as its president, and that I enjoyed an opportunity of expatiating whilst living upon those good qualities which, after life's fitful dream is past, we reflect upon with undiminished feelings of admiration; it was also my lot to second his nomination to the Professorship of Botany at the Royal Institution; and I likewise obtained from your president, permission to nominate him in this Society, little anticipating the time when I should mourn over him, dead, whom I ventured to praise whilst living. You—all of you—admired and respected him, and it was always with pleasure you received him here, and it was with the deepest sorrow we watched his gradual decay. He came to our councils, he assisted at our meetings to the last: he anticipated this evening's meeting, and looked forward to it with hope, yet with fear. He was with us the last night of our session, and we all inquired with anxious solicitude after his health, and heard him, with the self-deception that is so often attendant on disease, flatter himself with delusive promises, never to be fulfilled. His lectures here never failed to attract a large assemblage of fellows and of visitors, and he imparted his knowledge, which was most orderly and me-

thodically digested, with ease and with elegance. Determined to be accurate even in the employment of words, his discourses were remarkable for their clearness and their precision; indeed, he was a philologist of no ordinary merit, and he loved to seek, in our older authors, the names of the plants which he described, and from their quaint titles was often led to the discovery of their medicinal qualities, or the powers which our forefathers ascribed to them. It was still more delightful to accompany him in his botanical excursions, when surrounded by his pupils; he taught the grandeur of nature, her order, her simplicity, her truth; his mind was sensibly alive to the beauty with which the vegetable kingdom is adorned; he was richly endowed with that exquisite sensibility which exercises over some men the most delicious sway, and imparts to their thoughts an irresistible charm. He gave expression to these thoughts, with an enthusiasm which carried conviction to his hearers, and he clothed them in language which was classical, chaste, and impressive. He was beloved by his pupils, to whom he imparted his knowledge without reserve, and to whom he was indeed "a guide, philosopher, and friend." He taught them that botany was not a collection of names—a mere systematic arrangement—but that it belonged to agriculture, to commerce, to geography; he showed its utility, nay more, its absolute necessity to man, as furnishing him both with nourishment and with medicine for his support, and for the alleviation of the sorrows with which he is afflicted.

All his efforts have been directed for the improvement and happiness of man, and he has carried with him to the grave, the gratitude and the kind recollection of a host of friends, attached to him by the warmest ties. He has bequeathed to posterity the result of his labour and his industry, and likewise a reputation and fame, of which this Society reaps a rich and brilliant share, from the records it possesses in its Transactions.

It was unanimously resolved, that the report of the death of Professor Burnett be entered upon the minutes, in the language in which the secretary had announced it.

Charles Johnson, Esq. delivered an address upon the importance of the study of medical botany.

Mr. Foote read a paper on the application of the juice of the monchinal tree in cancer, translated by him, from the French of Mr. Germon.

—o—

WESTMINSTER MEDICAL SOCIETY.

Saturday, Nov. 21, 1835.

DR. ADDISON, PRESIDENT.

Mineral Magnetism.

DR. SCHMIDT repeated the experiments which had led him to believe the north pole produced a north pole, and the south a south

one, in opposition to the generally received opinion; a great number of experiments were shown both for and against the new "facts" adduced by Dr. Schmidt, and a long discussion ensued, in which Mr. Bird, Dr. Ritchie, and Mr. Everitt were chiefly distinguished. After three hours spent in the debate, no satisfactory conclusion having been come to, the Society adjourned at 11 o'clock—it having been moved by Dr. Johnson that the discussion of mineral magnetism, as a remedial agent in disease, be alone entered into at the next meeting.

Saturday, Nov. 28, 1835.

MR. RICHARD QUAIN IN THE CHAIR.

Death from Morison's Pills—Post-mortem appearances—Mineral Magnetism.

DR. SIONI, of Madrid, was elected an honorary member of the Society.

Dr. Granville said, he would be obliged to Dr. Johnson, if he would state to the Society the post-mortem appearances of the female who died from taking Morison's pills, whose case was reported in the newspapers.

Dr. Johnson had attended the inquest held on the body of the female in question, on the 23rd of the month. He had not the opportunity of seeing her previous to her death, in consequence of his being from home when he was sent for to attend her. Mr. H. Johnson and some other gentlemen examined the body twenty-seven hours after death, when the following appearances presented themselves. The abdomen was tumid, there was no peritoneal inflammation, but very slight marks of inflammation of the stomach, and also some slight appearances of abrasion of that organ. The duodenum was free from any signs of disease. The jejunum and ilium in different distinct portions, presented patches of an intense dark red colour, resembling dark mahogany, the vessels were so injected that many of them had given way, and the blood was extravasated in patches; there was no ulceration, but there were several points, which might be called abrasions, the mucous membrane rubbing off with the slightest touch of the handle of the scalpel; in the sound parts between the diseased patches above mentioned, there were rigid contractions of the membrane; the healthy and diseased parts did not blend together but were distinctly separated. Nothing particular presented itself in the large intestines; the colon was distended with air, the chest was healthy, the parietes of the heart were somewhat thickened, presenting appearances similar to those on the commencement of hypertrophy. In the head, the venous system was much congested throughout, but there was no actual disease of any kind; in fact, nothing was found in the body to account for death, except the morbid appearances in the jejunum and ilium, above mentioned.

In answer to a question from Mr. Verral, Dr. Johnson did not know whether there was a total cessation of action in the bowels for two or three days before death; but he had inquired of the medical gentleman who had attended her, who informed him, that shortly before beginning to take the medicine, about ten days before her death, the woman had been recommended to give her child Morison's pills for palpitation of the heart; she gave them accordingly, but the child got worse instead of better; she herself was seized with pain in the head shortly afterwards, and began taking the pills, which almost directly produced violent purging and vomiting; a neighbour told her the more they acted the better, and the more she was to take. She took eight to eighteen pills daily; the symptoms increased; she became delirious, and her friends would not allow her to take any more of the pills; she became comatose, and in that state died. The bowels could hardly be said to have acted for two or three days before her death, as there was nothing in them to be acted on.

Mr. Verral was induced to ask the question, from having had the opportunity some time ago, to witness two cases of death from taking these pills. One was the case of a phthisical young man, at Brighton, who took them for two months; at the end of which time, the bowels entirely ceased to act; enteritis came on, from the effects of which he died. The other case also happened at Brighton; it was that of an old gentleman who had been an inveterate swallower of Morison's pills. Mr. V. had assisted at the post-mortem examination. The small intestines were inflamed in patches, like those described by Dr. Johnson, but the intestines were not empty. The patient had taken thirteen to fifteen pills daily; their effect of purgation, however, stopped, and no other medicines would act. For nine days before death he had no dejection. The pills, with other medicines which he had taken to open the bowels, were found in a most offensive state.

Dr. Granville begged to ask Dr. Johnson, if he remembered whether the appearances in the case he related, were similar to those which had been described in other cases, in which death had been caused from taking these pills. Might not the woman have died from enteritis, produced from some other cause?

Dr. Johnson could not be expected to remember all the cases on record of death from Morison's pills; he would, however, state the reasons, why he had concluded the woman died from taking the pills. In certain convolutions of the intestines, there was intense inflammation, whilst other portions were not at all inflamed; he considered this to arise from the irritating substance having remained in certain portions of the intestines; the

portions so affected were well marked from the other healthy parts; had the inflammation arisen from natural causes, there would have been an imperceptible blending of the healthy and diseased portions. He considered the contraction in the healthy intervals, another proof in support of his opinion, for when irritating poisons were taken, the like effects were produced. Other irritating pills might have produced the same effect, if given so injudiciously as these had been; the vomiting was a symptom of an irritating substance being in the stomach. The absence of ulceration and all other signs, save those he had just mentioned, to account for death, had led him to believe the violence of the inflammation in the intestines had affected the brain, and she died from a shock given to the nervous system. People who had been in the habit of taking Morison's pills had complained to him of their producing headach and giddiness; he believed they contained a large quantity of extract of conium. It would be remembered, this woman died comatose. Here the subject dropped.

The subject of mineral magnetism was resumed, a very long discussion on which was entered into. Dr. Johnson said the Society had been employed during its last two meetings, about mineral magnetism, which had proved that doctors were not the only persons who disagreed, for natural philosophers of the first talent had been quarrelling all that time about one of the first laws of nature—attraction. The Society was like a ship becalmed between two poles, and could not move one way or the other; or like Mahomet's tomb, suspended between two great magnets. Nothing was decided at the former meetings. Now he contended, the power of the magnet as a remedial agent, like that of medicines, could not be decided by *à priori* reasoning, but by experience alone; he therefore considered it useless to discuss the subject until we had facts to work on.

Dr. Epps agreed with Dr. Johnson, that experience alone could decide on the properties of a medicine; but no medicine should be condemned because we could not explain its mode of operation; Dr. Schmidt had cured many diseases by the application of magnetism—amaurosis and cholera, in particular. Atmospheric changes were known to affect the system materially; why should not magnetism act on those nervous diseases which unfortunately are too common in our country? Dr. Ritchie had allowed that Dr. Schmidt was right when he asserted that the north pole produced a north pole, and Mr. Farraday had also considered it as a discovery.

Dr. Ritchie said he did not deny the north pole produced a north pole; but he contended that it must produce a south pole at the same time. Dr. S. had therefore only stated half the fact. The great question, however, to decide was this—Can the magnet, used in the way described by Dr. Schmidt, that of placing

the north poles opposite to each other, with the body to be acted on intervening, produce any physiological effects at all? Now, he contended that the magnet, without the aid of electricity, could under no circumstances produce any "physiological" effect. He challenged Dr. Schmidt to produce any effect in the way he had described.

Dr. Chowne wished the new power, which he understood Dr. Schmidt had discovered in the magnet, to be at once decided on, whether in existence or not.

After some further observations from various gentlemen—Dr. Schmidt said, he believed that the magnet undergoes some new modification from the facts he had observed; he had no wish to boast of what he *could* do with it; he *had* tried it in various diseases, and found it a successful remedy: he had no doubt of its value; and his object in coming before that Society was for the purpose of introducing its virtues to the notice of the medical profession. He should be happy to try the effect of magnetism on any poor patient of any of the gentlemen present.

Dr. Chowne asked if Dr. Schmidt's magnets were different from those of other persons? Dr. Schmidt replied they were precisely the same, but possessed more power: Dr. Farraday and Mr. Everitt had confessed this, and had purchased some of great power from him.

Mr. King expected some more scientific explanation from Dr. Schmidt; if the magnets possessed the virtues he ascribed to them, it would have been easy for him to have collected cases in which he had succeeded in producing good effects from the use of them.

Dr. Schmidt said nothing would have been more easy than to relate the cases, but he could not authenticate them, his chief cures having been made on the continent; he wished the Society to judge of cases for itself.

Mr. H. Thomson was authorized to give Dr. Schmidt as many cases of amaurosis as he might wish for, to try his remedy on; if Dr. S. would favour him by coming to Westminster Ophthalmic Infirmary, every facility should be given to him, and he would report progress to the Society.

Dr. Schmidt was most happy to accept the offer.

Mr. King believed he might confidently say the magnet had no power in curing disease. Dr. Elliotson had applied it in several cases; only temporary effects were produced—no permanent benefit. He now, however, wished to ask Dr. Ritchie whether he believed the magnet applied alone could have any physiological effect at all?

Dr. Ritchie contended that it could not.

Mr. Clarke thought the question of Mr. King a rather inconsistent one; he first stated that Dr. Elliotson had produced temporary effects by the magnet applied alone—that effect must have been a physiological one; and Mr. King now asks Dr. Ritchie

whether any effect *could* be produced by such application, after stating that an effect *had* been produced.

Some further conversation took place, in which it was strongly recommended to Dr. Schmidt that he would visit all the large hospitals, and try his remedy in all cases he could; for the virtue of a remedy like the magnet must be decided by an unlimited number of cases, and an unlimited time for its application. Under the impression that Dr. Schmidt would adopt this plan, the Society adjourned.

It is only due to Dr. Schmidt to state, that he appears willing to give every opportunity of deciding on the merits of his magnets.

LONDON MEDICAL SOCIETY.

Monday, Nov. 30th, 1835.

DR. WHITING, PRESIDENT.

Fractures of the Upper Part of the Thigh Bone.

MR. BRYANT exhibited a specimen of fracture of the upper part of the thigh bone, taken from a woman aged 63, who on the 27th of October was walking along the street, when she fell down, and was unable to rise again; she had struck the trochanter major of the left femur against the curb stone. She was taken home and put to bed, but no splints or bandages were applied. Three days afterwards Mr. Bryant saw her; he found the affected limb two inches shorter than the other, the foot was everted, and there was distinct crepitus on rotation of the limb. She was put on a fracture bed, but on the following night she became restless and uneasy, and tore off the dressings and splints that had been applied, and refused to have them on again. She was now placed on the affected side, the leg flexed, and the knee placed on a pillow. In this way she appeared to be going on very well until the 20th of November, when she became feverish; her tongue was dry and furred, the pulse rapid, and the skin hot and dry. She continued to get worse, and on the 28th she died. She had been a woman of very intemperate habits, and her constitution was much enfeebled by excess of stimulus. Mr. Bryant, when her strength appeared to be giving way, gave her her accustomed stimulus—gin. On examination after death, the bone was found to be fractured through the trochanter major; and the head of the femur was driven into the cancellated structure. The trochanter minor was broken off. The fracture was external to the capsular ligament; no attempt at union had taken place. Mr. Bryant had brought forward this case for the purpose of introducing to the Society the plan of treating fractures without splints, which has lately been so ably advanced by Mr. Radley, in several letters which have been lately published in the "*Lancet*."

Mr. Bryant thought that in fractures of the extremities of cylindrical bones, the plan was a good one, and worthy of trial; he did

not mean to say it would suit all cases; the present was one in which probably no plan would have succeeded. He should be fearful to trust to it, however, in fractures of the shafts of those bones.

After this statement of the case, a long discussion took place as to the cause of death in cases of accidents of this description, where the *post mortem* appearances were not sufficient to account for it. Mr. Bryant considered his patient to have died from the weakness of her constitution, and her intemperate habits, the abstraction of her accustomed stimulus bringing on a low fever, of which she sank.

Mr. Greville Jones thought she died from a *peculiar kind of irritation* in which exhaustion of the nervous power took place. He exhibited a specimen of fracture of the thigh bone of the gentleman who was a short time ago knocked down in Regent Street, and died in four days afterwards; the fracture was by no means a severe one, though comminuted, for there was no extravasation. Now the body was strongly muscular, there was no fever, and yet he sank. Another case in point was narrated: in Mr. Bryant's case he thought life had been prolonged by the judicious administration of the stimulus.

Dr. Johnson thought the shock given to the system at the time of the accident, might in old persons be sufficient to account for death, without reference to the accident.

Mr. Pilcher and Mr. Bryant considered the confinement to bed and constraint, were the cause of irritation in old persons, which frequently produced death in accidents of this kind. Mr. P. considered Mr. Bryant's patient did not die of irritation or collapse, but the reaction following it.

The subject of treating fractures according to Mr. Radley's plan, was then entered into.

Mr. Dendy thought the plan a good one in some cases of fractures of the extremities of cylindrical bones; but when the fracture occurred in the shafts, he thought the plan totally inadequate: he thought that it would be dangerous to leave the fractured limb to itself, for should spasm come on, or the limb be the least disturbed, a deformity might be the result. He was no advocate for complicated apparatus or bandaging; the less that could be safely used the better; but he could not consider that Mr. R.'s plan was a safe one in fractures of the shafts of bones.

Mr. Clifton thought the double inclined plane the easiest and safest plan of treatment—much better than laying the patient on the side. He would ask Mr. Bryant what advantage he considered was derived from the change of position he had adopted in the case in question.

Mr. Bryant replied he considered the position he had adopted a more easy one; though he did not expect to get perfect union of the bone, he thought it might have answered all the purposes of locomotion.

Mr. Dendy could not but consider the position on the side a bad one; the ends of the bones must rub together; however in Mr. Bryant's case, as there was no actual separation of the bone, such result might not have followed.

Another speaker thought Mr. Radley's plan a good one, in almost all cases. Mr. R. had given a very interesting case in which he had dispensed with splints and bandages, where both bones of the leg were fractured. The patient got about in five weeks, whereas, when he had once before only one of the bones fractured, and splints were applied, the union was much longer in taking place. With regard to the position, that must be adapted to the habits of the individuals, which is part of Mr. Radley's plan.

Mr. Pilcher thought the position should not depend only on the habits of the individual, but on the kind of fracture. He believed the plan of laying the patient on the fractured side, had been adopted by Mr. Abernethy, for the purpose of the pressure of the pelvis keeping the upper part of the fractured bone in apposition with the lower.

After some further remarks from one or two gentlemen, respecting the possibility of osseous union taking place in fracture of the neck of the thigh bone, within the capsule, it was believed by Mr. Pilcher and Mr. Clifton possible, but if it could be decided on the contrary, Mr. P. thought it cruel to keep the patient confined to bed, as had been done for weeks or months, for the purpose of procuring that union. The Society then adjourned.

MEDICAL BOTANY.

—

PLATE X.—DIGITALIS PURPUREA — FOX-GLOVE.

THIS is an indigenous biennial plant, very common on hedge-banks, and sides of hills, in dry, gravelly, or sandy soils, and the beauty of its appearance has gained it a place in our gardens and shrubberies. The leaves are large, oblong, egg-shaped, soft, covered with hairs, and serrated. They have a bitter, very nauseous taste, with some acrimony. We should choose the leaves of plants which grow spontaneously in elevated places exposed to the sun, and gather them before their inflorescence. Destouches analyzed foxglove. Four ounces of the dried leaves yielded successively nine drachms of watery, and seventy-eight grains of alcoholic extract. The first was brown, smooth, and of a consistence fit for making pills. The second had a very deep green colour, a virose and disagreeable smell, the consistence of tallow, but more tenacious; did not furnish ammonia by distillation, and was not acted upon by acids. The ashes contained salts of lime and potass. M. Le Royer thinks that he has discovered the active principle of digitalis, Digitaline. He describes it as brown, pitchy, deliquescent, capable of crystallization, but not crystallized, of intense bitterness, and seeming to possess the prop-

erties of the plant in a high degree. It has not, however, been admitted as an ascertained principle by other chemists.

The seeds are very small, and contained in an ovoid capsule.

Med. use.—The effects of foxglove, when taken into the stomach, are, to diminish the frequency of the pulse;* to diminish the irritability of the system; to increase the action of the absorbents, and to increase the discharge by urine.

In excessive doses, it produces vomiting, purging, dimness of sight, vertigo, delirium, hiccough, convulsions, collapse, death. For these symptoms the best remedies are cordials and stimulants. According to the doctrine of the new Italian school, it is one of the most powerful contro-stimulants.

Internally, digitalis has been recommended, in inflammatory diseases, from its very remarkable power of diminishing the velocity of the circulation; in active hæmorrhagies; in phthisis; in some spasmodic affections, as in spasmodic asthma, palpitation, &c.; in mania from effusion on the brain; in anasarca and dropsical effusions; in scrofulous tumours; and in aneurism of the aorta, and hypertrophy of the heart, I have seen it alleviate the most distressing symptoms.

Externally, it has been applied to scrofulous tumours. It may be exhibited, 1. In substance, either by itself, or conjoined with some aromatic, or made into pills, with soap or gum ammoniac. Withering directs the leaves to be gathered after the flowering stem has shot up, and about the time when the blossoms are coming forth. He rejects the leaf-stalk, and middle rib of the leaves, and dries the remaining part, either in the sunshine, or before the fire. In this state, they are easily reduced to a beautiful green powder, of which we may give, at first, one grain twice a day, and gradually increase the dose, until it acts upon the kidneys, stomach, pulse, or bowels, when its use must be laid aside, or suspended.

2. An infusion. The same author directs a drachm of the dried leaves to be infused for four hours in eight ounces of boiling water, and an ounce of any spiritous water to be added to the strained liquor, for its preservation. Half an ounce, or an ounce of this infusion, may be given twice a-day.

3. In decoction. Darwin directs that four ounces of the fresh leaves be boiled in two pounds of water, until they be reduced to one, and that half an ounce of the strained decoction be taken every two hours, for four or more doses.

Errata.—In page 546, in the Translator's note to Broussais' Lecture, for "So, on the one hand," read "To, on the one hand;" and, a little lower down, for "national" read "rational."

[Books and Correspondents next week.]

* Dr. Sanders, Dr. Epps, and others, contend that it increases the frequency of the pulse at first.—Ed.

SELECT LECTURES,

FROM

M. BROUSSAIS'

*Course of General Pathology and Therapeutics ;
translated and revised*

By JAMES MANBY GULLY, M.D.

LECTURE XXVI.

*Chronic Enteritis and Infantile Mesenteric
Disease.*

WE have still to examine the partial affections of the small intestine, which are less frequent than those of the stomach and duodenum, but whose existence is certain, and capable of being diagnosticated. In them digestion is effected in the stomach ; there is no pain in the passage of the aliments through the pylorus and duodenum ; lower down, and when they have reached the small intestines, abnormal movements commence, such as borborycni, nervous phenomena connected with hysteria, a host of distressing sensations, globus hystericus ; in short, a neuropathic state, which will be described in its proper place.

You may for the most part recognize partial phlegmasia of the intestines by percussion: on one or other side of the umbilicus, and sometimes beneath it, you perceive a spot that is more resisting and more painful, and the sound is then less clear ; there is no diarrhœa, but some colic: the intestines rumble in consequence of the alternate ascent and descent of gases in the points of constriction, and convulsive strangu-lation, &c. If there be no complication of acute or chronic inflammation of the upper portions, these are the only phenomena: the patients eat well, have no belchings, no regurgitations nor gastric heat ; but three or four hours after eating, nodosities begin to form in the intestines, percussion gives a clearer sound in some than other parts, and after the disease has continued for some time, pains come on. Generally speaking, pains do not readily obtain in the small intestines: it is rather colics that specially belong to them ; these do not produce strainings and desire to stool, but cause rending pains, as if the abdomen were about to give way, and

there is a feeling as if foreign bodies were in it: the patients bend to the side where such seem to be, and where the nodosities alluded to form, which shift their situation, now at the right and again at the left side of the umbilicus, and sometimes behind the bladder and uterus. The absence of the signs that belong to affections of the two last named organs prove that these colics have nothing to do with them.

Various shades of this enteritis may exist. It may be subacute, and such it is frequently found to be in children from five or six years up to puberty. This is the kind to which mesenteric disease is referable. You will read in authors that that disease occurs with diarrhœa, which however does not come on until the disease has passed the ileo-cæcal valve, and reached the great intestine. For a long time I had doubts on this subject, for want of sufficiently explicit observations: but I finally found grounds for dividing these enterites into two series—one with purging, the other without. Patients who in the first instance have none eventually, are attacked with them when the disease is not arrested, in which case they rapidly lose strength. Children are brought to you who have good appetite, eat with avidity, have an habitually small and frequent pulse, tongue somewhat red, as yet no diarrhœa, meteorized belly, nocturnal heat, and progressing emaciation. If you apply no treatment, and see them some months afterwards, you will find still the same meteorismus, and some hard lumps in the abdomen, which lumps are ganglions that are tumefied by the disease. At a later date diarrhœa commences. This diarrhœa by older authors is called lientery, and was regarded as the effect of an obstruction of the mesenteric glands ; they used to say that the glands being oppilated, chyle could no longer traverse them, but was evacuated by the stools along with excrementitious matters. And it is true enough that the stools are composed of greyish digested matters, that have not been deprived of their chyle by absorption. But this fact has been badly explained ; they thought that the mesenteric glands, primarily diseased and obstructed, no longer allowed the chyle to pass: but it is the enteritis

which hastens the flow of the food downwards, and it is the cæco-colitis that expels them. The glands are not primarily diseased; there may be an ileo-colitis with purging, without mesenteric obstruction—the latter, therefore, is not the cause of the purging, but the effect of the inflammation. The purging is owing to the phlegmasia of the mucous membrane, which hastens the movements of the muscular coat, and causes it to expel the chyle before it could have been absorbed. Subsequently, in consequence of sympathetic suffering from the irritation of the mucous membrane, the ganglions swell, and as children are more disposed to these kinds of swellings, they grow to a great size and degenerate into tubercles, if the disease be prolonged. Enormous masses of them are sometimes met with, and they strike the attention so much, that no thought is taken of the mucous inflammation, their primary cause. When at a certain pitch, this affection determines an effusion into the peritoneum, and this is not uncommon when purging is present.

Subacute enteritis is less frequent in adults, for one of whom that has it, there are twenty or thirty attacked by it. Adults have not, for the most part, fever, but, like children, they have meteorismus of the centre of the abdomen; there is some more resisting point: glands are also sometimes felt; the disease unchecked, diarrhœa comes on; sometimes lumps of considerable hardness form, caused by the annular contractions of the intestines. The disease ordinarily passes to the acute state, or a fatal peritonitis supervenes, or diarrhœa drives the patient into marasmus, and he sinks.

Chronic Colitis, or Diarrhœa. Contraction, and Obliteration of the great Intestine and Rectum.—Let us follow inflammation into the great intestine in all its portions, and into the rectum. In it there is always diarrhœa at the onset, for nothing stops the matters that have passed the ileo-cæcal valve; if the intestine be irritated, it expels them by the anus, unless there be a contraction. Contractions do sometimes occur in the great intestine, and colitis puts on different appearances according to their presence or absence. We will begin with colitis without contraction, or what is commonly called diarrhœa; we are speaking of the chronic form—if it were acute it would be dysentery.

Chronic colitis may be primary or secondary. When secondary it is the consequence of inflammation of the upper part of the digestive canal and small intestines; when primary, it comes on without any previous gastric symptoms, colics, fever, &c. As in the former case it is consequent on preceding affections, I shall dispense with any description of it: you may easily imagine a gastro-enteritis, not properly terminated, and which, after existing in company with meteorismus and pain, becomes complicated with

diarrhœa. I proceed, therefore, simply to describe that which is confined to the colon.

The most common cause of this disease is bad and incompletely digested food, and is produced as follows. Persons with sound digestive organs, take aliment that disagrees with their stomach, which causes but slight suffering; three or four hours afterwards they are seized with colics and have a motion. The appetite then returns, they eat again, and the same phenomena take place. Such persons feel little or nothing during digestion, that is to say, during the first three or four hours. But, as they go on, it comes to pass that three, four, or six hours after similar food they have colicky pains, and pass watery and fetid matters, which have an ammoniacal odour, and irritate the anus, producing heat in it. This is repeated until it becomes continuous; if the acute stage supervenes, it is an inflammation of which I have already spoken; if it does not supervene, the same individuals, even when they take proper food, continue to have the diarrhœa; the colon has lost its tolerance of matters. Some persons talk of the intolerance of the stomach for emetics; but they should also talk of that of the colon. This is fact, that any one may prove in his own person; let him only have a bad digestion, and an attack of diarrhœa, and he may retain the latter for a fortnight, even though he commit no more errors of diet; eat what he will, the diarrhœa will persist unless properly treated.

Another question arises: do you think it possible in a case of bad digestion occurring in a weak individual, whose stomach is unable to digest in consequence of insufficient stimulus—as in a convalescent, who takes too much food after having lost a great quantity of blood, and whose digestive canal is in an exceedingly mobile condition—do you think it possible, that out of this bad digestion, this diarrhœa from debility, an actual inflammation may arise? For my part, I do think so, and you will find reason to admit it. This individual continuing to take food, will continue to be purged; irritating fecal matters will stimulate the mucous membrane of the colon, give rise to an inflammation, marked by tenesmus, and subsequently to an inflammation, which, if not combated, will rise in the intestines and produce an enteritis, at first chronic, then acute, which may prove fatal.

Colitis having continued for some time in a chronic form, it often happens that the intestine is narrowed at its lower portion, from excessive sensibility, contracts, and no more matters find exit. You have an idea of this phenomenon at the period of the cure of all diarrhœas; from the time when copious liquid evacuations cease, the patients pass stools that seem to have been strained through a narrow tube, because the colon and rectum are narrowed. If the diarrhœa fails to return in three or four days, the colon

and rectum lose their irritability, and allow the matters to pass freely and to become moulded and large as before.

Let us see how these contractions are formed in consequence of colitis. Many people, after having had diarrhœa for a certain time, become constipated, pass thready stools, and finally have a more and more marked narrowing of the rectum or lower part of the colon; and this may even end in complete obliteration. This happens when, after several relapses, and an irregular life, some perturbing cause, such as sudden cold, fatigue, strong passion, &c., comes into operation: the irritation lights on the spot most inclined to receive it, and causes a narrowing there. At this very time I am in attendance on a gentleman so situated: it became necessary, in order to save his life, to dilate the rectum. He was in good health, but was a gourmand, was guilty of errors in diet, had diarrhœa from time to time, and was pressingly called on to go to the water closet, his colon having become intolerant. The intestine narrowed daily, and finally allowed nothing to pass; large masses of matters accumulated in it, hardened and remained there, until by dint of colics, and a flow of mucosities, which softened them, he ultimately, after nearly a fortnight's constipation, got rid of them. Talma, who died of complete obliteration of the rectum, had the disease induced by the administration of cold lavements; he found that nothing so well fitted him for the exercise of his brain as these injections, and he daily took them, especially when he was to appear on the stage. A phlegmasia supervened, and caused contraction of the organ: the constipation became more and more obstinate, and at length insurmountable, and he died the victim of a complete intestinal strangulation*. Thus then, a diarrhœa, with intolerance of the colon and rectum from excessive irritability, may have two terminations: either the patient, if not cured, will be exhausted by the purging, this being most frequently accompanied towards the close with effusion into the abdomen, and general œdema; or he will die with complete opiation, constipation succeeding on the diarrhœa.

Necroscopy of Chronic Gastro-intestinal Inflammations.—What we have to say under this head, applies to all the gastro-intestinal phlegmasiæ mentioned in preceding sections; and besides the interest that attaches to the

post-mortem examination of them, it is also requisite to know how to interpret what we see. You have traces of inflammation in many degrees, of old phlegmasiæ, of recent, of intermediate shades, of irritations communicated to tissues other than the mucous membrane, tumefaction, and degeneration of the cellular tissue interposed between the intestinal tunics and the reduplications of the mesentery, alterations of the mesenteric glands, suppurations, engorgements, divers degenerations of the principal appendices of the digestive canal, of the liver, the pancreas, and the spleen, and lastly, anatomical lesions of the third order, proceeding from the propagation of the disease to other organs, or, in other words, from its complications, such as pulmonary or cerebral affections, peritonitis, from perforation, or otherwise, &c. We should distinguish between these alterations, in order not to lay them all to the account of the same morbid condition, referring them, nevertheless, to their common cause, inflammation.

The most long-standing alterations of the mucous membrane are black or brownish: it is more friable, softened, sometimes ulcerated, thinned, or altogether destroyed: the muscular coat is often in the same state, completely obliterated, especially in the great sac of the stomach. In other regions of that organ, along the small curvature, and particularly towards the pylorus and cardia, the mucous membrane is rather swollen, thickened, indurated, together with the sub-mucous cellular tissue; so much so as to exhibit a lardaceous aspect, like congealed lard, or to constitute a species of degeneration, to which the name of encephaloid has been given, and which it has been attempted to abstract from the phenomenon of inflammation.

In the duodenum, black, brown, livid spots, prominent follicles, attritions of the mucous membrane, and ulcerations sometimes backed by scirrhusities, penetrating to the depth of half an inch. I have seen ulcerations that had extended as far as the great vessels, corrode them, and cause sudden death by perforation of them.

It has been maintained that, when a scirrhous exists in the stomach or intestines, and while at their internal surface there is an ulceration and excavation communicating in this scirrhous, the softening commenced in the centre of the latter, and that the disease subsequently proceeded towards the mucous membrane. I know not whether this can possibly happen, or whether they have found some means of beholding what does not exist; but meantime, having seen no instances of it, I am at least certain that, in the great majority of cases, the destruction commences in the mucous membrane, and that, behind this point of destruction, a hardness forms, which limits it, but into which, however, it makes more or less way.

I have been long engaged in the consi-

* Besides this, a tumour containing bloody coagula, and about the size of a pigeon's egg, was found after death at the apex of the heart, and communicating with the left ventricle: it was supposed to date from one of those sublime displays of passion with which the representation of *Britannicus* and of *Sylla* was wont to electrify the audiences of the Théâtre Français.—J. M. G.

deration of the formation of these scirrhus degenerations about hollow organs. When a mucous membrane is perseveringly worked upon in one point by an irritation, and ulcerates, a thickening and condensation takes place beneath it, the cellular tissue contracts, hardens, and is transformed; the glands, if there be any in the neighbourhood, unite with each other and with the organ. This cellular tissue and these indurated glands serve as a floor for the ulceration, and are, as it were, a means used by nature to prevent perforation.

There are considerable differences in the facility with which scirrhus is developed, according to age and constitution. Children, subject, as you know them to be, to lymphatic engorgements, exhibit them much more than old persons; scrofulous children especially, form a striking contrast in this respect with old men of dry habit of body. At Val-de-Grâce, we rarely find this kind of alteration in the veterans that die there of gastritis or chronic enteritis.

These scirrhus indurations are of two kinds in the digestive organs—those which implicate the cellular tissue, and those which implicate the ganglions. The former are more hard, and resemble rather a compact jelly or congealed lard; the latter are softer, and have a cheesy aspect, or like cerebral matter. For the rest, they run into each other, and are often intermixed.

Such then are the most long-standing alterations—softening, ulceration, and scirrhus.

Those of more recent date consist in various alterations of colour, consistence, density, &c., and approach more or less to the disorders consequent on the acute stage, which I have already described. After the inflammation has worn out one point, it passes to another, and there causes the usual ravages.

As regards the alterations of the other organs, they will be described in treating of their particular inflammations.

Of Hypochondriacism or Neuropathia consequent on Chronic Gastro-intestinal Inflammations.—I cannot quit the subject of chronic phlegmasiæ of the digestive canal, without mentioning a phenomenon that very commonly accompanies it; namely, a nervous condition that goes by the name of hypochondriacism or neuropathy. You are aware that this state is variously classed by authors: some place it among the diseases of the brain; others, following the ancients, in the hypochondria and digestive canal; and some again, spread it vaguely through the visceral nervous cords. As science now stands, nothing vague should be allowed: better to confess we know nothing about it, and wait patiently. Let us see whether we can be more precise in our ideas of it.

In our idea, hypochondriacism is a state of extreme sensibility of the nervous system, which induces the patient to consider him-

self more deeply affected than he really is, to relate his ailments with exaggeration, to individualize all painful feelings, and all the extraordinary commotions he feels, and to regard all his symptoms as so many different diseases. As we do not, for the most part, see any falling off in them, no vice of nutrition or circulation, which corresponds with the frightful picture themselves trace, such persons are apt to be taken for visionaries or madmen. Hypochondriacs have generally a mental exaltation, which makes them bestow minute attention to all that is going on in them. Primarily, and in the majority of instances, they owe their disease to a chronic phlegmasia of the digestive canal, and especially of the stomach and small intestines; for that of the large intestine is by no means capable of producing it, except it be situated in the ileo-cæcal region.

When these patients recite their ailments to you, they, of necessity, give the most accurate details of what is going on in their organs: they talk to you of swellings, of wind, of distention, of heats, of prickings, of animals that move, and bite, and tear them. Next, as you know there are sympathies between the digestive canal and the locomotor and cerebral apparatus, they describe fatigue, bruises of the limbs, extraordinary noises, &c.—in short, there is no end to their talk; yet what they relate is not purely imaginary—they feel it, otherwise they must be regarded as madmen.

Although long-continued suffering of the digestive canal is the most frequent cause of hypochondriacism, it does not follow that this affection is invariably and solely owing to such cause. There are hypochondriacs from affection of the heart, indeed many such; there are others from affection of the uterus, and these are called hysterical; but there are none from affections of the skin or of the lungs. The most rare are those that are owing to chronic gastritis, duodenitis, and jejuno-ileitis, complicated with hypertrophy of the heart. These various possibilities or complications will oblige me to return to the subject, and give a lecture on it alone, when we have despatched the inflammations, and arrived at the neuroses.

The phenomena of hypochondriacism that depends on the digestive canal, are more particularly observable when the morbid portion of the canal is in action. Thus, is the stomach the *mobile* of them, they are commonly remarked towards the second or third hour of digestion; does the duodenum or small intestine excite them, they appear two or three hours later.

It is to be remarked, that the more the patients are treated with stimulants, the more they become hypochondriacal, and that they become less, or cease to be so altogether, if we can contrive to diminish the exalted sensibility of the canal. The same observation is applicable to affections of the heart that are complicated with those of the

stomach or duodenum, and of the liver. It is, therefore, stimulated individuals that become hypochondriacal. I have seen some suddenly become so after a fit of indigestion. A lady, whose medical attendant had given her large doses of tartar-emetica—and in order to be sure of her taking them he remained at her bedside—became so after vomiting four successive days. She only recovered by perseverance in the use of mild remedies, and after a long course of them.

Some individuals readily become hypochondriacal, and many do not become so, or at least very slightly, in the same circumstances that drives others into that state. To solve this question, I sought for assistance in the data of the phrenologists, and I observed, that timid persons, with caution predominant, and in whom the organ of courage is small, readily pass into hypochondriacism, if they be tormented by an obstinate visceral irritation of the kind formerly alluded to, and this the more if they are stimulated. There are even some persons whose encephalon is so organized as that, without the presence of any real disorder, they imagine themselves to be suffering under a very serious one; these are visionaries, in whom, I believe, the organ of marvellousness plays a prominent part, and is, perhaps, somewhat superexcited. You should early accustom yourselves to believe, that each of our intellectual functions is connected with a particular region of the brain, and that to attempt to conceive of spirit without matter, is an illusion. No series of thoughts whatever exist, in which there is not some nervous system in motion. This study is daily acquiring greater consistence, and will finally force its way to predominancy, for it is founded in nature. People have laughed at it—but at what have they not laughed? Was not physiological doctrine itself subjected to the laughter of fools? Yet it has triumphed. And so it indubitably will be with the phrenological doctrine.

Prognosis and Treatment of Chronic Gastro-intestinal Inflammations.—General chronic gastritis approaches very nearly to the acute state, and readily passes into it, if stimulated; but this is not the case with partial gastritis, for, previous to passing into the acute state, it is necessary that they should extend; and this you learn by the loss of appetite, a more extensive gastric sensibility, sympathetic phenomena that did not previously exist, &c. The same obtains in chronic enteritis and duodenitis. These latter, however, do not readily pass into the acute stage, the evacuations preventing it: and this is the reason why purgatives palliate them, and induce effusions of fluids; meantime, they very rarely put an end to them, unless they be recent and only feebly inflammatory. When duodenitis tends to the acute stage, the constipation becomes more obstinate, the tension of the part augments, the right

hypochondrium tumefies and becomes more sensible, &c.

Enteritis also passes with difficulty to the acute stage, especially when the inflammation has gone beyond the ileo-cæcal valve, and the evacuations are copious. However, it does occur in daily practice, for a vast number of acute gastro-enterites are preceded by these chronic inflammations.

The symptoms indicative of these transformations are to a certain point common to all, and prove their uniformity of nature; they consist in diminution or loss of appetite, malaise, pains of the limbs, shiverings, sinister presentiments, depression of spirits, elevation of the pulse, flushes of heat about the head, burning and distressing digestion, &c. These symptoms are independent of scirrhus, of cellular, tubercular, or glandular induration, and appertain to the mucous membrane, particularly to its nervous papillæ, which are the structures of the digestive, which sympathize with the economy.

To prove fatal, these chronic gastro-intestinal inflammations must pass to the acute stage for some days at least: this is the general law of the case. We have, however, no right to assert that it may not happen otherwise; for there are individuals who die of bona fide inanition, without acceleration of pulse, from actual want of digested food. Such cases are exceedingly rare, and are scarcely ever met with in the course of several years of extensive practice.

The prognosis is drawn from the duration of the disease, from the manner in which it has been managed, and from the symptoms.

1. A general rule is, the longer the duration of these affections, the more difficult they are to annihilate. Reference must, however, be had to temperaments and climates. Individuals endowed with great gastric susceptibility, or in whom such disposition is hereditary, are cured with difficulty, and are subject to relapses during ten, fifteen, or twenty years; they are unhappily organized beings, who are unable to run a race with the agents of this world. You must therefore first ascertain whether you have to deal with such a person. Should the disease have commenced without a powerful cause, under the influence of ordinary modifiers, there is scarcely any thing but change of climate that can put a stop to it. Generally speaking, you should, in forming an idea of the future event of a disease, begin by appreciating the causes or modifiers by which it has been generated: if they be such as are easily removed, the chances of cure are greater: if not, so much the worse for you. When chronic gastritis, duodenitis, and enteritis are owing to change of climate, for instance, to transition from a cold or temperate to a burning climate, they are ordinarily cured by a return to the former. Of this I saw numerous instances in our Italian and Spanish cam-

paings. I have also seen opposite instances; persons whose reactive power is feeble, and who are subject to congestions during the winter, are seized with chronic gastrointestinal affections in cold seasons and countries, and only get rid of them in warm seasons or countries. I have known those who were well enough in Spain, but who fell ill in passing the Pyrenees; and in Paris you may observe a great number of individuals whose digestive organs are only disturbed in the winter season, most likely owing to the impulsion of blood by the cold, from the skin to the viscera.

When the disease has lasted a long time, and has returned in several successive years, it is more difficult to manage. In any case we should be on the alert for relapses, for they too easily take place. It often happens, that after taking considerable pains to bring a person round, the disease, when the patient has acquired a certain degree of strength and plethora, relapses. This you should expect, but not be discouraged by: very many see nothing more of the disease after having had repeated relapses. Here I may lay down an important principle of pathological physiology; namely, that when an individual has lived for a long time in a state of repletion inferior to plethora, or to the provision of blood that is requisite to the constitution and the state of full health, he is subject to congestions. This is not, or very rarely, observed among the consequences of accidental acute diseases, but is more common after chronic diseases that have relapsed or that have been cured by strict regimen and hygienic means. Be not alarmed at such congestions; prompt attention soon dissipates them. If they return, they are more and more slight, and finally cease to reappear; provided the patient be docile and the physician vigilant, they are prevented, and the health is consolidated.

2. As regards the treatment that has been pursued, you must first learn that persons who have been stimulated in the onset, are cured with more difficulty. I have daily opportunity of verifying this fact, because, in my present medical position, very many patients came to me, either of their own free will, or they are sent me by my professional brethren, from different motives—either, because they place confidence in me rather than in themselves, or being unable to cure them, they wish to embarrass me with them, or for the purpose of putting me to the proof. In such cases, I remark, that those who have been for a long time stimulated, and whose disease has been opposed by tonics and purgatives (the latter are not so dangerous, provoking, as they do, evacuations which counteract to a certain degree the bad effects of their stimulating power) not only retain a permanent inflammatory condition, but also a nervous one, and that then the disease takes a longer

time to cure, and is, even sometimes interminable. Even in this case you must look to the temperament: the consequences of bad treatment would be less to be feared in a robust person, than in one that is delicate, nervous, or lymphatic, disposed to scrofulous affections and rapid disorganizations,

The remaining circumstances of the prognosis and the treatment in our next.

LECTURES

ON THE

PHYSICAL EDUCATION AND DISEASES OF INFANTS, FROM BIRTH TO PUBERTY.

By DR. RYAN.

Delivered at the Medical School, Westminster Dispensary, Gerrard Street, Soho;

Session 1834-35.

LECTURE LIII.

—

Vices of Conformation—Intra-uterine and Extra-uterine Diseases of the Circulatory and Cerebro-Spinal Apparatuses.

GENTLEMEN—I concluded at our last meeting an account of the principal intra-uterine and extra-uterine vices of conformation, and diseases of the tissues that compose the thoracic organs, with the exception of those of the heart and its large vessels, which are next to be described.

Development and Vices of Conformation of the Heart.—It has been frequently observed that the heart is not formed before some of the large vessels, especially the vena porta. It first appears in the form of a semi-circle, presenting three dilatations, two contractions, which are the auricle, ventricle, and aorta. Such is the description given by the indefatigable Haller and others. As the development advances the cavities appear; and, according to Meckel, the left ventricle is at first larger than the right. It has also been remarked, that the auricles, in proportion as the infant is undeveloped in the early months, are larger than the ventricles, but as the growth advances this disparity disappears, and at birth the ventricles are much larger than the auricles. About the seventh week the aorta gives off the pulmonary artery.

Without prosecuting the history of the development of the heart any farther, as it will be found in the works on physiology and embryology, I may observe here, that the organ may be totally absent, as in acephalous infants, or sometimes have but one auricle or ventricle*. In some cases, the right auricle may be an inch in length, and

* Dr. Maaran (American Journal of the Medical Sciences, No. X.), and others.

in others the whole heart may be hypertrophied to double its usual size. The auriculo-ventricular apertures may be considerably contracted, and cause difficult respiration, or infantile asthma. The heart has also been found in the right side of the chest.

It is important to determine when the peculiarities of the fetal circulation cease, but as the account of M. Billard is the best I have seen, I shall quote it concisely.

This able pathologist observed, in nineteen infants of a day old, there were fourteen in which the foramen ovale was completely open, in two it had commenced to obliterate, and in two others it was perfectly closed. In thirteen of these infants the ductus arteriosus was open, and filled with blood; its obliteration commenced in four, and was completed in one. In the last, the foramen was also closed. The umbilical arteries were pervious at the iliacs, but their calibre was evidently diminished. In all the infants the umbilical vein and ductus venosus were open and free, and usually gorged with blood.

It may be concluded, from these observations, that in most cases the foramen ovale and ductus arteriosus are pervious on the first day after birth, but that these apertures may be obliterated even at this period of life. In twenty-two infants of two days old, the foramen ovale was pervious in fifteen, but completely closed in four cases. The ductus arteriosus was open in thirteen, it had commenced to close in six, and was entirely obliterated in three. The umbilical arteries in all were more or less obliterated in their whole extent, but the umbilical vein and ductus venosus, although empty and collapsed, admitted the introduction of a moderate-sized probe. These facts prove that the foramen ovale and ductus arteriosus are generally unobliterated on the second day after birth, and that the function of the umbilical arteries has ceased.

In twenty-two infants of three days old, the foramen ovale was pervious in fourteen, it had begun to be obliterated in five, and was entirely closed in three. The ductus arteriosus was open in fifteen, its obliteration commenced in five, and it was completely closed in two. These two had also the foramen ovale impervious. The umbilical vessels and ductus venosus were obliterated in all. We may conclude from these observations, if we admit them to be sufficiently numerous, that in infants of three days old the ductus arteriosus and foramen ovale are not generally obliterated. In seventeen infants out of twenty-seven, of four days old, the foramen ovale was open, and in six the aperture was remarkably large, and distended with blood. In eleven others the opening was barely free; in eight the process of obliteration had commenced, and in two it was completed.

The ductus arteriosus was open in seven-

teen of these infants, it was contracted in seven, and completely closed in three: the umbilical arteries in all were nearly obliterated at the navel, but still capable of being dilated at the iliacs. The umbilical vein and ductus venosus were empty and considerably contracted.

In twenty-nine infants of five days old, thirteen had the foramen ovale open, but it was more or less contracted. It was greatly dilated in four bodies, and diminished in ten others. It was almost entirely obliterated in six others, and it was so closed in six others, that it was impossible to establish any communication between the auricles. The arterial canal was open in fifteen bodies, and very much so in two. The obliteration was considerably advanced in five others, it was nearly closed in seven, and completely so in seven others. The umbilical vessels were perfectly obliterated in all.

It is important to observe, that none of the infants, whose autopsies are given, presented any sign of disorder in the functions of respiration or circulation.

In twenty infants of eight days old, there were but five in which the foramen ovale was open; it was incompletely closed in four, and its occlusion was perfect in eleven. The arterial canal was free in three only, and in one of which it was aneurismal; and in six it was nearly obliterated, and completely so in eleven. The umbilical veins and arteries were entirely impervious.

In infants from the twelfth day to the third week of age, the foramen ovale may remain open without any disorder of respiration or circulation.

It appears from the preceding facts, that the fetal apertures are closed at different periods of life, and that the foramen ovale and arterial duct are generally obliterated from the eighth to the tenth day. We may also conclude that the fetal vessels are obliterated in the following order:—First, the umbilical arteries; next the veins of that name; then the arterial canal; and, lastly, the foramen ovale. Let us now examine the mode of obliteration of these apertures and vessels.

Mode of Obliteration of the Fœtal Apertures.—There are two causes which close the apertures peculiar to the fetal circulation after birth—1, the establishment of respiration and pulmonary circulation; 2, the change of tissue in the umbilical arteries. The umbilical arteries, at birth, possess a great power of contractility, and oppose the effusion of blood from the infant. It has been long observed, that when infantile respiration is completely established, little, if any, blood will escape from the umbilical cord, and this fact has led some to contend that a ligature on the cord is unnecessary. I have adduced reasons to disprove the validity of this opinion on a former occasion,

and I may now add, that the navel cord is tied, or a ligature is applied round it, at present, in all civilized countries.

But as soon as respiration is established the blood ceases to flow through the arterial canal, for this is no longer necessary, and that tube becomes closed. (Berndt, Carcano, Trew, Arrowsmith, and many others of the modern physiologists). I have already explained this point of physiology, when describing the mode of applying a ligature on the umbilical cord. I may here observe, that at the moment the umbilical cord is divided, the vein of this name becomes incapable of receiving blood into its calibre, as there cannot be a regurgitation into the vena cava inferior. The coats of the umbilical vein collapse, and speedily become obliterated, like all other canals through which fluid is not constantly or frequently passed. These facts are so highly important in cases of infanticide, that Mr. Chitty, the eminent barrister and voluminous legal writer, has written to me, as the author of a work on medical jurisprudence, on the subject, requesting me to describe these changes.

Intra-uterine Diseases of the Heart and Great Vessels.—The heart and its large vessels are liable to malformations, which consist in diminution or enlargement of some of the cavities, atrophy, hypertrophy, various degenerescences, inflammation, aneurism, &c. The commonest disease of the heart is, however, the persistence of the inter-auricular aperture or foramen ovale. This does not always produce inconvenience after birth, or in early life, and it does not prevent the proper oxygenation of the blood in the lungs, as is generally supposed. If, however, there exists at the same time a considerable plethora, with difficulty or impossibility of the establishment of respiration, the oxygenation of the blood may be prevented, and cyanopathy, or blue disease produced. Nevertheless there are numerous examples on record of the persistence of the foramen ovale, without the production of cyanosis or cyanopathy. Again, we see a transient form of the disease when the new-born infant respires with difficulty, and is pressed on during a protracted labour, or in pneumonia, in asphyxia, and in malignant cholera, although there is no malformation of the heart. Nevertheless, it is extremely probable that the blue coloration of the teguments is caused by a mixture of arterial and venous blood in the heart, or by a defect of oxygenation in the lungs. When the cavities of the heart are normal, and when there is any condition of the lungs which prevents oxygenation, or the change of venous into arterial blood, cyanopathy, to a greater or less extent, may prevail. It therefore follows that this blue disease is caused by want of oxygenation of the blood in the lungs, and not from the

existence of an opening between the auricles. But it may also be produced by this vice of conformation of the heart, with or without pulmonary congestion, or inflammation, or by such conditions of the lungs without any organic disease of the heart.

This pathology is correct, but there may be another cause of cyanopathy. Thus M. Breschet describes an autopsy of an infant a month old, in which the left subclavian artery arose from the pulmonary, so that the upper extremity of this side was supplied with black blood, and, strange to say, was as well developed, and as well coloured, as the other.

We may conclude, from the preceding facts, that cyanopathy of new-born infants, whether local or general, depends, in a majority of instances, on sanguineous congestion of the heart or lungs; and that the best means to remedy the disease is, according to the advice of Corvisart, to place the body of the afflicted infant before a clear fire, and rub well with warm cloths. This practice ought to be persevered in for a considerable time, with frictions over the face, cervical and dorsal portions of the spine, made with some stimulating liniment, which are far preferable to the various aspersions of cold water and ardent spirit, so much recommended by some obstetric writers. When cyanopathy is caused by pneumonia or asphyxia, the proper means for the removal of these diseases ought to be employed.

There are other intra-uterine or congenital diseases of the heart, such as aneurism of the organ and of the ductus arteriosus, which are described by M. Billard. He also detected only seven well-marked cases of pericarditis in 700 infants at birth. In one of these cases the adhesions were so firm that they must have taken place during intra-uterine life. In the other six there was a sero-albuminous effusion, and filaments extending from the pericardium to the heart.

The inner surface of the pericardium and external of the heart have been studded with petechiæ of a red or violet colour, accompanied by sero-sanguinolent or sanguineous effusion. This condition depended on passive congestion, and not on inflammation.

It is also worthy of notice, that we usually find more or less serosity in the pericardium of very young infants.

It is scarcely possible to distinguish between pericarditis and pleuritis in new-born or very young infants, or those at the breast, but this is of little consequence, as both diseases are treated with the same remedies.

Cöhler has observed lymphatic concretions in the cavities of the heart and great vessels, about the size of a bean; but others have supposed that they were formed immediately after death*. They were most frequently

* Dict. de Méd. Art. Œuf.

found in scrofulous children who laboured under mesenteric disease.

M. Billard found scirrhus of the heart of an infant who died on the fourth day after birth. This is a most rare occurrence in adults, and many have even doubted its existence.

There are many other vices of conformation and congenital diseases of the heart besides those already noticed; and these I shall now proceed to describe. I shall prove hereafter that a knowledge of the intra-uterine and extra-uterine pathology of infants is of immense importance in the treatment of the diseases after birth, and in our decisions on the viability or non-viability of infants in cases of prolicide, fœticide, and infanticide. If it is proved that an infant was so formed that it could not live or arrive at maturity, the humanity of our laws awards a slight punishment, compared to that for abortion or infanticide in those cases in which the conformation is natural, and the fœtus might have arrived at the adult age.

Simple Displacements of the Heart.—There are two species of displacements of the heart: 1, when the organ is displaced in the precordial region, as when its apex is turned to the left side; 2, when the organ is in the right side of the chest, or in the abdomen, or in the head.

Lancisi, Morgagni, and Corvisart designated displacement of the heart, *prolapsus*, when the organ had descended from its ordinary position; and the latter celebrated pathologist held, that a large aneurism of the aorta would cause such displacement. Senac described an example in which the heart was placed on the diaphragm. The heart may be pushed upwards by large tumours in the left side, or by a copious effusion into the peritoneum—ascites.

Numerous authors have observed the heart in the right side of the chest (*dextiocardia*), in consequence of effusion into the left side of the chest, after pleurisy, among whom are Boerhaave, Sennert, Stoll, Merey, Becclard, Laennec, Larrey, Bouillaud, Velpeau, and many others. Weyland describes a case, on the authority of Chaussier, of an infant that died soon after birth, in which the stomach, a great portion of the intestines, the spleen, and the pancreas, were contained in the left cavity of the chest. The heart, both lungs, and thymus, were in the right thoracic cavity. (*Dissert. Inaug. Med.*, Jena, 1831). The heart has also been situated on the median line, and M. Chaussier reports a remarkable case in which the lower part of the sternum was absent, and the heart placed under the skin. (*Bull. de la Faculté de Med. de Paris*, 1814). Vaubonais gives the history of a fœtus born at the eighth month, in which the heart protruded from the superior part of the thorax, through an aperture; it was uncovered, and hung like a medal from the neck. (*Mem. de l'Acad. des Sciences*, 1712).

Dr. Martin Martinez reports a similar case in an essay published at Madrid in 1723. Tournelle saw an infant who had an opening in the inferior part of the chest, through which the heart escaped, and descended to within an inch of the umbilicus. Baudelocque mentions a singular example of bicardia in an infant, who died a short time after birth. It had two distinct hearts, one situated in the abdomen, the other in the chest; and these communicated with each other by different vascular ramifications.

In an infant extremely deformed, which was born at the Maternity of Paris, in 1812, M. Chaussier found a hernial tumour at the umbilicus, which contained the greatest part of the abdominal viscera, and also the heart. There was an aperture in the diaphragm. The same distinguished professor related another remarkable case of cardiac hernia to the Faculty of Medicine in 1814. He examined a female infant born alive at the Maternity, which presented at the superior and anterior part of the abdomen a soft tumour, which contained the heart. The infant was alive, sucked the breast, and performed its functions.

M. Breschet has published an interesting memoir on *ectopia* of this organ, and divides displacements of the heart into three genera—1. *Thoracic ectopia* of the heart; 2. *Abdominal ectopia*; 3. *Cephalic ectopia*. In such cases there is a solution of continuity, or malformation of vicinal organs; and infants so constituted generally die soon after birth, and never arrive at maturity. In such cases, the pericardium is sometimes absent.

Acardia—Absence of the Heart.—M. Becclard has described several examples of this defect in his work on *Acephalous Monsters*. Vogli furnished the history of a singular case to Valisnieri, in which an infant was born *alive* without heart, lungs, diaphragm, liver, spleen, or renal capsules. It had the spinal marrow, kidneys, bladder, uterus and appendages, stomach and intestines. Bianchi and Valsalva saw this infant. Notwithstanding their testimony, few can believe that a monster without a heart, lungs, or diaphragm could perform any movements after birth. Billard considers that absence of the heart is caused by atrophy, dependant upon destruction of the centre or a part of its nerve. He concludes that an accidental disease during intra-uterine life, which indicates atrophy or destruction of the medulla oblongata, and of the superior part of the medulla spinalis, is the cause of all the irregularities and defects in acephalous infants.

Absence of One Half of the Heart.—There are cases recorded of absence of one half of the heart. Kreisig relates a case of this kind in his work on diseases of the heart; and M. Breschet mentions another. Mauran gives the history of an infant that lived ten days, and at the expiration of that period died of suffocation. The heart was composed of one auricle and ventricle, and the

pulmonary artery was obliterated. (American Journal of the Medical Sciences, 1827). It is not easy to understand how life could be continued so long with such conformation.

Dr. Turner published the report of a case in which both auricles were absent. (Journ. Gen. Med., t. xcvi.) M. Destrés communicated the following facts to the Royal Academy of Medicine of Paris:—In a monstrous foetus, born at five months and a half, the heart was very voluminous, situated to the right side of the chest, its apex being under the false ribs of this side, and its base corresponding to the vertebræ. It had but one auricle, which communicated with both ventricles. The pulmonary artery opened into both ventricles. The pulmonary veins opened directly into the left ventricle. The right ventricle wanted the tricuspid valves, the left had no mitral. The aorta and pulmonary artery were without the sigmoid valves. The aorta gave off the brachiocephalic trunk, and the arterial canal, and then terminated in the left subclavian artery. The pulmonary artery, after having supplied the large branches to the lungs, and received the arterial canal, ascended before the aorta to the summit of the left cavity of the thorax, then turned along the spine, and supplied the mesenteric, splenic, hepatic, renal, and crural arteries, and terminated by the umbilical. The left side of the chest was occupied by the stomach and small intestines. The left side of the diaphragm was wanting. All the valves of the heart may be absent, or any part of them, (Bouillaud, *Traité Clinique des Maladies du Cœur*, &c., 1835). I am indebted to this splendid work for many of the preceding observations; it is one of the most graphic, laborious, and valuable monographs which modern times have produced.

Bicardia—Tricardia—Augmentation of the parts forming the Heart.—Plurality of heart is extremely rare, according to Meckel, unless when there is foetal duplicity. This anomaly leads us to suppose so great an aberration from the laws of evolution in general, that we can scarcely consider it compatible with the duration of extra-uterine life.

I think it is scarcely possible to admit, with Plazzoni, Baudelocque, and Collomb, that in well formed adults there existed two hearts. But are we to conclude on the reports in the (*Ephermides Curios.*), which set forth the histories of two individuals, each of whom had three hearts? M. Geoffroy Saint Hillaire and M. Bouillaud declare these facts inadmissible; and I fully agree with them.

In cases of two monsters united together, such as the Siamese brothers, Hungarian sisters, and Retta-Christina, &c., there are two hearts, as attested by Dupuytren, Baudelocque, Gintrac, and others.

Augmentation of the parts that compose the heart are of very rare occurrence. Che-

mineau described a heart with three ventricles*.

Kerkring relates an example of an infant of three months old, in which the right ventricle was bifid.

De Hean mentions a supernumerary appendage to the left auricle (Rat. Med., part ix); and Billard, a similar case in a female infant, that died a few days after birth, from whose auricle there was a prolongation of an inch, which floated in the pericardium in front of the heart.

Vices of Conformation in the vessels connected with the Heart.—The aorta has arisen from both ventricles, according to Nevins, in this country, and to Sandifort, Stander, and Tiedemann, in Germany. The pulmonary artery has also taken its origin from both ventricles. At other times, both these great arteries have arisen from the same ventricle. In some instances, the aorta has arisen from the right, and the pulmonary artery from the left ventricle; and in such cases the respective veins were normal. Infants having this abnormal disposition of these arteries, generally survive only a short time after birth, though Farre described one subject who lived to the fortieth year.

The vena azygos is sometimes inserted into the right auricle. Lecat found it divided into two branches, one of which opened into the right, and the other into the left auricle.

M. Breschet found the hepatic veins form a common trunk, which opened into the right auricle†.

Other pathologists have observed the ductus arteriosus connected with the left ventricle. Some anatomists have described two venæ cavæ superiores, which opened into the right auricle; but M. Saint Hillaire considers that this disposition was caused by the non-union of two subclavian veins.

The right auricle has given insertion to one, or many pulmonary veins; and the left, on the contrary, the inferior cavæ and a superior cavæ, there being really two distinct venæ cavæ superiores (Bouillaud, *op. cit.*)

Meckel has observed the great coronary vein opening into the left ventricle.

These anomalies of insertion and connexions of the veins, coincide with other vices of conformation of the heart, and have been observed in infants aged a few days, weeks, or about a year, most of which died very soon after birth.

Diseases of the Cerebro-Spinal Apparatus.—The ancients supposed that the spinal marrow was a continuation of or an appendage to the brain (Galen, &c.); but Plato, Praxagoras, Philotene, and others, maintained the contrary opinion. In our days, Gall and Tiedemann have demonstrated that the spinal

* Hist. de l'Acad. des Sc., 1569.

† Mem. sur les Ectopies du Cœur.

marrow is developed before the brain, which is only an expansion of it, and is at first extremely small. It is admitted by all authors, that there is continuity and sympathy between both; and for this reason they are termed, by physiologists, the cerebro-spinal apparatus, or system.

Vices of Conformation.—The medulla spinalis may be entirely absent (amyelia); and in such cases there is also absence of the brain. Morgagni has enumerated several examples of simultaneous absence of the brain and spinal marrow; and M. Ollivier remarked, that in such cases, there is spina bifida.

The spinal marrow is often deformed at its superior extremity in cases of anencephalus; and sometimes the spinal cord is divided wholly or partially, into two lateral halves (Zacchias, Manget, Hall, and others). The medulla spinalis has presented a cavity in its centre, and the fluid in hydrocephalus, has partially passed into it. I have already observed, when describing congenital dropsies, that there is often a communication between hydrocephalus and hydrorachitis. In some cases, the medulla spinalis has been jaundiced (Kyrrenose, Lobstein); and in others it has been completely divided in a transverse direction. Ollivier describes this last condition in the adult.

The vices of conformation of the cranium and brain are very numerous; but I have described them on a former occasion.

Diseases of the Cerebro-Spinal Apparatus developed after birth.—Congestions of the cerebro-spinal system are common to new-born infants, in consequence of the great vascularity of these parts, the slowness of the circulation, and the influence of respiration on the cerebral and spinal circulation. The slowness of parturition, the tractions necessary in certain cases, the difficulty with which respiration is established, and the sudden change in the foetal circulation, explain the causes of the frequency of sanguineous congestions, which vary from simple injection of the meninges to apoplectic effusion. The term apoplexy is applied to various degrees of congestion in new-born infants; but in most cases of death from this disease, there is no sanguineous effusion or circumscribed hemorrhage, as in cases of adults.

Injection of the meninges or membranes of the brain, is so common in new-born infants, that it ought to be considered a natural, and not a pathological, condition. It is most frequently observed alone, or accompanied by sanguineous effusion at the inferior and posterior part of the spine; and seldom causes any characteristic symptoms during life. But when the injection is considerable, it is often followed by a sanguineous effusion on the surface of the meninges, the blood is coagulated, compresses the brain or spinal marrow, causes stupor, and the other signs of apoplexy. There are five

species of meningeal apoplexy, according to the observations of M. Serres.—1, meningeal apoplexy without effusion; 2, with serous effusion; 3, with sero-sanguineous effusion; 4, with arterial rupture or aneurismal dilatation; and 5, with venous rupture. There are the same number of species of cerebral apoplexy.—1, with hemiplegia; 2, with paralysis of one arm; 3, with paralysis of one leg; 4, with double hemiplegia; and 5, with complete paralysis from a single attack. This experienced pathologist cites numerous cases, to prove that *the sanguineous and serous effusions are the effect, and not the cause, of apoplexy*—that in simple apoplexy, the membranes of the brain are affected in various degrees, or there are serous collections in the ventricles or convolutions. When the apoplexy is followed by paralysis, there are no effusions, no affection of the membranes, but the substance of the brain is materially altered in structure; it is lacerated, or some vessel has given way, which was proved by filling the carotids with a fine injection. When the whole body is paralyzed, and death rapidly occurs, the extravasation will be on the pons varolii, or tuber annulare. It is worthy of recollection, that in apoplexy, the patient falls upon the affected side, a fact which will lead us to modify the treatment. Such are the results of 3000 cases.

The injection of the substance of the brain is also of common occurrence; it consists of red or dark spots, and is generally observed on the corpora striata, the optic thalami, or in one or both ventricles. The vessels of the brain are most numerous in those parts which are the most common seat of inflammation and hemorrhage at all periods of life. Morgagni, Lallemand, Serres, and Bouillaud, have rendered this fact incontestable.

It is important to state, that M. Billard had observed but one apoplectic infant, in whose brain there was circumscribed hemorrhage, about which the substance of the organ was a little softened, to the extent of an inch in length and half an inch in breadth. M. Berard has met with intra-uterine apoplexy at the eighth month and a half, and the clot was about the size of a nut*.

Ramollissement or Softening of the Brain may exist in new born infants, with or without inflammation. In the latter form of the disease, the affected part appears to be softened or decomposed without any signs of increased vascular action. The diseased part is found soft, or dark, mixed with small clots. The medulla oblongata and medulla spinalis may be similarly affected. In such cases there is flaccidity with immobility of the extremities, the pulse is feeble and the deglutition difficult. The symptoms, when the brain is affected, are very obscure. The lateral parts of the hemispheres and the corpora striata are most commonly affected.

* Compte rendu de la Soc. Anatomie. 1828.

The symptoms are those of encephalitis; sensibility and muscular power are gradually diminished, somnolence supervenes, there is strabismus and dilated pupils, with paralysis, rigidity of the muscles, or convulsion. The disease is often confounded with arachnitis of the base of the brain, both in infants and adults.

The symptoms of ramollissement of the medulla spinalis are, pain in some part of the spine, sensation of pricking and darting in the extremities, no derangement of the intellectual faculties, unless the disease is seated near the pons varolii; when there is loss of sense, aphonia, with trismus, paralysis of the whole body, retroversion of the head, and difficult respiration. When the cervical portion of the spinal marrow is affected, the signs are rigidity of the neck, permanent contractions, or convulsions of the superior extremities, which are succeeded by paralysis and impeded respiration. When the dorsal portion is diseased, there are convulsive motions of the trunk, fever, pains in the abdominal viscera, and embarrassed respiration. Lastly, if the lumbar portion is the seat of the disease, there may be paralysis of the lower extremities, retention, or incontinence of alvine and urinary evacuations. When the disease is slight or becomes chronic, the paralysis of the lower extremities, and of the bladder and rectum, supervenes gradually.

The treatment of cerebral or spinal congestions in new born infants, consists in depletion, by allowing the umbilical cord to bleed before it is tied, and applying one, two, or three leeches to the base of the cranium, or one over each jugular vein. In fine, the remedies proper for cerebral congestions, apoplexies, or hydrocephalus, ought to be employed.

Cerebritis, or *phrenitis*, is a rare disease in new born infants; and *meningitis* is still more rarely observed except in hydrocephalus, which will be immediately described.

Spinal meningitis is much more common than myelitis, or inflammation of the medulla spinalis. This disease, when seated near the base of the skull, gives rise to convulsions of the face and upper extremities. In thirty cases of convulsions of new-born infants, there were twenty of the subjects affected with spinal meningitis, six with cerebral and spinal—facts attested by M. Billard. Rachitic meningitis is often complicated with pleuritis and peritonitis, and accompanied by fever.

Cerebral Meningitis.—The symptoms of this disease are nearly the same as in hydrocephalus; there is fever and general disturbance of the whole economy, the infant is peevish, fretful, it screams suddenly while awake or asleep, and there is a well-marked remission of its symptoms. This has led some authors to describe a remittent hydrocephalic fever. There is disturbance in the functions of digestion, respiration, secretion,

&c. The countenance is anxious and distressed, the superior extremities are agitated or convulsed; convulsions, coma, dilated pupils, and strabismus, supervene. In fine, all the symptoms of hydrocephalus, which I described on a former occasion, become developed. These I have also enumerated, when speaking of cerebritis, meningitis, and hydrocephalus, in my edition of Hooper's Physician's Vademecum, and in my Lectures on the Principles and Practice of Medicine. I shall, therefore, content myself with observing on the present occasion, that the diagnosis between cerebritis and meningitis is difficult, but this is of little importance, as the treatment is the same as I have already stated.

Inflammation of the brain, or its membranes, is much more rare than congestion, which is a common occurrence in all diseases of the respiratory organs which embarrass their function, as pneumonia, pleuritis, bronchitis, pertussis, tracheitis, or croup, spasmotic croup, or asthma of infants, and the various diseases of the heart, abdominal, and pelvic viscera. The diseases of the trunk, superior or inferior extremities, or any part of the body may also induce it.

The treatment consists in general and local bleeding, purgation, cold to the head, sinapisms to the feet, warm bath, with cold to the head while this remedy is being employed.—(See Apoplexy and Hydrocephalus).

Convulsions.—This disease is most commonly the result of cerebral or spinal meningitis, but may be produced by irritation in any part of the body. Thus, retained meconium, acidities, or flatulence in the stomach and intestinal canal, worms, the milk of a nurse who has lately suffered from exciting or depressing passions, who is intemperate, or uses too much vegetable aliment; painful dentition, pain in any part of the body, surprise, fear, dread, and irritation, are remote causes of convulsions. To these may be added the non-appearance or repression of cutaneous eruptions, such as small-pox, scarlatina, measles, and numerous chronic diseases of the skin, the ingestion of poisonous or irritant medicines, or local injury of any kind, surgical operations, burns, scalds, &c.

When there are signs of cerebral congestion, local and general bleeding, purging, the warm bath, with cold to the head, whilst it is being used, and warm or sinapised pediluvia, are afterwards required. If atony or debility characterise the attack, antispasmodics, opium, sedatives, and carminatives are indicated, with animal and vegetable, jellies, tonics, quinine, chalybeate preparations, &c. The exciting cause of the disease which produced the former complaint, ought to be controlled, or removed when possible.

When convulsions is caused by fear, horror, or disgust, it is to be combated by moral, sedative, and antispasmodic remedies.

Tetanus.—Modern pathology has thrown no light on the cause of this disease, either in infants or adults: it still remains among the *opprobria medicorum*. When it attacks infants, it generally proves fatal in twenty-four or thirty-six hours.

The *treatment* proper for adults, appropriately modified, ought to be employed. Fortunately, the disease very rarely attacks infants in temperate climates, and is now much less common than formerly.

Chorea.—St. Vitus's, or St. Guy's dance is a disorder whose pathology is as yet unknown. The symptoms are involuntary and irregular movements of all the voluntary muscles of the upper and lower extremities, which produce remarkable grimaces and contortions. The disordered muscles are often affected with a sensation of pricking, creeping, or numbness. The disorder attacks children from the age of seven to fourteen years, females more frequently than males, and very rarely adults, unless when it has been congenital. I have seen a young lady in Gray's Inn Square, who had chorea from the earliest age, and after puberty; she also suffered from a hysteric, and spinal curvature. A vast number of the most eminent physicians and surgeons were also consulted in this case. If the patient is desired to convey a cup to the mouth, the hand shakes and is carried in an opposite direction, and this appears to be a voluntary act to the spectators. This, however, is an error: in some cases fatuity ensues.

It was long considered that the cause of this complaint was the feebleness of the nervous system, which is remarkable in infancy, and which disappears at puberty when the constitution is more developed.

This affection is often contracted by imitation, as observed at the fêtes in honour of St. Vitus at Ulm. It was even considered epidemic and contagious in former times, as it often attacked several children in the same school. This notion is now exploded. The *treatment* consists in purgation, or depletion in full habits (Sydenham), tonics and chalybeates (Cullen), electricity (Detteau, Gardane, Underwood, and Fothergill), assa-fetida, (Wanters), camphor (Poissonier), and oxyuriate of mercury (Bosquillon).

I have invariably found that moderate purgation, quinine, carbonate of iron, and other tonics, speedily cure this disorder, unless when it is congenital, and the patient has arrived at the adult age. In those cases in which it is complicated with hysteria or spinal irritation, appropriate remedies are required.

Epilepsy.—This complaint may attack infants, from birth to the age of seven years, and from this period to puberty: there are more girls than boys affected. Its pathology is still unknown, and its *treatment* is unsatisfactory in most cases. Various disorganizations have been found in the brain and its membranes, which no remedies could

remove. But the disease often ceases at the seventh year, when dentition is completed, and childhood commences, or at puberty, the adult age; but it may continue for life. When it is of short duration and violent, it is termed acute, and also designated eclampsia by some authors.

It resembles convulsions, but may be distinguished from that disease, by being succeeded by stupor and temporary derangement of the intellectual functions. We, therefore, do not confound these species of neuroses.

Epilepsy is more or less dangerous according as it is idiopathic or primary, or symptomatic, or secondary. The first species often depends on a hereditary predisposition, which is seldom cured or eradicated. The second species may be violent and repeated, and speedily destroy life; or become habitual, and cause deafness, blindness, dumbness, paralysis. When it is caused by excessive hemorrhage, local irritation, moral emotions, as fear, terror, disgust, &c. it often proves fatal to young infants or children.

It is always difficult, and often impossible to cure the idiopathic species of epilepsy. When it is essential or idiopathic, and the infant is robust, general and local bleeding will be useful, with purgation and low diet. Setons, issues, counter-irritation, blisters, antimonial ointment, &c., followed by antispasmodics, opium, valerian, musk, camphor, zinc, iron, &c. may be cautiously employed. The ammoniated copper is also a valuable remedy. I have successfully treated some cases from the age of seven years to puberty, with strychnine in very small and increased doses.

When there are signs of debility, quinine, tonics, ferruginous preparations, nutritious aliment, and all hygienic means are beneficial.

In these cases, caused by mental emotions, we ought to inspire confidence and courage, and improve the general health. The infant or child should never be left alone at night, nor in the dark. Nurses are in the habit of frightening children by threatening them with horrible objects, and the result may be convulsions, epilepsy, idiocy, or death. I have known an infant of three years of age frightened to death, by the nurse covering herself with a sheet, and addressing it in an hoarse sepulchral voice. I was lately consulted by my friend, Mr. M'Can, of Parliament-street, about a female child, aged six years, who became an idiot from having been frightened by a nurse, and all the functions of the body were imperfectly performed.

In cases of sympathetic epilepsy, the exciting causes, or the disease which produces it, ought to be removed—as worms, effusion into the brain, &c. &c.

Agrypnia—Insomnia of Infants.—A thousand causes of irritation induce want of sleep in infants. It has been remarked that those

born of nervous or melancholic parents are very watchful, sleep little, and are easily roused by the slightest noise. Insomnia with these, is almost constitutional. In general, however, it is but a symptom of some other disease, as disorder of the digestive organs, caused by bad breast milk, or improper diet of the nurse or infant, which may induce griping, colic, vomiting, hiccup, flatulence in the stomach and bowels, diarrhœa, or obstinate constipation. All acute and painful diseases may produce it—fevers, inflammations, irritations in any part of the body, as worms, &c.

It is, therefore, evident that the *treatment* must be varied according to circumstances. The exciting cause ought to be removed, and the aliment of the nurse or infant properly regulated. It is a bad practice to have recourse to narcotics or soothing syrups until the cause is removed, and even then, they must be given with great caution.

Some infants, on the contrary, have a great tendency to sleep; and these are generally predisposed to determination of blood to the head, and to hydrocephalus or other diseases of the brain. Obstinate costiveness is also a common cause of this disease. Many children have very disturbed sleep, or night-mare (incubus), in consequence of being over-fed at bed hour. When the stomach is distended, the diaphragm cannot fully descend, the lungs are not sufficiently expanded, the respiration becomes laborious or difficult, the return of the blood from the head is prevented, the patient sighs or moans, the countenance is distressed, and the face, neck, and chest, are sometimes covered with sweat.

The *treatment* consists in moderate purgations, diminution of food at the approach of bed time, placing the infant on the right side, so as to favour the passage of the contents of the stomach through the pylorus, or lower aperture of the stomach, into the intestines. In addition to these means, the head and shoulders ought to be elevated, so as to facilitate the return of blood from the head; and when this part is large, the hair abundant, and the superficial veins easily distended, the application of a suitable number of leeches behind each ear and to the nape of the neck, and the means advised for encephalitis, apoplexy, and hydrocephalus will be necessary. Lastly, there are some infants from the age of three to seven years, who are subject to starting suddenly from sleep, and expressing dread or horror at external objects which they have seen or been frightened by. Parents and nurses too often induce this disorder by telling frightful tales, about ghosts, robbers, murders, &c., threatening children, or confining them in dark solitary situations.

The indication of *treatment* is to soothe the mind, to improve the general health by tonics and other appropriate means, which I have seldom observed to fail of success.

Reviews.

The Obstetrician's Vademecum; or, Aphorisms on Natural and Difficult Parturition; the Application and Use of Instruments in Preternatural Labours; on Labours complicated with Hemorrhage, Convulsions, &c., &c. By Thomas Denman, M.D., Licentiate in Midwifery of the College of Physicians, London; and Honorary Member of the Royal Medical Society at Edinburgh. Considerably Augmented, and Arranged according to the Present State of Obstetricy, by Michael Ryan, M.D., Member of the Royal College of Physicians, London; Professor of Medicine and Obstetricy at the Medical School, Gerrard Street, Soho Square, &c. &c. Ninth Edition. Illustrated with Seventeen Plates, and a Portrait of the Author. 12mo., pp. 231. London: E. Cox. 1835.

Manual of Practical Midwifery: Containing a Description of Natural and Difficult Labours; with their Management. Intended chiefly as a Book of Reference for Students and Junior Practitioners. Illustrated by Fifteen Engravings. By James Reid, M.D., M.R.C.S.L. and E., &c. 12mo. pp. 246. London: Churchill. 1835.

THE first of these works is long known to the profession in all countries, and the merits of the new edition need only be placed before our readers by presenting to them the editor's preface:—

“ Dr. Denman's Aphorisms on Obstetricy have passed through eight editions. He was the most eminent obstetrician of his age, and is justly acknowledged as such wherever medicine is cultivated. There never was a physician whose practical opinions were more generally adopted. His works are of standard authority and reference.

“ The following pages were the result of his extensive experience and careful observations. The principles and practice recommended in them, are most admirable and instructive. The justly celebrated author, actuated by that diffidence characteristic of great minds, offered to the world, in this work, a partial and imperfect view of his practical conclusions. He had given all his views in his Introduction to Midwifery.

“ In this little work, he confined his observations to ‘The Application and Use of the Forceps and Vectis, to preternatural Labours, and Labours attended with Hemorrhage and Convulsions.’

"So far as the aphorisms extend, there could be none more judicious or excellent. They are not, however, sufficiently comprehensive, nor could they contain the vast improvements made in the practice of obstetrics, which have been discovered since the decease of the revered author.

"The editor has therefore deemed it advisable to make the necessary additions, and to arrange the work according to the present state of obstetrics. He has considered it essential to prefix the anatomy of the pelvis, and the mechanism of natural parturition, without a knowledge of which, no one can perfectly understand the precepts of the author.

"He has given a minute description of the duties of the obstetrician, male or female, and the assistance which ought to be afforded during natural and difficult parturition. He has fully described the use of the ergot of rye, which possesses the power of expediting labour, and which was not employed in the time of Dr. Denman. He has also explained the methods of managing the numerous causes which retard parturition, but of which the author had only given the heads. He has also appended copious notes to the text, where these were required. He has explained more minutely than the revered author, the methods of applying and using instruments, and the numerous cases in which these are required. He has further described the manner of performing all obstetric operations, as craniotomy, symphyseotomy, gastrotomy, transfusion, &c., which were omitted by the author. He has, on some occasions, differed from the text, as on spontaneous evolution, which all modern obstetricians consider as the only objectionable and untenable part of Dr. Denman's valuable production.

"In fine, the editor has thought it his duty to add every doctrine and practice which are now universally adopted, and to render the work, which he was requested to revise, as complete as the present state of obstetrics admits. Whether he has succeeded in executing the task he has undertaken, remains to be determined by his professional brethren. The publisher has gone to considerable expense in illustrating the work with beautifully executed copper plates, and offers it to the medical public on the most moderate terms.

"This little volume has been designated the 'Obstetrician's Vademecum' by the editor, and contains all the practical precepts in modern obstetrics. Every medical practitioner who engages in this branch of practice, will find it a valuable companion at the bedside; but it by no means supersedes elementary or systematic works on the same subject. It describes, as concisely as possible, every case, and its treatment; but it does not contain the reasonings and facts which have led to practical conclusions. These must be sought for in elementary or systematic works. It is scarcely necessary to observe, that it is

impossible to include the matter of a large octavo volume in 235 pages duodecimo, nor did the editor attempt it. His object was to add to the original work, and render it what it was intended to be, and really is, a pocket companion for the lying-in room, and not a treatise of reference. In further proof of this statement, the reader may be reminded, that Dr. Denman did not intend to supersede his large work by the publication of the present little volume; as the works are totally different—do not in the slightest degree interfere with each other. The one is a vademecum, the other intended for the study, and for deliberate reference. In fine, it is right to observe, that all the editorial additions are included in brackets, and the initials of the editor added both in the text and notes."

The second work, whose title we have inserted above, was commenced while Denman's Aphorisms were passing through the press. The profession will form a correct estimate of their respective merits. We shall, however, offer our opinion on those of the latter production.

Dr. Reid thus proceeds in his preface:—

"The author has long been impressed with the belief, that notwithstanding the many voluminous and valuable works on Midwifery already published, there yet exists a deficiency in one respect;—indeed, he has frequently heard students, and those just entering on the arduous practical duties of the accoucheur, complain of the want of a work, which, while it should include all the information that might be necessary in the moment of doubt and difficulty, could still, from its size, be portable, and easily referred to, at the precise time when assistance is so anxiously required, and delay might be so perilous. Denman's excellent Aphorisms answer, to a certain extent, this object; but they are, perhaps, *too* limited, and as they refer principally to cases in which the use of the forceps is required, they do not fully attain the end proposed.

"It is with a view to supply this deficiency, that the author ventures to offer this little work to the notice of students and junior practitioners. It is almost exclusively confined to the department of Tokology, or Labour. The subjects of Conception, Menstruation, Diseases of Utero-gestation, and some others, are necessarily excluded, as the introduction of them would, if treated at sufficient length, have increased the size of the work far beyond the prescribed limit; moreover, as they do not demand so urgently the immediate assistance of the practitioner, they might, perhaps, have been foreign to its object.

"The wood engravings which are inserted with the letter-press, have been introduced for the purpose of illustrating those facts, on the knowledge of which the most important

practical rules are founded, and of which, in many instances, language conveys but an inadequate and vague notion: they are taken, with some alterations, from the plates of Smellie, Maygrier, and Velpeau.

"The author has made use of the tables drawn up and published by several eminent obstetric authorities, showing the detailed results of a very large number of cases, and he has added a similar return of a considerable number which have fallen under his own notice or superintendence, during the last four years and a half, in a somewhat extensive field of observation, afforded chiefly by the practice of two large parishes—St. Giles, and St. George, Bloomsbury. These statements occupy small space, but it is hoped may be useful, as tending to give a just idea of the relative frequency of the various presentations, or accidents, during labour, which may be met with in the course of practice.

"In the composition of the work, brevity and plainness of language have been kept always in view—attention being directed rather to distinctness of explanation, than to any attempt at laboured elegance of style."

This work is well executed, so far as it goes, but is too concisely written. It was intended as an improvement on Denman's *Aphorisms*, but in many respects far inferior to them. Thus, there are no directions given for the use of the lever, although many practitioners prefer that instrument to the forceps. The whole work is far too concise and particularly the practical part. The wood-cuts are miserably executed, and often inaccurate in many parts. Nevertheless, this little volume contains a great deal of useful information, in a small space. But, let us prove the justice of our censure on the plates. In page 5, is an illustration of the outlet of the pelvis. The representation is that of a deformed and not of a normal outlet. If the author can quote any work, or illustration in any standard treatise, we can only say, we have never seen such, nor do we believe it exists.

Fig. 3, in page 22, is a caricature of the os uteri at the ninth month of pregnancy.—(See the plate of Maygrier).

The fig. in page 54, is a bad copy of Smellie's—the vagina is of an inky black colour.

The fig. page 27, representing the natural presentation of the head is also faulty, as the face is represented as removed from the sacral concavity.

The fig. in page 60, represents the forceps applied when the face is towards the pubes, and the occiput in the sacrum. The opposite or natural presentation ought to have been

illustrated before this one. The directions for performing catheterism, are by no means so minute as they should be, and in our opinion, not one student in a thousand could pass the catheter according to them.

We should be sorry to be hypercritical, but we hate to see the word *child* used for infant throughout this work. Every midwife calls a new-born infant a child, and so do the majority of practitioners in this country. There is, however, a physiological distinction between the term infant and child, that ought to be maintained in scientific works.

The directions as to the performance of instrumental operations, are by no means sufficiently explicit, clear, or instructive. A well-educated obstetrician would understand them, but nobody else.

In page 146, is the representation of a brachial or arm presentation, in which the external genital fissure is delineated as like its normal condition as the moon. The position of the arm and shoulder does not warrant the excessive dilatation and elongation of the os externum, and we should advise the author, when next he calls on the artist, to nail his ear to the pump nearest his residence.

The next article is on Spontaneous Evolutions, the only bad thing that Denman ever published. It has misled many of the profession, and ourselves among the number. Sober and careful observations have since led us to conclude, that to wait for the spontaneous evolution at the full term of pregnancy, would be sacrificing the infant, and in almost all cases the mother. When version cannot be accomplished, and spontaneous evolution does not occur, Dr. Reid cites the authority of Dr. Robert Lee, in favour of amputation of the arm, and evisceration of the infant. We have also performed this operation, but recent reflection has convinced us that it is scarcely ever necessary in transverse presentations, if bleeding, opium, tartarized antimony, and tobacco enema, be fairly employed. We must draw our strictures to a close.

In the preceding remarks we may appear too severe on the author; but we may state we have not the pleasure of his acquaintance, and we treat his work as it deserves. We censure certain parts of his manual as a text book for students, because it is calculated to mislead them. Had there been no

wood-cuts, it would be a useful manual. It contains a vast deal of instructive information. We must observe, however, that the author has borrowed very freely from his contemporaries, without using those little crooked marks, called inverted commas.

Should his work pass through a second edition, we have no doubt but he will take the hints we have given him.

It is our opinion that Dr. Reid is exceedingly well acquainted with the science and practice of obstetrics, but that he has failed, on account of his extreme conciseness, to enable students or young practitioners to comprehend his precepts, is obvious. His manual is a good memorandum for well educated practitioners, but certainly not for those commencing the profession, and much less for apprentices, who can know nothing of the subject; and there are many such, before they begin to attend lectures.

—o—

ON SUPPURATION.

A Paper read before the Medical Society of the London University. By THOMAS MORTON, Esq., M.R.C.S.

THERE are few subjects in pathology, concerning which more numerous and extraordinary opinions have been at various periods advanced, than concerning the formation, nature, and uses of pus. That it is a subject highly interesting in itself, and greatly deserving the attention of either the physician or surgeon, will, I have no doubt, be freely admitted, when we consider the great number of its shades and differences, as exhibited under various circumstances—the curious and important local phenomena exhibited in its formation, together with the dangerous and fatal results which are not unfrequently induced by its existence.

We are accustomed to give the name of pus to several species of fluid, which differ greatly from one another in their physical, probably also in their chemical, and certainly in their specific properties. Thus we have what is termed laudable pus—a fluid, bland, homogeneous, likened to cream in its consistence, of a yellowish white colour, insipid taste, and nearly devoid of any odour, un-irritating to the human body. Or when it is mixed with blood, thin and fetid, and irritates the surrounding surfaces over which it may flow, we recognize it by the term Sanies, Ichor, &c. We may have it loaded with sulphuretted hydrogen, and other chemical constituents, as in scrofula, where the pus is usually found to contain more of soda, and muriate of soda, than in that se-

creted from the body of a healthy individual.

Again, what remarkable and striking properties do we not observe pus to possess, secreted in the system when labouring under certain diseases; for example, gonorrhoea, syphilis, small-pox, glanders, plague, and many others? There is no subject which shows so much or so clearly the insufficiency of chemistry as applied to the elucidation of pathological physiology than the total absence of any useful results from the careful attention which has been paid by different observers to the analysis of pus. Sir E. Home subjected pus to the most careful examination. He states that it is made up of two principal elements—one of which is a transparent watery fluid, somewhat resembling the serum of the blood, and the other consisting of opaque globules. The latter he considered as the essential constituent of pus. Added to these are certain salts of soda and of lime, some albumen, &c. But we derive very little advantage from this knowledge in our pursuit of the inquiry in what manner, and by what means pus is formed in the living body; for the same elements are found to exist in nearly the same proportions in many other fluids of the body, which possess no analogy whatever to pus in their properties and qualities. It would have given great interest to the analysis, could we by such means demonstrate wherein the specific properties of the fluid reside. But such success hitherto has not followed the labours of the chemist, though it may not be absurd to hope, that at some future period, as the science is so rapidly advancing to perfection, a further knowledge may be attained.

We come now to the consideration of the mode or process by which pus is produced in the animal economy.

Suppuration implies life; for no pus can be formed in the dead body—parts which are dead may become the seat of putrefaction but not of suppuration. Thus we see every day, that when any portion of the body is destroyed either by mechanical violence or by chemical agency, it is not in the dead, but in the adjacent living surfaces that suppuration is established. The opinions of writers may be reduced into two classes: 1. “That pus is formed within the vessels of an inflamed part by an action of these vessels upon their contents, similar to what takes place in secretion.” The other, “That pus is formed without the vessels of the part inflamed, by a change taking place either in the solids affected with inflammation, or by a change in the fluids extravasated, similar to what occurs in fermentation or putrefaction. The most ancient doctrine attributed the formation of pus to a species of coction, or putrefaction. Hippocrates says, “Suppurantur autem ulcera, alterato et califacto sanguine, donec putrescens talium ulcerum pus fiat.” Boerhaave taught

that pus was formed by the dissolution of the solid constituents of the parts attacked by inflammation, which went on to suppuration.

Vorduc to the admixture of chyle, with a variable proportion of blood, and the remains of the ruptured vessels.

Heister conceived that in those instances where inflammation did not admit of resolution, the gorged capillaries of the part were burst by the force of the circulation, and that the fluids thus extravasated in the adjacent tissues became putrid—causing the tissues themselves to become putrid also—consequently that in his opinion pus was the result of the heterogeneous admixture of the various elements which he in this manner supposed to take place.

Grashius said that pus owed its origin to an alteration, or change impressed on the fatty parts of the body; for, observing that in long continued and extensive suppurations there is generally a remarkable loss of flesh, he thought that the fat must have disappeared under the form of pus. He concluded that suppuration had its seat in the cellular tissue, and that the fat is the principal element which enters into the composition of pus. Pringle imagined that pus was produced by a putrid fermentation, and that the element which chiefly assisted in its formation was the serum of the blood. De Haen held that pus was elaborated from the arterial blood whilst it was circulating in the vessels, and that it was deposited ready formed under the form of abscesses, or the discharge from exposed surfaces, &c.

Towards the end of the last century the opinion that pus is produced by an action of the capillaries of an inflamed part, analogous to secretion, was first introduced by Dr. Simpson of St. Andrews, Dr. Morgan, and as we have already observed, De Haen supported somewhat similar views with regard to suppuration. About this time the illustrious Hunter turned his attention to the subject, and to his labours we are indebted for much that is known at the present day. He says, "Pus is not to be found in the blood, similar to that produced in the first stage of the process of suppuration; but is formed from some change, decomposition, or separation of the blood, which it undergoes in its passage out of the vessels, and for effecting which the vessels of the part have been formed." "That we must look upon it as a new combination of the blood itself, and must be convinced that in order to carry on the decompositions and combinations necessary for producing this effect, either a new or peculiar structure of vessels must be formed, or a new disposition, and, of course, a new mode of action of the old must take place. This new structure or disposition of vessels, I shall call glandular, and the effect or pus, a secretion."

The present doctrines concerning suppuration embody many of the principles of the

more ancient—chiefly inclining, however, to that class which regards the process as analogous in many respects to secretion. I shall presently revert to their consideration after having shortly noticed one or two other points connected with the subject. It has been frequently disputed whether inflammation is necessarily antecedent to, or coincident with the production of pus. Is pus ever formed, under any circumstances, without some inflammatory condition of the part affected having existed previously? De Haen held that suppuration might take place without any previous inflammation. He alleged that pus might be formed by the mere existence of what he chose to term a purulent diathesis. But this is a position not easily acceded to, for it assumes on the existence of a condition of the system, of which we have no positive and satisfactory proof. In the greater number of instances where pus is formed, there is sufficient evidence of the existence of inflammatory action, commonly in the part affected, though occasionally at a distance from it. At the present day the opinion that inflammation always precedes the formation of pus is generally adopted as the established one; it is one that John Hunter strenuously contended for; he says no suppuration takes place which is not preceded by inflammation, and that pus is never formed but as a consequence of it. Some have held that collections of matter may be formed without inflammation, and they instance those cases of visceral abscesses, and other purulent collections common after phlebitis, injuries of the head, severe operations, as amputation, &c., in support of the opinion. It is true that in these cases it is difficult, perhaps impossible, always to demonstrate the existence of inflammation of the parts in which the pus is formed; yet I think we shall be able in a future part of this paper to adduce satisfactory reasoning that inflammation has a real if not an apparent influence in this production. One argument in favour of the opinion that inflammation precedes suppuration as a cause is, that if the inflammatory condition can be early subdued no pus is ever formed. Again, if inflammation exceed in violence a certain point, pus will not be formed, but the part dies—becoming affected with gangrene, but after a while, when the inflammatory action begins to diminish in intensity, then a change is observed to take place, and in exact proportion to the gradual subsidence of the inflammatory symptoms, do we notice the successive steps taken towards the formation of matter. Hence that rule in surgery, that we may always derive considerable information as to the probable results of a case of mortification, by closely observing the character of the discharges, the most favourable symptoms of the cessation of the disease being the appearance of true healthy pus. Broussais considers pus is the result of certain changes induced in the

gelatinous and fibrinous particles of the blood, by some peculiar action of the capillaries of an inflamed part. Suppuration, according to him, cannot occur, except the inflammatory action be intermediate in its intensity between that which induces mortification of the part, and that congestive state or condition usually termed chronic inflammation. For example, when a wound is attacked by violent inflammation, the discharge of pus is stopped, and bloody fluid, little resembling true pus, is secreted in its stead, and before we can establish a healthy suppuration, we must, in the first place, reduce the inflammatory state of the sore. On the other hand, we may remark that many scrofulous, and other sores of an indolent nature will not suppurate kindly, until some strongly irritant substance has been applied to the part, so that we purposely excite an increase of action, resembling, probably identical, with what occurs in inflammation.

It was a question long agitated by the profession, whether there is a real loss of substance in the organs or tissues which are affected by suppuration. The ancients contended that such was actually the case. They supposed that every purulent discharge from the several cavities of the body, from the respiratory, digestive, or urinary organs, was a sure indication of the existence of ulceration of some portion of their surface, and that the extent of the ulceration was to be estimated by the quantity, and quality of the discharge. So much was this the case, that great exertions have been made to ascertain a knowledge of some certain test whereby we might distinguish between pus, and other fluids which might resemble it, but more particularly from mucus. Dr. Young and Dr. Darwin, jun., are both celebrated for their experiments to establish distinctive marks. The former introduced the practice of deciding the character of the expectoration of phthisis by an optical experiment. As pus contains globules, if the suspected fluid be placed between two plates of glass, and viewed against the light, and a corona of variegated colours be observed, then it is pus; but if instead of a bright rainbow tint, we only observe an opacity, then it is mucus. Dr. Darwin established certain chemical tests. He gained great fame at the time by his paper on the mode of distinguishing pus from mucus, published in 1778. These tests however have lost all their value, and sunk into neglect in consequence of the change which has taken place in the opinion that suppuration is necessarily an effect of ulceration, and therefore a proof of its existence. At the present day all agree that pus is often formed in the largest quantities without ulceration, or loss of substance. Dr. W. Hunter was among the first to establish this fact. He relates a case in the 2nd vol. of the *Med. Obs. and Enq.*

It has been said that there are cases in which suppuration appears to be accompanied with actual loss of substance. Thus we may cite the case of an inflamed gland. During the commencement of the attack, it is immensely swollen, forming a very large and dense tumour; but as soon as suppuration is established, it softens where it bursts, or is opened, and decreases in magnitude; and often when the suppuration has been very complete, the gland seems to have disappeared altogether. Another case brought forward, is the extensive destruction of the texture of a lung, which is frequently observed in advanced cases of pulmonary phthisis, when the lung is a mere bag, containing purulent fluid. If these examples, together with many others, do not prove that in such cases suppuration is accompanied with true loss of substance, they may be said at least to give an air of probability to the opinion that this is the case.

It might however be asked, does the apparent loss of substance arise from absorption, or from the nutrition being impeded by the pressure of effused matter, or from both these causes acting in concert, rather than from the conversion of the texture of the organ into pus?

Present Opinions of the Mode by which Pus is formed.—It was mentioned, in a former part of this paper, that John Hunter strongly advocated the doctrine that pus was always preceded by inflammation, and that suppuration was an effect of such inflammation. He describes the process thus, that when inflammation has been fairly established, there succeeds to the vascular congestion an effusion of serum, followed by that of coagulable lymph; and last of all pure pus is thrown out—all of these phenomena being frequently observable on the surfaces of incised wounds, and of serous membranes. Though Hunter does not say precisely how far he might have ascertained the exact changes which took place in the formation of pus from the blood, yet from his expressions, there can remain no doubt of such having been his opinion. His words are, "This matter (*viz.* the discharge which accompanies the suppurative stage) is a remove further from the nature of the blood, and becomes more and more of the nature of pus." That pus is formed from the blood, within the vessels of the part inflamed, by an action of these vessels, similar to that which takes place in secretion, is I think proved, by observation of the fact, that in inflamed mucous membranes, pus exudes directly from the affected surfaces, from inflamed cutaneous texture, and from the cellular substance, when in the state of healing by granulation. In these three surfaces there can be no doubt of its being formed in the vessels from which it exudes; and from this it follows that we are not warranted in supposing that the pus constituting in-

ternal suppurations is formed in a different manner.

According to the latest observations, the process by which pus is formed as a consequence of inflammation, is the following:—

“When inflammation is excited in a web of a frog’s foot, or other transparent and vascular membrane, the capillaries are observed to become gorged with the red globules which have ceased to circulate; the part is of a uniform red colour, serosity, coagulable lymph; if the inflammation be severe, blood itself is thrown out of the vessels into the surrounding cellular tissue; the part loses its transparency, and is opaque. Shortly the red colour of the part begins to diminish, and soon disappears altogether; a yellow granular looking matter occupies the capillaries, and surrounding cellular tissue. In the centre of the inflamed part, several of the capillary vessels which were before obscured by extravasated blood, begin to reappear, some containing reddish, and others reddish-grey globules. These gradually become more and more distinct, increase in number and size, begin to move slowly, and traversing the capillaries, arrive at the surface of the tissue, or at the edges of the solution of continuity, if this has occurred in the form of globules of pus.” Such is the account given by Dr. Carswell of the process.

Gendrin has very carefully examined the whole of the process in the frog’s foot and mesentery, and he arrives at nearly the same conclusions. He states to have distinctly seen the globules of blood which had loaded the capillaries lose their colouring principle, and become opaque, gradually assuming the yellowish grey colour peculiar to pus, and that gradually moving towards the wounded, or irritated surfaces, either in the capillaries, or in newly formed vessels, finally acquire all the physical properties of perfect pus.

Kattenbrunner agrees with these accounts, but adds that he has observed some of the solids of the diseased part to become converted into pus; that some of the granules of the parenchyma separated from the rest, entered vessels prepared for their reception, and mixing with the globules derived from the changes which have been described as occurring in the blood, assist in the formation of true pus.

From these observations we are led to the conclusion that pus is derived from the blood, which is arrested in the capillaries during inflammation; that the capillaries are the seat of this conversion; and that these vessels conduct the globules thus modified to the exterior, where they are found combined with the serum of the blood, in that particular form which we are accustomed to designate pus.

This is one of the modes by which pus is formed, yet there is another, the ignorance of which has produced the greatest con-

fusion, and given rise to most erroneous doctrines upon this topic. It is the formation of pus under circumstances by which the influence of the capillary system, as exercising a function of secretion, can have no existence.

Dr. Carswell terms it “*Extra vascular.*” It was before observed that in the inflammatory condition of any part which is about to be followed by suppuration, there is an effusion or extravasation of a certain quantity of blood into the cellular tissue of the part so affected.

For indeed in every case of severe inflammation of the cellular tissue, a great proportion of the swelling and induration is owing to the presence of effused blood. A section of any part in the state of high inflammation shows that this is really true.

The same changes, then, take place in the blood thus extravasated, as we have already noticed, as occurring in the blood, which is stagnated in the capillaries of an inflamed part; viz. gradual change of colour, from red to yellowish-grey; the globules in each case becoming opaque, acquiring an increase of bulk, and gradually advancing to the surface of the part, either in the original, or newly formed vessels, in the form of pus. Dr. Carswell states that he has observed this to have actually occurred under his own inspection, in cases where inflammation has followed the effusion of blood into the cellular tissue, as a consequence of contusion or other mechanical injury. He has also frequently noticed it in cases of phlebitis, where the blood has ceased to circulate on account of the obstructed circulation induced by an inflamed state of the interior of the venous system. Gendrin has made a direct experiment which admirably supports this view. “If,” says he, “after having injected a quantity of blood into the cellular tissue of a part, we pass a seton through the same part, so as to excite a certain degree of inflammation, the blood is rapidly converted into pus, just as though it had escaped ready formed from the vessels of the part.”

We can also demonstrate this conversion of blood into pus, by recurring to the phenomena which are observed to occur in phlebitis. When the inflammation of a vein has attained a certain height, its function is suspended; the blood, which is contained within its interior, no longer circulates, but becomes coagulated; and it is at this stage that we observe the hardness, and cord-like feel usually described in treatises as one of the distinguishing characters of inflammation. At a more advanced period of the disease, the hardness disappears, and if we submit the vein to ocular examination, we will find that the change is owing to the presence of pus within its interior. The gradual change of blood into pus has been carefully noticed in cases of phlebitis, the blood being found, in different stages of the

transformation, in different parts of the same vein, and even in different veins. There is an experiment of Gendrin which is very satisfactory in support of this statement.

Having interrupted the circulation in a vein or artery, for an instant, he then injected a caustic solution, and retained it for a minute space of time, and then withdrew it; this done, the blood was again admitted, and retained between two ligatures: he found that inflammation was excited, which ran on to suppuration.

"The contained blood, having become coagulated, loses its red colour, and is progressively changed into pus. This conversion of blood into pus, can, he affirms, be followed by the eye between the layers of the coagulum, and by the aid of the microscope, may be observed in the molecular or globular structure of the fibrine."

From these observations, it follows that in these instances the capillaries could have no share in the conversion of blood into pus. Yet in all, we notice the precise order of sequence observed in the succession of the changes which occur in the parts affected with inflammation. Hence it follows that the formation of pus cannot in all cases be confined to a morbid process induced in the capillary vessels by inflammation, and the subsequent separation of the elements of this fluid from the blood. Yet it cannot be doubted that inflammation is the common origin of the production of pus, because we see the same succession of changes occurring without variation in both; viz. the cessation of the circulation, the coagulation of the blood, and the conversion of the fibrine, or globular structure of the fluid, into pus. The globules of pus are observed to appear in the fibrine of the blood, which had become deprived of its colouring matter after having been brought to a state of stagnation in the capillaries, in venous and arterial trunks and in lacerated extravasations formed in the cellular tissue.

It was mentioned before, that though inflammation was allowed by all to be the real cause of the formation of pus, in the generality of cases, yet there were some instances in which this cause did not appear to have been in operation. For instance, in those cases recorded by Andral and a few others, of pus being detected in the centre of coagula contained within the heart, but not possessing any organic connexion with its lining membrane, and consequently beyond the influence of any pathological condition of the heart; cases of visceral abscesses, collections of pus within the synovial capsules of joints, which are occasionally met with after severe compound fractures, amputations, &c., &c. It is explained by a more careful inquiry into all the circumstances of the cases wherein pus is thus found; for in all that are on record there has always been satisfactory evidence that inflammation followed by suppuration had previously ex-

isted, to a greater or less extent, in some distant part of the system. We may cite a few of the most common of these coincidences: fractures, where there is always more or less laceration of the soft parts by the broken ends of the bone; operations, in which parts of the body have been removed; phlebitis after venesection, and by the exposure of the interior of the uterine vein; the separation of the placenta after delivery in childbirth. In all these instances pus has been first formed within the veins of the injured part. It has been found in the smallest veins, and also in the largest, as the femoral, the iliac and their contributory branches, and even in the cava itself. In these cases, it is worthy of notice that pus is not observed within the arteries. Dr. Carswell states, that in all the cases which have come under his notice, there was always an evident communication maintained between the diseased vein or veins with those that remained healthy. We have, then, a pretty satisfactory chain of evidence. Let us take the case of visceral abscess occurring after amputation of the thigh—we have phlebitis of the femoral and iliac veins. This is followed by the formation of pus in their interior, but there is no distinct obstacle to the circulation of this pus along with blood of the part, and hence we are warranted in assuming that the pus thus formed is carried into the adjoining veins, and by them carried into the general circulation. It is agreed by all that the pus so formed is carried into the general circulation, but a difference of opinion is held as to the exact mode in which this transportation of pus is effected; some, as Velpeau and others, alleging that the pus is absorbed from the surfaces on which it is first secreted, and carried by the lymphatics into the circulation. Others, again, contend that it is not by the absorbents, but through the medium of the veins themselves, that the pus reaches the circulation. In favour of this last opinion, we may urge the great probability which attends its existence, and the advantage that it possesses over the former by the absence of assumption—for the former implies a more intimate acquaintance with the nature and functions of these vessels than we really possess: whereas, in the latter, we have as it were the whole process actually exposed to our view—for we see pus present within the veins, and a perfectly complete communication of those with the rest of the venous system. Again, we may urge, that we frequently find abscesses and other collections of pus disappear by absorption, without any such ill consequences as those now under consideration ensuing. May not, then, the pus, carried in this manner into the general circulation, excite a diseased action in whatever part of the body which at the time may, from the influence of either constitutional or local causes, be less able to resist it, which may be brought to bear upon it?

The opinion that pus circulating with the blood is the cause of these visceral abscesses, &c., is strengthened by the consideration of the peculiar character of the constitutional symptoms which occur towards the close of this fatal disease;—the sudden attack, the great prostration of strength, the disturbance of the mind, the altered colour of the skin, fetor of the breath, &c.—all which symptoms may be produced at pleasure, by injecting pus and other putrid fluids into the veins of animals.

Suppuration, in common with almost every other function of the animal economy, is liable to be influenced by all agents which act upon it, whether moral or physical: it may not only be deranged, but even suspended, by their operation—thus affections of the mind, but especially those of a depressing character, a disordered condition of the digestive organs, the presence of foreign bodies, as portions of diseased bone, musket balls, splinters, &c., an attack of fever, and many other local and constitutional affections, all exercise great powers over this operation of the system, and consequently deserve the careful attention of the surgeon. It is, indeed, very difficult to account why one sore suppurates in the most healthy manner, while another, in the same individual, and perhaps not far apart from the former, secretes matter of the most unhealthy description. Do we not see contagion connected in some inexplicable way with the matter produced by suppuration? Has any one, as yet, been able to give an explanation of this connexion, which is at all satisfactory to our understandings? Can any one point out in what the pus secreted by a contagious sore differs from that discharged from a healthy ulcer? If we operate on, or wound parts which are in a state of inflammation, when the capillaries are gorged with blood, we run a risk of putting a stop to suppuration altogether, and incur a chance of mortification, or we may very much disturb its due progress. So much so is this the case, that the surgeon carefully avoids performing amputation, or other important operations, so long as the parts which he must divide are in a state of inflammation (Case in ward 2). We find that exposure of the suppurating surface to the air acts very injuriously by altering the nature of the pus secreted, causing it to degenerate in its qualities, and become irritating to the adjacent surfaces. To avoid this the surgeon takes the precaution to protect, as much as is possible, ulcers and other suppurating surfaces from atmospheric influence by the interposition of dressings. It is a general opinion, that the dangerous and frequently fatal results which take place after the opening of large collections of purulent fluid, as psoas, abscess, &c., arise from the admission of air into the secreting cavity, the internal surface of which it irritates, inducing a total alteration in the

properties of the discharge, so that the constitutional irritation consequent upon this depreciation, in the majority of instances, quickly brings the patient to his grave.

We observe that suppuration is, in some degree, under the influence of the tissue by which it is secreted. We seldom observe tendinous or ligamentous structures to become the seat of suppuration. The cellular and adipose tissues are those that are most liable to this affection; but, as a general rule, we find that the more vascular a tissue, the more prone is it to fall into a state of suppuration under the influence of the slightest causes. Thus the mucous membranes are very commonly observed to secrete pus in large quantities under the agency of causes which would have no power over many others of the elementary tissues.

Pus has been supposed to be possessed of very acrid properties, but now it is well established that pus is altogether devoid of any irritating influence over the surface which secretes it. Pus, however, may, and often does, irritate the surfaces adjacent to that which secretes it; but this is no more than we observe to take place with regard to many other secretions; thus the tears secreted during many morbid conditions of the lacrymal apparatus never irritate the conjunctiva, though they may excoriate the cheeks over which they flow. The urine never irritates the kidney nor bladder, though it induces inflammation and gangrene when effused into the scrotum in rupture of the perineal portion of the urethra, or when it is involuntarily discharged in cases of paralysis.

The limits to which suppuration may extend are very indefinite, for it may continue one day, or many days; nay, weeks, months, and even years. Hence writers have been accustomed to describe two leading varieties of suppuration, viz. acute and chronic.

The process of suppuration, particularly when it occurs in the internal parts of the body, is often accompanied by constitutional symptoms, which indicate its existence in a manner almost unequivocal. This would lead to the consideration of hectic fever, but time will not permit me to enter on that portion of the subject.

A Letter to Lord John Russell, Secretary for the Home Department, in reply to the first report to his Lordship of the Poor Law Commissioners, upon the subject of Medical Attendance on the Poor. By George Bottomley, Surgeon, Croydon.

10th December, 1835.

MY LORD—I trust I shall be pardoned for addressing your lordship upon a most important subject, as regards a very large proportion of the industrious population of this country—I allude to the medical and surgical attendance upon the poor. I believe there is

not a set of men more anxious to afford relief to that class at all times, nor can there be a better feeling than exists between the medical attendants and the poor under their care; which must, of course, prove, that the latter are generally attended to in a manner satisfactory to themselves. The Poor Law Commissioners, in their first report to your lordship, make a most unwarrantable and unjustifiable attack upon that class of medical men who enter into contracts for attendance upon the poor. They state that medical men are in the habit of taking a very low contract, with an understanding, that they are allowed to make whatever charges they may think proper, for paupers under suspended orders; that their charge for medicine is at the highest rate, and against such charges, the parish to which the pauper is removed has not any protection; and that the pauper has been drenched with medicine, considerably beyond what was necessary; and that in some populous parishes the profits upon orders of suspension have exceeded 300*l.* per annum; and that the inferior officers have been bribed by the medical attendant to search out and give information of such cases; that paupers, with their families, have been removed at a great expense, when they would have preferred remaining where they were, and seeking employment in the parish where the sickness occurred; and by continuing these practices, parishes were in the habit of creating burdens for each other. Now, to all these most serious charges I feel myself called upon to reply, being one of those who for years have had the medical and surgical attendance of a very extensive and populous parish. In the first place, the salary is not in general at all adequate to the very great charge and heavy responsibility attached to such appointments. I feel confident the fault has not arisen with the medical men, but with the parochial authorities. The next is one of a most important nature: it is that of charging extravagantly, and such charges being sanctioned by the overseers, in cases of suspended orders. Such an accusation involves the character and reputation of not only the medical officers (who, I should hope, after having received a liberal education, and being connected with a scientific profession, would be placed far above such base and fraudulent transactions), but also of the parochial authorities. If the Poor Law Commissioners had discovered such a case, both the medical officers and the parochial authorities ought to have been exposed, that such medical men might have been treated with the contempt they merited; and the parochial officers should have been immediately ejected from their appointments, as unfit to hold any responsible situation in their respective parishes. If such a case has occurred, it is, I trust, a solitary one. In the next charge, which is that of distant parishes not having any protection if it should amount to a certain sum, they have the power of appealing, and I believe it is customary to send the particulars; it is a

plan which I have always adopted, that they may be shown to the medical officers of the parish to which such paupers were removed, that they may be enabled to point out, and deduct any overcharge. According to the commissioners, the charges are exorbitant. My system has been (one which I believe is generally adopted) to charge one third less than to private patients, and to send the medicine in the cheapest form, reducing the sum to about one half. The report states, "that in large and populous parishes the profits upon suspended orders exceed 300*l.* per annum." The population of the parish I attend is about 1500; the miles of road in the parish between 40 and 50; the annual amount of receipts, including salary, midwifery, surgery, journeys, and attendance upon non-resident poor, and suspended orders, has rarely exceeded 300*l.* The next charge, which is that of inferior officers being bribed by the medical officers, is too monstrous to be entertained for a moment; and as far as regards the removal of paupers; I believe it is never done, unless the removing parish derives the principal benefit from it; it is the law, and not the parochial officers that is to blame. It is a subject of great hardship to the paupers, and of serious expense to the rate payers; a subject calling aloud for the interference of the legislature.

I am of opinion that the settlement of the poor ought to be exploded, with a view of putting a stop to suspended orders, thereby preventing removals and expensive litigation; that there should be a general assessment, that the poor might be relieved from a public fund; and that there should be district establishments for the relief of the poor, and as a receptacle for the sick. As far as regards the appointment of medical officers, the plan recommended by the commissioners, and in some instances acted upon, of selecting the young and inexperienced, is both cruel and unjust; cruel to the poor, and unjust to the rate payer. Although the examinations for medical and surgical qualifications are more rigid than formerly, still such as obtain them may have superior theoretical acquirements with scarcely any practical. Would the Poor Law Commissioners like to place themselves or families under the care of such inexperienced practitioners? then why allow the poor man to be so placed? The love and affection is as great in the poor man's family as in the rich, and their lives are equally valuable—then what reparation can be made for the loss of such a life? I have as great a respect as any one for the juniors in the profession; but they must gain experience at the elbow of an experienced hand, before they ought to take upon themselves so great a responsibility. The labourer is exposed to every kind of accident, some requiring immediate and intricate surgical operations: then is it just to place such a case in the hands of one who has never before performed an operation? Would it not be cruel to the poor man, and, in the event of death, unjust to the rate

payer? as the wife and family would immediately become a heavy burden on the parish; and, in respect to the sum per head, *that* would be attended with serious inconvenience, as it then must be done by order, and the delay occasioned by the absence of the relieving officer, or the doubt he may have upon his mind about giving such order, might be attended with fatal consequences.

THE LONG DESIRED METROPOLITAN
UNIVERSITY. JUBILATIONS OF THE
LIZARD.

Quem Deus vult perdere prius dementit. The Green Lizard is clean distraught. Will it be believed that this infatuated creature is itself the first to announce—yea, and says that it is *glad* to announce—"that every thing is now arranged for the establishment of the long-desired central University in the metropolis!" *Desired!* By whom, we pray. By the Lizard? By the ugly reptile hatched in the hot-bed of corruption, and set to guard, like a griffin, the entrance of those dens of medical iniquity whose inmates now read in the charter of a metropolitan University the fiat of their own extinction? By the Lizard, hired to advocate the base monopoly of the College of Physicians, and, by a necessary connexion, the monkish bigotry of those Universities which have fostered the talent and learning of Britain, only to enlist them against the best interests of society? Yes, by the Lizard itself! The very Lizard which erewhile poured out a deluge of slime at the bare mention of a London University, now twists its tail with rapture at the idea of "the long-desired central University in the metropolis!"

This is not all. Our respected contemporary is not content with rejoicing

over the approaching annihilation of every thing which it used most strenuously to uphold, and the establishment of all that it formerly declaimed against with the utmost virulence, but, on the back of all this, it proceeds to rate the men of Gower Street most severely for changing their tune!

What has been the actual conduct of the projectors of the London University? Simply this; having endeavoured with laudable perseverance to establish a University in the metropolis, and having met with insurmountable opposition from other schools whose interests were at variance with their own, they now acquiesce willingly in a more extensive scheme, which compromises the interests of none, and is fraught with incalculable benefits to the whole community.

Let the patrons of the Gower Street school rest assured, that the ravings of the Gazette afford the best testimony to their own merit and success. We speak not under the influence of any political feeling; as medical journalists we acknowledge no distinction among Whigs, Tories, and Radicals; but we will, and do declare, our conviction that to Lord Brougham and his enlightened coadjutors in this patriotic enterprise, the English nation is most deeply indebted, for an attempt to place London on the same footing with other great metropolitan cities, in the possession of an University, and to afford our youth an opportunity of becoming scholars without becoming bigots, and of addicting themselves to learned professions without imbibing the anti-social vices which have too long disgraced those professions, and rendered them the very reverse of what they are called—*liberal.*

The London University has *not* been a failure, as the Lizard would insinuate. Let the Lizard answer this question. If the Gower Street school had not been founded, would government now be occupied with the establishment of

a "long-desired Metropolitan University?" or would the Lizard have ceased to extol the superhuman excellence of Oxford and Cambridge degrees, and the immaculate purity of the College of Noodles in Pall Mall?

How fortunate then is it for the Lizard that the joint stock company in Gower Street was set up! Why, if it had not been for this, our valued contemporary would either have burst outright with the vehemence of its pent up desires for a metropolitan University, or have pined away under the wasting influence of

—"gentle wishes long subdued,
Subdued and cherished long."

The founders of the London University endeavoured to attain certain highly desirable ends in connexion with the prosperity of their own institution: in this they exercised a species of *philoprogenitiveness* (we borrow a term from phrenology) which is inseparable from all human undertakings, and essential to their success. In acquiescing readily in a plan which merges their own in one of greater extent and utility, they merely show their good sense and consistency by retaining their attachment to a principle, apart from the details of its application—thus differing most widely from the dishonest Lizard, which, resisting all that is good or useful as long as it answers its own vile purposes so to do, adopts at last from fear and self interest the very thing it had previously opposed both in principle and detail; and, slavish alike in opposition and conformity, at one time echoes the howl of its corrupt masters against the very name of a London University, and at another is equally obsequious to their bidding in hailing the establishment of the "long-desired" institution!

The men of Gower-street, according to our contemporary, have determined with a good grace to make a virtue of necessity, and they are wise, since they

can do so without any sacrifice of principle; the Lizard has also made a virtue of necessity, but with the bad—the wretchedly bad grace of a floundering reptile that sprawls on the earth, because it has no longer a leg to stand on.

With how much ingenuity does our contemporary labour to give a colour to its proceedings! Verily the Lizard hath many hues; we thought it was a *green* lizard, but doth it not now look exceeding *blue* in this matter of "the long-desired Metropolitan University?" The Lizard is surely a chameleon! Leaving this turn-coat reptile to the contempt of honourable men of all parties, we heartily congratulate the profession on the prospect of a London University reared in a spirit of science and benevolence, and we cannot but express our sincere gratitude to those public spirited men who laid in Gower-street the foundation of so "long-desired" and necessary an institution.

—o—

Foreign Medicine.

Scald-Head.

M. A. Palmieri gives the following method for curing this disease. First carefully wash the head with soap and water. Then cut the hair to the length of half an inch. Cover the parts affected with a plaster composed of cow dung and common red earth, which is to be allowed to remain four days. After this we proceed to the depilation with facility, as the hairs may be pulled out with the fingers or forceps, as easily (says the author) as the tenderest feathers of a young pigeon. If any resist, they are taken away by means of fillets of linen, covered with fresh linen. Afterwards wash the head every third day with soap and water, in order to obtain a complete cure; which is generally effected at the end of ten days. If there are any chaps, or bleeding fissures, they are covered with a little soot, which hastens the cure. The author assures us this mode of treatment is not at all painful. It is at any rate, economical.—*Lancette Francaise*.

Académie de Médecine.—Dysentery.

M. VILLENEUVE made a verbal report of a Memoir by M. Toulmouche, of Rennes, intitled—"History of an Epidemic Dysentery which prevailed in 1834, in the Department of *He-et-Vilaine*, with remarks on a new mode of treatment, called the Chloro-opiatic."

Struck with the ill success of other methods, and impressed with the idea that the intestinal inflammation was of a specific nature, and occasioned by a deleterious principle which it was necessary to neutralize, the author submitted his patients to the action of chlorine, with which he associated opium, to remove the griping pains. Of eleven patients thus treated, not one died. M. Toulmouche gave the history of various cases, and concluded as follows:—

Dysentery is a violent inflammation of the rectum, colon, and cæcum, quickly going on to ulceration and destruction of the tissues, and having but very little resemblance to diarrhœa, and ordinary inflammation of the rectum and colon. Even with respect to epidemic dysentery itself, its nature and anatomical characters are apt to vary. The chloro-opiatic treatment has been followed with more success than most others; and when employed in slight enteritis, has appeared to be attended with similar effects. This treatment consists in administering by injection half an ounce or an ounce of the chloruret of the oxide of sodium in a pint of water; giving for drink a solution of the same substance, in the proportion of two drachms to a pint; together with a grain of opium in a pill, morning and evening.

M. Maingault.—The dose appears to me rather large; nor is it stated whether it is employed in all stages of the disease. In the majority of cases, its use has been accompanied by that of bleeding and leeches. Then the medicine has not always succeeded, or has not succeeded till after the employment of other remedies; in which case it cannot with certainty claim the merit of success.

M. Villeneuve.—The ordinary means were employed at the commencement, and the chloruret at the decline. How it acts I know not.

M. Lonyer-Villermay.—The dose is from

half a drachm to a drachm by the mouth, and from half an ounce to two ounces by the rectum. Now the action is much the same by whichever way administered; as is also the case with sulphate of quinine and opium. It is now recommended for everything; and I fear, therefore, it will meet with the fate of creosote.

M. Marc.—I remember a Memoir on Dysentery (though I have forgotten the name of the author), in which the opinion was maintained that in that disease there was constipation; and that the matters discharged were only the product of secretion from the intestinal mucous membrane; so that whatever would restore the stools would be useful; such as the sulphate of soda. There is an analogy here; the chloruret being also a neutral salt.

Absorption of the Crystalline Lens.

M. Faure read some general and practical remarks on the absorption of the crystalline lens and its membrane, and on some peculiarities of its non-absorption after the operation of cataract. He draws the following conclusions:—

1. The crystalline deprived of its membrane is always absorbed, and much more quickly in the anterior chamber.
2. The softer and more minutely divided is the lens, the more quickly (all other circumstances being the same) does its absorption take place.
3. The lens removed from its situation, but enveloped in its entire membrane, is never completely absorbed, but loses some of its less consistent parts, and diminishes more or less in volume, and its capsule becomes thickened or wrinkled.
4. The crystalloid membrane, torn into shreds, and well detached from the hyaloid, is easily absorbed, and more quickly in the anterior chamber.
5. The shreds which remain adherent to the hyaloid membrane, at a point more or less extended, are never absorbed, whether the crystalline lens be extracted, or depressed, or broken up. These shreds sometimes even unite with the hyaloid at various points, and more or less interfere with vision.
6. The crystalline divided and well de-

tached, but engaged and retained in the pupil, as a sort of plug, sometimes gives rise to spasmodic contraction of that opening, and to a secretion of plastic matter, which prevents the entire absorption of the little plug, and thus prevents sight, but does not preclude a very strong probability of the establishment of an artificial pupil.

7. A small opening in a crystalloid membrane, containing a milky or very soft capsule, gives issue to a part of that matter, which is quickly absorbed; but if we draw out the instrument, without pursuing the operation farther, the wound in the capsule, even though a line in length may cicatrize, notwithstanding the tenuity of the membrane, and the cataract will thus present pretty nearly the same character as before.

8. The crystalline, although completely depressed and plunged in the vitreous humour (of which some cells have been destroyed, in order to allow sufficient liquid to escape, to prevent the lens being pushed up by the elasticity of the vitreous body), nevertheless sometimes rises after a longer or shorter period, especially if the capsule has not been torn into shreds. It may then irritate the iris in such a manner, that it is not uncommon to see inflammation of a serious character, or cruel neuralgia supervene, so as even to produce atrophy of the eye.

9. The anterior part of the vitreous body, which forms a sort of receptacle for the crystalline lens, is sometimes altered from its natural state, and even becomes adherent to the posterior part of the capsule. In this case, whatever mode of proceeding be adopted, we must not forget to destroy or tear up this membrane, which is sometimes very little opaque. We thus favour the swelling of the vitreous body, which is very conducive to the clearness of vision; but which we must endeavour to produce with tenderness and caution.

10. When a large quantity of the vitreous humour escapes, it may be secreted afresh; but sometimes the anterior cells are not filled again; and small opaque membranes are perceived, which are never absorbed, and which are an obstacle to vision. They are difficult to remove, and are renewed with still greater opacity.

M. Faure afterwards distinguished the cases in which, in consequence of a blow on

the eye, and the rupture of the capsule, the crystalline lens may be absorbed, from those cases in which the capsule remains entire. In the latter circumstances, the lens, if partly detached from the hyaloid membranes, becomes white and diminished in size, and offers to our view a trembling cataract, which may become detached altogether. After the operation by depression, if the crystalline (completely removed from its capsule) again rises and becomes entangled with the iris, it may cause very sharp pains, especially to those subject to rheumatism. The absorption is then suspended as completely as if the capsule still enveloped the lens. On the subject of the trembling cataract, M. Faure cautioned his hearers not to confound with it a trembling motion of the iris and the aqueous humours, which may depend on the weakened resistance of the tunics of the eye, and perhaps, also on the diminution of extent in the diameters which correspond to the attachments of the iris; both these effects being (to a more or less serious extent) the consequences of removing the lens. He is also of opinion, that a collection of purulent matter, more or less abundant, may form between the crystalline and its capsule, and never be absorbed. Perhaps, the first hyaloid membrane may be prolonged further than is generally thought, and may add to the thickness of the capsule anteriorly: if so, these abscesses may have their seat between these two tunics, instead of in the lens.

Homœopathy.

M. Turck, of Nancy, read with warmth, a kind of diffuse disquisition, in which he pretended to have the power of curing and producing the gout at pleasure; and promised to publish shortly, in a large volume, his theory, his treatment, and his success. An animated discussion followed this unacademical communication. M. Bousquet called it a prospectus, and referred to the disapprobation expressed towards M. Cancoïn, who, nevertheless, indicated pretty nearly in what his therapeutic means consisted. Upon the suggestion of M. Bouillaud, M. Turck was requested not to join in the discussion. Messrs. Maingault, Planche, Renaudin, Gimmel, and Louis, remarked more or less severely on this mode of rendering the academy a party; as it were, to the propagation

of charlatanism; and on the motion of M. Louis, they passed to the order of the day.—*Lancette Francaise.*

Typhoid Fever.

The Secretary read a letter from M. Piédagnel, in which he replied to the assertions of M. Bouillaud, respecting typhoid fever.

M. Bouillaud, when the *proces-verbal* was read, said that he should not have taken part in the discussion, if it had not attacked the method which he employs, and which he thought it his duty to defend. He had not exaggerated the success he had obtained, as would be proved by a reference to numbers. He always distinguished serious from simple cases. Results proved that in four years he had lost fewer patients by one half, than those who died under the treatment recommended by Messrs. Louis and Chomel—a method which he considered preferable to all others. M. Chomel confesses to one death in three cases. Now, in four cases, out of one hundred and eighty-one well marked cases of typhoid fever, (excluding those of simple gastric irritation and embarrassment, and even bilious fevers), M. Bouillaud had had a hundred and fifty-three cures, and twenty-eight deaths; or 2 in 8.

M. Gérardin regretted that they had not read M. Piédagnel's letter, which placed the numbers side by side, and proved that the method of M. Bouillaud had not given statistical results of a more favourable nature than those of M. Chomel. In three months, M. Piédagnel had lost only two patients out of sixty; while M. Bouillaud, in the same time, had lost two out of thirty. Besides, typhoid fevers were more or less curable, according to circumstances.

M. Louis.—It has been said that no mistake can occur in the diagnosis of typhoid fever; but the fact is, that what is typhoid fever with one, is with another, simple enteritis. The results obtained by M. Bouillaud, in four years, have not equalled mine. Out of a hundred and four patients, treated by a uniform method, only twelve died. This method consists in two bleedings, more or less copious, in the first eight days; syrup of gum in two parts of water, for drink; and a bottle of Seltzer water, daily. I will not affirm that this treatment is the best in the world; but all typhoid fevers are not

equally serious. Perhaps those of M. Bouillaud were more so than mine. I never bled but one patient after the first eight days.

M. Castel reminded the Academy that the general mortality in these fevers was one in eight.

M. Bouillaud said we ought to avoid common-places. The cases of which he had spoken, were weighed and counted; and M. Chomel had justly rated the mortality in such cases at one in three. He paid a high compliment to M. Louis's diagnostic powers in this affection; and congratulated him on having saved, by the antiphlogistic method, more patients than himself. He had also frequently used the chlorides, cinchona, musk, &c.: but it was the *general* treatment with which they had to do. An enlightened commission was necessary for the satisfactory investigation of this important subject. He was devoid of all prepossession on the subject; and it was not till after visiting all the hospitals for twenty years, and examining all the methods employed, that he had chosen one, from which his personal interest ought, perhaps, to have dissuaded him.

M. Rouchoux also wished to have an inquiry speedily instituted, and applied to typhoid fevers, what d'Alembert said of concerts; that there were never two of the same tone—the pitch varying every time. Every one knows, however, that notwithstanding the differences between one man and another, there is a uniform mass, which allows of a comparison being instituted.

Compression in Hernia.

Dr. Fournier, of Lempdes, read a memoir on the inutility of operations and medicines for the cure of hernia when not strangulated, and the curability of that affection by pressure. The author looks upon topical applications as exerting no action upon a ring, composed, not of fleshy and contractile tissue, but of aponeurosis, destitute of the power of contracting; especially when these medicines have previously to traverse a certain thickness of skin and cellular tissue. He regards therefore, as illusive, the promises of curing hernia by bandages with medicamented cushions, and topical applications; and to prove their curability by compression, refers to Lawrence's treatise; in which the author states he has found, on *post-mortem* exami-

nation, large hernial sacs entirely empty, with their necks strongly contracted, wrinkled, and adherent. Petit, Arnault, and Ambrose Paré cite analogous cases of cure; but in all these instances the cure was owing to chance.

For fifteen years past, in his publications and his practice, Dr. Fournier has proved the cure by compression (by means of a simple bandage) of the oldest and most voluminous hernias, among old men, children, &c. He cites three cases: one was that of an advocate, whose hernia was cured in fourteen days, by means of a soft bandage, the pressure of which was increased day by day; and the cure was so solid, that he was able to exercise himself in lifting and carrying heavy burdens, after having left off the bandage. He is a married man; and five years afterward he had had no relapse. A single lady, twenty-seven years of age, had been cured in twelve days, and an officer of artillery, in eight, by bandages differently combined.

LONDON MEDICAL SOCIETY.

Monday, December 7, 1835.

DR. WHITING, PRESIDENT.

Treatment of Fractures—Gonorrhœal Rheumatism.

MR. DENDY exhibited a specimen of badly united fracture, resulting from a wrong diagnosis, and treating the patient in the manner recommended by Mr. Radley. The specimen was taken from a female aged sixty-five, who had fallen down six or seven stairs, and fractured the thigh bone just below the cervix; she sent for her surgeon immediately, who could not detect any crepitus, and thought the fracture was through the neck of the bone. He said he could do nothing for her, and he adopted Mr. Radley's plan, and the consequence was, that the patient became a cripple; the affected leg was two or three inches shorter than the other; osseous union had taken place.

Mr. D. considered the crepitus could not be distinctly felt in this case, from some of the *synovial fluid* having insinuated itself between the fractured portions of the bone.

Mr. Radley had put forward his plan so decidedly before the public, that Mr. Dendy thought it was fair to comment fully upon it; he considered that Mr. Radley had only given *ex parte* statements—his own cases—and a few that he had seen treated by his friends; he objected to splints in any case; and one reason he had advanced for so doing was, that they gave pain. Now he, Mr. D., was certain that Mr. R. was reasoning from the abuse, not the use of splints: he had seen cases, and so must every surgeon, in which splints had relieved pain by prevent-

ing spasm; he was convinced there are many cases in which the attempt to procure union without the aid of splints, would be attended with deformity, and the limbs would be of little use.

Mr. Bryant thought Mr. Dendy's case could not be advanced against Mr. Radley's plan being adopted in fractures of the neck of the thigh bone; the fracture in Mr. D's case being below the trochanter minor.

Mr. ——— advocated Mr. R.'s plan, that gentlemen having only lost two patients out of a great number he had treated. Mr. Radley did not object to splints merely because they produced pain, but that when they were dispensed with, local applications were much more easily applied.

Mr. Clifton thought novelties involving the welfare of the patient to such an extent as the one in question, should be cautiously received into practice. He thought the present plan fully sufficient for all purposes; and if the splints were properly applied, lotions and other applications might be easily used; he still thought the double inclined plane the most advantageous plan in most cases.

Mr. Hooper was satisfied that splints often prevented pain; he had a patient with a fracture of the tibia and fibula; on the removal of the splints severe pains came on, though the patient was perfectly easy before; the splints were again applied, and the pain was removed. He believed the fractured portions of a bone could not be kept in apposition without splints.

Mr. Roberts, when studying at St. Bartholomew's, had seen a case of fracture of the lower ends of the tibia and fibula, in which there was great inflammation and tumefaction; the dresser left the patient without splints and applied leeches; there was excessive pain, which was not at all relieved until the following morning, when, on the application of the splints, it was entirely removed.

Mr. Cripps was at a loss to know how the application of splints could relieve pain, inflammation, and tumefaction.

Mr. Dendy wished Mr. Radley's plan might be found an effective one, for he had often great difficulty in applying splints. Apology was due to Mr. R. for the manner in which his plan had been opposed by Mr. D., and he now offered that apology. The reason why splints relieved pain was this,—they prevented spasm, and the extremities of the fractured bone from riding over one another. Mr. D. related two cases in proof of the danger attending the non-employment of splints, and in which the after application of Mr. Amesbury's apparatus was attended with favourable results.

Mr. Bryant was satisfied that in all cases of fracture, splints and bandages would not be effective in keeping the portion of bone in apposition. He did not see any reason for the hasty application of splints.

Mr. Crisp thought Mr. Radley's plan

should be tried before it was decided on. He had seen cases in the hospital which would have done as well if not better without splints.

Mr. Hughes asked the experience of the Society in rheumatism, when connected with gonorrhœa. He had seen a patient with gonorrhœa, who, after exposing himself to cold, had an attack of acute rheumatism affecting the shoulders, knees, and muscles of the back, but chiefly the small joints about the foot. It was treated as rheumatic gout, with colchicum and small doses of mercury, without effect. The patient had applied to another surgeon, who pronounced it a case of "gonorrhœal rheumatism," and ordered him to take sarsaparilla and iodine: the case had not, however, improved under this treatment, which had been carried on for a fortnight. He had been five weeks under Mr. H.'s treatment before he commenced the iodine, &c. The rheumatism came on about a week after the gonorrhœa; he had gonorrhœa at the time.

Mr. Pilcher had seen so many cases of rheumatism affecting persons labouring under gonorrhœa, that he was convinced there was some connection between them, though what that connection was he could not say; he had found the rheumatism generally affect the joints of the lower extremities; he had always treated it as common inflammatory rheumatism, by bleeding, purging, and in many cases had found colchicum very useful. Dover's powders, in small doses, was good, but the use of mercury better.

Mr. Dendy thought gonorrhœa was a predisposing cause of rheumatism; he had seen so many cases in which it was followed by that disease. Rheumatism, he believed, was now more prevalent than it had ever been, and the cases were generally of the neuralgic character; he begged to ask the president whether he had found colchicum as effective in that form of the disease as when it attacked fasciæ and tendons, and if not, what other remedy was the best? He (Mr. D.) had found colchicum fail in a number of instances.

Mr. Robarts had seen rheumatism, chiefly affecting the joints, sometimes in gonorrhœa; it generally got well very soon, but in protracted cases he had found an ointment composed of the Ung. Hyd. Fort., and Ung. Cetacei, $\text{ā ā } \frac{3}{4}$ ss, and camphor, $\frac{3}{4}$ j, of very great effect.

Mr. Headland did not doubt that there was a species of rheumatism coexistent with gonorrhœa; he had a patient who always had both the diseases at the same time; he was unfortunately very liable to contract gonorrhœa, the consequence of which was, he was now a cripple from the effects of the rheumatic affection. Rheumatism was not, however, a good definition of the disease: it differed, in many respects from rheumatism. Opposed to that disease, the swelling never bore any proportion to the pain, which

was often great; it was not generally to be cured by colchicum, which was so invaluable a medicine in common rheumatism. He had found calomel and opium the best medicine.

Dr. Whiting believed the disease totally distinct from rheumatism; the inflammation attending it was of a different character. He considered the rheumatism attending gonorrhœa a specific disease, and that the treatment must be as specific. Colchicum relieved the inflammation in these cases merely by lowering the pulse; it did not act as a specific, as it does in gout and rheumatism. Having been appealed to for his opinion respecting the treatment of rheumatism, he might say, that in rheumatism affecting the muscles, colchicum was the best remedy; in neuralgia, the antiphlogistic treatment should be adopted; and in inflammation of the joints, existing with gonorrhœa, he considered calomel and opium most efficacious.

Mr. Horn exhibited Dr. Scott's improved hydraulic patent stomach pump, and enema syringe. The Society then adjourned.

—o—

WESTMINSTER MEDICAL SOCIETY.

Saturday, Dec. 5, 1835.

DR. ADDISON, PRESIDENT.

—

Extraordinary Case of Exfoliation of the Cuticle—Combination of Sulphate of Quinine with the Alkalies—Stricture of the Sigmoid Flexure of the Colon.

MR. HALE THOMSON related the following case of remarkable desquamation of the cuticle, in a patient affected with eczema:—

Thomas Cass, a carpenter, aged 24, tall and thin, of pale complexion, deeply marked with the cicatrices of the small-pox pustules, was admitted November the 17th, into the Westminster Hospital. The surface of the body in various places presents the cuticle in a state of desquamation, especially the thighs, the mammillæ, and the soles of the feet, in which latter situation this process is in the least advanced stage. The palm or surfaces of the hands and fingers have only recently parted with their cuticle, and are extremely red and tender; the fingers especially are studded with very minute drops of perspired fluid; the appetite is good, and bowels regular; tongue reddish, and slightly furred; pulse 84, of moderate force; general feeling of malaise in the chest, accompanied with a feeling of trembling and fluttering. By auscultation, an increased impulse of the heart's action is detected. The history of the case is the following: about six years since, had the small-pox very severely after vaccination; the left eye became opaque from a pustule forming on the cornea. After this he remained well during four years. An eruption now appeared all over the body, of minute vesicles (or as the patient terms them, pustules) as large as pin's heads; the intermediate portion of the integument

deep red, the red rash preceding the vesicles by a day or two. There was severe pain, burning heat, and great itching; these symptoms likewise succeeded the development of the eruption. The vesicles, in the course of a short time ran into each other, broke, or were ruptured by scratching, and discharged a watery fluid: the whole course of the affection occupied about six weeks, and its termination appears to have been in a moist desquamation of the cuticle. Preceding, and attending the local affection, there was considerable general disturbance of the functions; pain in the head; dazzling light before the eyes; slight delirium; uneasiness in the chest, with a distressing feeling of oppression and beating all over it; tongue very much furred, rough, and white; appetite but little affected, and no thirst; urine scanty, and high coloured; no sore throat. Twelve months after this he had a second attack, precisely similar in its course, symptoms, and termination. Six months had scarcely elapsed, when five months ago, he had a third attack; this he describes to have been preceded as in the other instances, by pricking and tingling of the skin, attended with a burning pain, followed by a general feeling of coldness all over the body. He did not take, as before, powerful sweating medicines. The affection returns at intervals of about a month or seven weeks: this is the third attack. On the 22nd, he went to bed as usual, but being restless, five grains of the pil. sapo. c. opio were given him: he complained in the morning of pain in the head, and he had a rigor; and a uniformly red rash came out about the neck, which, before morning, had invaded every portion of the body; he was bled twice, and opiates and salines given him. He continued to the 24th, with opiates, saline effervescing mixtures, with diuretics, and purgative doses every alternate morning. On that day Mr. White saw him, and prescribed a mixture, containing the following ingredients, as he thought he perceived a periodicity about the disease.

R. Quinina sulph. gr. xvj;
 Pul. gum Acaciae ʒji;
 Liq. arsenicalis, m. xlviij;
 Aq. puræ, ʒ viij.

M. ʒ i. ter die, to be continued for four days.

This treatment had not the expected effect, and the former plan was returned to this morning. Mr. Thomson wished to know if the disease could be termed eczema, and if so, in what class it might be appropriately placed. The patient had not, in any of the attacks, shed his nails, but on the contrary, they seemed to grow; and now showed marks on them of the three different attacks. His hair falls off, leaving an abundant scurf, attended with a disagreeable odour. The desquamation began when the vesicles first presented themselves on the shoulder and about the axilla, but he looked upon the

novelty of the case, as consisting in the periodicity of its character.

Dr. Copland inquired what decomposition would take place in the mixture prescribed by Mr. White; he understood there was pain in the epigastrium; most likely there was some degree of gastro-enteritis, and he thought it likely to be increased by that medicine.

Mr. Hale Thomson said, there was no tenderness at the epigastrium; he could not say what was the decomposition resulting from a mixture of the sulphate of quinine and the liquor arsenicalis; he had often used the medicines, so combined, and found them useful.

The President thought Willan and Bateman had accurately described this form of eczema under the title of *E. rubum*—they mentioned periodicity as one of the characteristics of the disease; though no vesicles in this case had been observed, he thought they might have been so minute as to be almost imperceptible. He had found the liquor arsenicalis the best medicine in eczema.

Mr. Thurnam contended there were no vesicles present—there was merely redness, ending in desquamation. He thought Rayer's division of eczema, into acute and chronic, much better than the varieties of the disease given by Willan. In answer to a question, Mr. T. said those parts of the cuticle which were thinnest exfoliated first—not those exposed to the atmosphere.

Mr. Hale Thomson thought Rayer's division of eczema into acute and chronic the best. Willan and Bateman dwelt particularly on vesication—there was none in this case, where the skin desquamated chiefly, but simply inflammation; the desquamation was not influenced by atmosphere, the last portion of cuticle that came away being from the heel, and that was accompanied with a portion of the previous exfoliation.

Some conversation now took place with regard to the effect of the alkalies when mixed with quinine. Dr. Johnson had often ordered them with great benefit—there was no sensible decomposition, and the properties of the quinine did not appear to be affected. Liquor potassæ, however, was an exception, for it formed, with sulphate of quinine, a substance of the consistence of putty.

Dr. Copland maintained that the sulphate of quinine was decomposed by the liquor potassæ; it must also be affected by the carbonate; he believed the two fixed alkalies both decomposed it; he knew ammonia did, and thought the same might be said of magnesia.

Dr. Johnson had not been in the habit of combining magnesia with quinine, therefore, could not speak as to the result.

The specimens of the exfoliated cuticle brought by Mr. Thomson were sent round for inspection—they were perfectly unique-looking, like beautifully worked transparent gloves; here the subject dropped, and

Mr. Salmon was requested to favour the Society with a history of a remarkable case

of disease of the colon—a specimen of which was on the table. Mr. S. said the specimen was removed from a lady, aged 60, whose general health had been good; but she had been subject to great costiveness. When Mr. S. was called in to the case, there had been no evacuation for three weeks and three days, and there was none during his attendance, which lasted two weeks more. The physician who had called him in considered it to be a case of ileus, and supposed, from the long continuance of the constipation, that some mechanical obstruction existed; there was not the least desire, on the part of the patient, to relieve the bowels—an important fact, with regard to the opinions he (Mr. S.) had advanced on the functions of the rectum. For the purpose of examining the intestine, a tube two feet long was employed, when a stricture was found to exist fifteen inches up, at the sigmoid flexure of the colon: the means employed for relief failed, and the patient died. Mr. S. believes that had proper means been resorted to in the commencement of the disease, the patient's life would have been prolonged. After death, the collection of hardened feces in the colon filled three large chamber utensils; the colon was of course immensely distended, its ascending portion being 13 inches in circumference, the caput coli 14, whilst the strictured portion was only $1\frac{1}{4}$ inches. Its coats had become exceedingly thin. Mr. Salmon said this was a case proving the possibility of detecting stricture when situated as high up as the sigmoid flexure; and that an instrument might be passed higher up the bowel than where it was usually supposed stricture could exist. A very long discussion followed with respect to the safety of using bougies of great length in strictures of the rectum, and as to the possibility of detecting a stricture from a natural obstruction resulting from some angle of the bowel. It was contended, on one side, that no rules could be laid down for the introduction of the instrument, and that it was mere chance where it went to; that if the bougie were of very soft consistence, it would turn back upon itself; and if hard, would be attended with much danger. Mr. Salmon said, that experience alone could be relied on in the employment of the rectum bougie; he had used it in at least 20,000 cases without any ill effects resulting from it. His bougies were constructed like the common elastic urethral bougie, but contained 9-10ths more bees' wax; he made them rather soft by a heat beyond that of the blood, before introduction; they cooled and became hard in the intestine, and moulded themselves to the stricture. He contended bougies might be used with perfect safety.

We have not space to give the discussion in full—should we have room next week we may probably do so.

BOOKS.

Elements of Bedside Medicine and General Pathology or General Disease, with a sketch of the Origin, Progress, and Prospects of Clinical Medicine and Surgery, followed by an exposition of the Creeds of Medical Materialism and Vitalism, and a Confession of Mixed Medical Faith: entitled, Vegetable, Brute, and Human Organizationism, &c. &c., the whole chiefly grounded on a digested range of select analytical and condensed translations, with eductions from the writings of standard authors, French and British, By J. Stewart Thorburn, M.D. 8vo. pp. 473. London. 1836.

A Practical Treatise on Midwifery, containing the Result of Sixteen Thousand Six Hundred and Fifty-four Births, occurring in the Dublin Lying-in Hospital, during a period of Seven Years, commencing November, 1826. By Robert Collins, M.D. late Master of the Institution. 8vo. pp. 526. London. 1835.

The Cyclopædia of Anatomy and Physiology. Edited by Robert B. Todd, M.D., Lecturer on Anatomy and Physiology at the Westminster School of Medicine, Physician to the Western Dispensary, and to the Royal Infirmary for Children, &c., &c. Part IV. Illustrated with numerous Engravings. London. December, 1835.

The present number of this work excels, if possible, those that preceded it.

Education Physique des Jeunes Filles, ou Hygiène de la Femme avant le Mariage. Par A. M. Bureau de Reofrey, M.D., &c. 8vo. pp. 352. Paris and London. 1835.

This is a sensible, well written work, and well worthy of the attention of the general and medical reader. There are some points on which we do not agree with him, but great allowance is to be made for a foreigner who has taken up his abode amongst us.

—o—

CORRESPONDENTS.

—o—

A Liverpool Correspondent.—We shall notice the work as early as possible.

A Brighton Friend, A Manchester Subscriber from the beginning, An Edinburgh Subscriber, &c., &c., are informed that the Lectures will be commenced so soon as the plates are engraved, which are now being done. This series of plates will be the most extensive and best executed ever published, on the subject, in this country. If our subscribers support us, we may give one every week, or alternately with the Medical Botany. We pledge ourselves to fulfil the promise; and we assure our friends that we have incurred very great expense in the undertaking.

Communications have been received from Dr. Hunter Lane, Dr. Bardsley, Mr. Stevenson, A Foreigner, and others.

SELECT LECTURES,

LECTURE XXVII.

*Prognosis and Treatment of Chronic Gastro-
intestinal Inflammations—continued.*

3. Of the symptoms. You should learn to distinguish between those which afford hope, those which diminish it, and those which give none. About one of them—great appetite—a great noise has been made, but it does not frighten me; on the contrary, I consider the continuance of the appetite as a favourable sign, or, at least, one that should cause no alarm in chronic gastritis and enteritis, even when it reaches the degree of bulimia. This bulimia may be subdued by bleeding, and mucilaginous drinks, with low diet. I prefer it as a symptom to anorexia, which is a bad sign. Loss of appetite is frequently an announcement of some thinning of the coats of the great sac, or of its softening, particularly when it supervenes at an advanced stage, or when the mouth is always in bad condition, and filled with fetid, nauseous, and viscid saliva. In such case the disease is rarely curable. If to these symptoms are joined redness, and bleeding of the gums, caries of the teeth, uncertain sight or blindness, it is impossible to recover the patients: I never saw any one recover after these symptoms had lasted more than three days. Some patients remain in this state as long as three weeks, without drinking, or eating, and quite blind. Phenomena like these, shew you the activity of the sympathies, on which ill-judging people have attempted to heap ridicule. When the stomach is softened and almost perforated in chronic gastritis, the patient is unable to swallow any thing, notwithstanding the efforts of his entire will. I remember having to see a lady with two of my brethren: she had lost her sight, and was unable to swallow. It was proposed to introduce a sound by the

œsophagus, and pass food into the stomach. I remarked upon the danger of such an attempt, stating, that there was, probably, not more than a thin layer of peritoneum to form the great sac, and that the patient might die during the attempt; and I advised that she should be supported by gelatinous and farinaceous clysters. She died a few days after, and we found a spot in the stomach as large as the hand, without the slightest appearance of mucous or muscular membranes. A minute cellulo-serous net, almost as thin as spider's web, was all that remained, and it yielded when slightly touched. Had anything been forcibly introduced into the lady's stomach, when alive, she would assuredly have died on the spot.

The most dangerous symptoms, therefore, in chronic gastritis are unpleasant salivation, loss of sight, and inability to swallow. Yet, if these symptoms appear, after some excesses in a person that has not passed through all the stages of the chronic condition, it is sometimes possible to do away with them. Of this I have an instance in point at this very time: I had augured badly of the case, and I am glad to say that I augured erroneously.

Vomiting is a bad sign, in as much as it indicates an intense irritation of the stomach, as well as a nervous condition. As nervous phenomena are apt to become habitual, the vomiting may continue, and is then difficult to overcome. But we must not look to this symptom alone; for there are some who, having gastritis, and merely thinking of anything disgusting, are subject to emesis: such persons are particularly liable to obstinate vomiting, when they have gastric irritations. You must then refer to other signs: if the redness of the mouth, tongue, and larynx be not very intense, if the epigastrium is not sensitive, the pulse rather slow than rapid, if there is not very strong pulsation of the celiac, or any of its main branches at the epigastrium (remark that these pulsations are important, and should be examined with the stethoscope, so as not to be confounded with those of the heart, which are double, or with those of the aorta, which are cylindrical, or elongated), if vomiting is present without all these signs, it indicates no

great degree of irritation, and, therefore, no danger. Sometimes it suddenly disappears when least expected, in consequence of some moral affections, some change of beverage, a piece of bread, or some new kind of food which the patient has taken. Some one will say that it is a deceptive symptom; but let us be precise—vomiting may be, but it is not always a symptom of gastritis; sometimes it is only a convulsive movement remaining in the stomach subsequent to inflammation. We have only to distinguish cases, and this is not done by those whose judgment is only grounded on words, and who are rather engaged in the act of contradicting, than with the desire of improvement. If the symptom in question be joined with epigastric arterial pulsation, redness of the tongue and mouth, frequency of pulse, &c. it is dangerous, and indicates inflammation; if it stands alone, it is of slight consequence. If it persists, with bad symptoms, and brings the patient down to marasmus, with inability to swallow, and derangement of the intellectual and visceral functions, there can be no doubt of approaching death. At this period the skin is strewed with red patches, and spotted with petechiæ; the patient is extremely feeble, and cannot move without having nausea. When vomiting is conjoined with the positive signs of a scirrhus state, it is still more fatal in aspect; in that case the phlegmasia almost invariably becomes general in the digestive canal one or two days before death, and the pulse becomes frequent.

When a man that has gastritis, with slow pulse—forty or forty-five beats in a minute—diminution of external temperature, and concentration of heat internally, suddenly has an acceleration of circulation, and return, or increase of heat of the skin, it is favourable, provided the disease has not been too long in existence.

When, upon being bled, the pulse of a patient that has a concentration of blood in the stomach, with vomiting and twisting colics, without fever, rises in frequency at the same time that the heat of the skin returns, it is a good sign.

But when this acceleration of pulse and elevation of temperature occurs in an individual that is exhausted by a long standing chronic state, which you have been unable to relieve, they indicate a generalization of the phlegmasia, or a peritonitis, or the development of pulmonary inflammation. In such instances the gastric sensibility is extreme, and adds powerfully in exhausting the nervous power of the patient.

If an individual with chronic gastritis and duodenitis combined with constipation, becomes purged, it is difficult to give an opinion on him. Should this happen in the onset, in consequence of antiphlogistic treatment, the malaise at the same time diminishing, good; but if the same does not occur until a very late period, in one who has not been

well cared for, whatever means you may have employed, bad: the diarrhœa soon takes from him his remaining strength, and he dies in a deplorable condition, sometimes infiltrated and distended by effusions.

In chronic duodenitis, when the symptoms of depravation or suppression of bile, before mentioned, are seen, our hope must be less sanguine. The causes of this suppression must, however, be sought for. Not long ago, I was consulted by a brother medical man who had had chronic duodenitis, with constipation and decoloration of the fæces, for two months: at first he was able to eat tolerably well, but latterly, deterred by the pain caused by food, he gave it up altogether. I told him that if he did not take at least some light aliment, his liver would fall into complete inaction, and lose the habit of secreting bile, and that his health would break down, daily without the possibility of re-establishing it. He took my advice and got round. This suppression of bile may be produced in another manner, which I shall afterwards point out.

In the same kind of duodenitis, when the patient is constipated, his complexion waxy, his strength gone, and he can no longer bear food, or be nourished: when his motions are no longer coloured with bile, but white and earthy, and his liver enlarged, it may be presumed that that viscus is affected consecutively on the duodenitis, that it will be unable to renew its function, and that the patient is on the high road to cachexy and marasmus.

Enlargement of the liver, joined or not to constipation and decoloration of the fæces, in one labouring under a recent attack of chronic duodenitis, whose complexion is still good, and who is in good state of nourishment, may be dissipated by means of antiphlogistics: but when the enlargement, constipation, and fæcal decoloration is accompanied with incipient dropsy in patients who have had relapses, and have been treated improperly, there is rarely any hope of recovering them: all we can do is to keep them alive for some time with an ill-conditioned digestive canal, prolong their existence eight or ten years, but anything like constitutional vigour they never recover.

As regards the chronic inflammations of the small intestines, you cannot answer for the cure so long as you feel hardness, tightness, and persistent sensibility in any portion of the mid-belly. An individual may have had a sensitive point in some portion of the small intestines which he has neglected, and at a time when he least thinks of it, he shall discover a tumour in the spot. This tumour may increase with varied rapidity. How often have I not seen this, even in medical men, who having abandoned the physiological treatment, and tired of low diet and a slow cure, had had recourse to stimulants! For some time these masked their sufferings, and they thought themselves cured, when

all at once, the pains returned, and they lighted on a tumour. The slowness and insidiousness with which tumours of this kind form, are owing to the fact, that the cellular and glandular tissues of the abdomen are not in immediate contact with the stimulants, are not the first to be affected, and to the necessity which there is of long stimulation of the corresponding mucous membrane previous to the development of indurations in those tissues. So long, however, as their size does not increase, there is hope of their resolution; but when they have attained a certain volume, it is no longer possible—they go on increasing, or remain stationary. Patients may certainly live with a mesenteric, or cellular, or epiploic tumour situated behind or before the intestinal tube, but they will be subject to colics, to painful digestions, uncertain health, and also to the symptoms of hypochondriacism.

When the inflammation occupies the lower portion of the small intestines, and has not passed the ileo-cæcal valve, there is always a tumefaction and lancinating pain in the direction of the valve, at certain periods of digestion. You know how abundant lymphatics are there, and then it is that indurations most readily form. So long as the inflammation does not exceed the valve, the patients are constipated, tortured with flatulence and borborygmi, and have a yellowish complexion, for the biliary secretion is changed, and the liver in a state of lesion. Indeed, it is a general law, that organs which do not act become deteriorated: if you refrain from chewing for a certain time, your gums will become so; if you eat not, your stomach will be so: all organs intended to be stimulated, or to act after some manner—and none is free from this liability—ought to be exposed to a certain degree of stimulation in order to their preservation. Thus the liver, which ceases to act in consequence of a gastro-duodenitis, or a jejuno-ileitis becomes deteriorated, and you would be wrong to look upon such deterioration as corresponding to duodenitis alone, for it may correspond with all the affections that derange the digestion, and prevent the biliary secretion.

If chronic inflammation has passed the valve, and you have an irregular diarrhœa, with pains of the belly, and a tumour, the case is serious, and the danger is much more commensurate with the size and progress of the tumour than with the pain. The latter, indeed, will scarcely suffice to guide you in ascertaining the exact seat of the disorder, in as much as visceral pains are often referred to the median line; a fact, the reason for the omission of which in pathology, I cannot imagine. So also in bronchitis, the pain is referred to the same line, except when the irritation predominates laterally in the pleura or the substance of the lungs. The same is observed in affections of the heart. Yet the stomach appears to be an exception,

and why? because it has a particular nervous system, and its sensibility is less obtuse than in the other regions of the digestive canal: notwithstanding which, do not place too much faith in its perceptions. Rather, in ascertaining the irritated point, refer to the manner in which it performs its functions, to the deglutition, to the sympathetic phenomena caused by the sojourn of aliments in it, and to what occurs when they pass out of it—all which is more certain than the evidence of the patient.

A large tumour of the right iliac region with difficult defecation is more serious than in the left iliac fossa, or in the sigmoid flexure. In the majority of instances, the physician can only partially relieve the patient, and put off for a time the fatal event.

Contractions of the lower portion vary in situation, and are distinguished from each other by the following signs:—when they are in the left side, the matters are voided with colics and efforts, whilst on the right side, in the iliac fossa, or ileo-cæcal valve, there is no effort, but only colics during the passage of the matters through the diseased part. In the latter case, the fæces are fluid, fetid, mixed with mucous secretions, bile, and a residue of chyle; whereas in the former they are less diluted, thready, and only make their exit immediately after the colics, and during the efforts: above the contracted point or obstacle, an increased volume and hardness, round which the abdominal muscles contract, is observed.

Such are the signs that announce the formations of these contractions. Generally the patient begins by being unable to retain the fæces, and has diarrhœa: subsequently he is constipated, and whenever he has a motion, is obliged to make considerable efforts: he has the sensation as if the matters were traversing a hot and burning passage, and there is shooting pain of the anus. If he be examined previous to the want of passing the excrements, the latter are found collected above the obstacle; when he is about to pass them, pains are experienced, then come contractions and efforts, during which, if the patient is emaciated, you may see the contractile movements of the intestines; the matters come out sometimes fluid, sometimes strangulated and more consistent. After their evacuation there is sometimes tenesmus and sanguinolent glary matters that have no fecal odour, and which proceed from the rectum below the contraction. The patient is sometimes a whole fortnight without passing by the anus anything that resembles excrement, in which case there can be no doubt of the disease, and it only remains to ascertain the point of contraction, for which purpose you employ feeling, percussion, and actual touch. Its most frequent situation is in the sigmoid flexure, but is sometimes lower down, near the anus, when it is more tractable. Above all, observe well the moulding of the abdo-

minimal muscles upon the knotty parts of the intestine.

A word on the neuropathic conditions of chronic gastro-intestinal inflammations. When such condition depends on this inflammation—for it may be owing to other causes—it indicates only a slight degree of intensity of the latter: nor is it a bad sign. If the proper means be persevered in, it disappears with the irritability of the digestive canal; or if an acute attack supervenes, it also disappears. Hence it is that you read in authors of hypochondriacism having been cured by fever and acute disorders, a manner of speech that indicates the fact to which I am alluding, only you must understand that the neuropathic state is cured by the dissipation of the chronic condition by the acute stage.

Treatment of Chronic Gastro-enteritis.—

We have seen that there are several degrees of inflammation of the stomach—the general inflammatory state, in which there is anorexia, or such excessive pain on eating as to render patients fearful of taking food, and a minor degree, in which they eat with *gusto*, but suffer during digestion.

In the former degree low diet is necessary. Then, as there is imminence of the acute state, antiphlogistics, and especially topical bleedings, are indicated. This chronic gastritis often commences with that irritation of the stomach that is called gastric disorder, which, when badly treated, may not perhaps pass into the acute state, but after being opposed by emetics may be continued under the form of gastritis with hypochondriacism: the treatment, however, is the same. You hear people say that this gastric disorder will yield to emetics alone: it is false—thousands of observations prove the contrary, and I cannot imagine the impudence that has caused such an assertion to be put in print. In my time I have used emetics, and I gave them up because I discovered the mischief they do. Those who assert that I have only employed, and do only employ, leeches and gum water, have no respect for the truth, and are calumniators: they give me ideas that I have never sent forth, and, in order to make me as absurd as themselves, they make me deny facts. I know as well as they do that a slight irritation sometimes yields to stimulants—I have seen it in external organs: but I maintain and repeat, that though an irritation does yield to stimulants it is not the less an irritation. Whether you cure a gonorrhœa or ophthalmia with emollients or astringents, an erysipelas with a blister or with leeches, these are not the less inflammatory. Those who maintain the contrary must have given up all logical reasoning, or be intent upon abusing superficial minds. They are astonished to see me refer so many diseases to irritation!—but am I building up a theory, or laying down certain facts? Besides, why are they not

also astonished to behold so many physical phenomena explained by attraction, so many chemical phenomena referred to affinity, and both these forces even condensed into one? Why should not a series of facts in medicine be referred to irritation? Should it not rather excite our admiration of nature, that, by one simple means, produces so many and so various effects, exhibiting the wonderful sight of an organized machine obedient to a small number of laws? Should it not be a consolation to him who is striving to relieve humanity? But they will none of this—they will only hold by gastric disorder as independent of irritation. Ask them what this means, they will tell you that something is collected in the stomach, that the patients have a bitter mouth, mucous tongue, headach, &c., and that this something is only urable by emetics. Here is another falsehood—I tell you again, it is better cured by antiphlogistics.

As to the asinine objection, that I see nothing but irritation in diseases, you may learn my thoughts on this point by reading the third lecture of this course. I never advanced any such thing—it is the old trick of printing what I never uttered. Mark what I say to-day—to-morrow you will see the exact contrary in some journal.

Gastritis of a slight shade may be treated and cured in different ways, by emetics and purgatives, by leeches and mild drinks: but the antiphlogistic treatment is preferable, because it is more rational and cures both more surely and more rapidly, even in the supposed cases of gastric disorder. That is my proposition.

When gastritis is of a shade that allows of appetite and a commencing digestion, but one accompanied with pain, the seat of this pain must be sought for, and when you have discovered it, practise topical bleeding. In saying that this bleeding will be efficacious, I advance a fact: in saying that if you place leeches on the portion of skin immediately corresponding to the irritated part, you will have a darker coloured blood than at the distance of an inch from it, I advance another fact, and not an idea *à priori*. If blood comes on you apply cupping glasses on the part, then poultices, then cupping glasses again, if necessary. In this manner you get rid of circumscribed irritations both of the cardia, the pylorus, and the great sac. You must then insist for some time on a mild diet. You succeed if the stomach has not been ruined by polypharmics, who see forty diseases in one, and have as many remedies against it, who pass the entire contents of an apothecary's shop through the stomach, and adjust a drug to a symptom like a hair to a hole. If you come after that race of people you have plenty to do: a long time is required for the cure, and not unfrequently you are not able at all to effect it, unless your own confidence in your remedies is strong, and that of your patient

in you is equally so. The most difficult cases you meet, are those that are consequent on acute diseases: that have been treated by stimulants and tonics; for patients so treated do not always die—nature will not allow them all to be killed; when she is too much tormented in the visceral centres, she flies by another route, and critical discharges come to her aid; but the super-irritated organs remain for a long time out of order, and sometimes do not get round at all. This method, essentially bad in the present case, ought to be restrained but not proscribed. It is false to say that we never make use of it, and that we confine ourselves to leeches, and gummy and mucilaginous substances. I profess that these latter means are fit for recent diseases, but that when they are of very long date, and reduced as much as possible, stimulation becomes supportable, or even sometimes necessary, either directly to change the vicious mode of vitality, or indirectly to turn it aside. A great length of time is sometimes required for the cure of gastric irritations caused by stimulants, to which a neuropathic condition is often joined. Mild drinks are then proper, but not all in the same degree—they should be chosen: one person bears acids, another mucilaginous, another feculent, and a fourth gummy substances. Some will only bear water. Most commonly patients prefer cold drink, but after some time their drink should be warm. Phlegmasia sometimes exists in different degrees in the same stomach, and requires various modifications. The greater part of the organ is sometimes uninfamed and relaxed, at the same time that a spot remains where irritation persists; the difficulty is to root out this remnant of irritation. It is pretty readily done by fasting and emollients in the first instance, and then by mild aliments, baths, &c. it may be so far reduced that in order to exasperate it the employment of stimulants for some time is requisite. It is this latitude of stimulation that puts the stimulants at ease, and gives them power over their patients, who are at first relieved by stimulants, become cheerful, get rid of languor, and the tedious process of the antiphlogistic regimen, not foreseeing, meantime, the relapse that awaits them. It must also be allowed that they sometimes recover by these means. Then comes a glorious text, and opportunity for the sophisms and declamations of our contradictors; they have gathered all the laurels and advantages of a cure prepared and almost perfected by the physiological physician that preceded them, and in return, they abuse him. This happiness, however, is not always theirs; more frequently, and almost invariably, they obtain relief for a few weeks, or months only, and the patients become worse than ever. If you doubt this, I do not doubt that experience will one day teach you its truth.

After having treated a partial gastritis, and got rid of the sensibility that existed, if the

patient strongly desires to take food, yield only gradually, and do not pass from one extreme to the other by the sudden administration of tonics and wine. Gradually increase the food, and at the same time produce external revulsion by means of frictions with irritants that cause eruptions, pustules, or even suppurations: prescribe country air, moderate exercise, occasional baths, constant warmth of the surface, particularly of the extremities, change of locality, &c.

If the sensibility of the stomach is excessive, should we immediately give opium? No. Should it always be prescribed? No. When the antiphlogistic treatment has been continued for a sufficient length of time, that is say, when the tongue is pale, the skin colourless, without morbid heat, or rather tendency to cold, you may administer it. Lest you should be deceived, do not at first give it internally, but by the endermic method—an eighth of a grain of acetate of morphia sprinkled over a small blistered surface.

After antiphlogistics and narcotics have been unsuccessfully employed, if you have reason to fear (the patient being of a lymphatic temperament) that some point is scirrhus or ulcerated, have recourse to suppurative revulsion; establish several cauteries and setons.

I return to a precept above laid down in a general manner, into some details of which it is requisite to enter. I said, above all use the antiphlogistic treatment: this should be done in a reasonable way. If the inflammatory condition of the stomach is general, you apply leeches to the epigastrium, and the number of them should vary. In a good clinical course, you may learn to proportion the number of leeches to the powers of the patient: to an adult who has not yet undergone treatment, we apply thirty or forty: if he has suffered much from sickness, only twenty; one, two, or three suffice for a child; ten to fifteen for a female. Sometimes, when the patient has had several relapses, you proceed by epicrasis: you first apply two or three leeches daily, and then increase them, always looking closely to their effects. If the patients are nervous, have but little blood, if the leeches irritate them and produce malaise, wait a couple of days before you return to them: these symptoms frequently disappear, and the leeches are then as beneficial as ever. Possibly they may persist, for some persons make blood with difficulty, and these losses of blood throw them into a state of excessive nervous irritability: we are then obliged to give up leeches, and have recourse to other means; to the mildest emollients and anodynes.

Supposing you have contrived to bring your patient into eating order, but that disagreeable symptoms recur after each meal, that the digestions are laborious, accompanied with pyrosis, gastralgia, cramps of

the stomach, pains proceeding to the loins, ribs, shoulders, and liver, symptoms of hypochondriacism, flatulence, restlessness, flushings of the face, sombre and melancholy feelings, &c.—what should you do? The remedy is very simple, too simple to have been the last thought of: at the end of two hours and a half or three hours of digestion, when the chymous mass is nearly formed, give water in small quantities, at short intervals, small doses to weak and larger doses to strong persons. You must give it by spoonful, alone or sugared, to delicate, pale, and feeble individuals, who have lost blood: such persons do not very well bear aqueous fluids, though it is absolutely necessary they should have them. This, however, is the case with by far the smaller number of patients; the majority of them have a vehement desire for them. You therefore, at the time stated, pour into the stomach a refreshing fluid that calms it, does away with the spasm of the pylorus, the pain of the cardia or great sac, and the stomach evacuates its contents with infinitely less disturbance. This simple precaution has cured thousands of gastritis. Do not believe that by giving tonics the stomach will digest better; on the contrary, it will digest worse, and will even cease its function altogether. Still, however, it requires nutritive substances, and will not digest watery and herbaceous vegetables alone, which contain but little alible particles.

This aqueous beverage, to be taken towards the close of digestion, may be either lemonade, or simple water, or sugared water, mucilaginous infusion, gooseberry juice in water, or a mild syrup, in short, any light and refreshing drink, according to the patient's taste: this is to be taken in small quantities at once, and the whole quantity taken to be something less than that of the chyme. It ought to be just sufficient to calm the irritation arising from the labour of digestion, and not so much as to drown the chyle. A physician who had left the country to establish himself in Paris, having contracted a gastro-duodenitis in consequence of some corroding vexations and *arbitrary acts** of which he had been the victim, had undergone a very severe antiphlogistic treatment, and could bear no more bleeding. With considerable difficulty he had contrived to recommence eating, and on the approach of the third hour of digestion he suffered exceedingly, and could not tell what to do. I advised him to drink a small quantity of water at the close of each digestion; he did so, and in a fortnight was well. I tell you again, water should be taken in small quantity†, otherwise it will

disturb instead of assisting digestion. And so of all our remedies—they should be, in the first place, well chosen, and then used in proper time, place, and quantity; in this the practice I teach essentially consists—in the most appropriate employment of modifying agents: I reject none, I apply them all, but in fit time, in an appropriate way, and in the most beneficial quantities. Foul criticism of such a system is in bad taste, and ridicule of it is little less than criminal, for it is ill placed in so serious a subject as the recovery of man's health.

LECTURES ON THE PHYSICAL EDUCATION AND DIS- EASES OF INFANTS, FROM BIRTH TO PUBERTY.

BY DR. RYAN.

*Delivered at the Medical School, Westminster
Dispensary, Gerrard Street, Soho;
Session 1834-35.*

LECTURE LIV.

Development and Intra-uterine Diseases of the Organs of Locomotion, or Osseous and Muscular Apparatuses—Intra-uterine Diseases of the Lymphatic System—Development and Diseases of the Organs of the Senses—Vices of Conformation and Diseases of the Eye.

Diseases of the Organs of Locomotion.—It is necessary to refer to the development of the extremities before I allude to their vices of conformation. The extremities begin to appear about a month or six weeks after conception, in the form of small salient points, which are flattened on the sides. The superior limbs are developed before the inferior, and both are manifest at the end of

late Mr. Abernethy, who also recommended water two or three hours after meals, but in large draughts. In a late visit to Liverpool, my very learned and excellent friend, Dr. Carson, of that town, told me that he had seen the best effects in cases of distressing digestion, from the copious employment of water during meals, and that he was in the habit of advising it in all such cases: "I set the food floating in water," was his expression. My own experience certainly rather coincides with that of M. Broussais than Dr. Carson. Should this meet the eye of the latter gentleman, he may perhaps be induced to give the profession the results of his experience in this matter: his reasons for the particular practice are doubtlessly good, and I, of all others, have the least reason to question it, recollecting as I gratefully do, the consummate skill, attention, and kindness that he exercised in rescuing me from a frightful attack of illness some years ago.—J. M. G.

* Italics are used in the original: the expression has probably reference to some acts of the French Government, acts that too frequently deserve the adjective above employed.—J. M. G.

† This precept runs counter to that of the

the eighth week. The vices of conformation of the extremities are very numerous. The limbs may be entirely absent, or deformed in every part; they have been divided, or amputated, fractured, and luxated during intra-uterine life.

Haller cites numerous cases of absence of one or many members, of both arms and legs, or of some portion of one or both extremities. He also records supernumerary members on one body. (*Opera Minora—De Monstris*). Dr. Montgomery, of Dublin, and Mr. West, of Allsop, have related cases of amputation of the lower extremities in the uterus. The former very politely shewed me a fœtus in his museum, the inferior part of whose leg was considerably compressed by a band formed by organized coagulable lymph. An infant was born at the Maternity of Paris, whose arm was amputated and cicatrized, and the separated portion was implanted on the surface of the placenta. M. Chaussier thought that this kind of amputation was caused by gangrene, but Dr. Montgomery's explanation appears much more satisfactory.

Mr. Atkinson relates a case of an infant born with one lower extremity amputated and the stump cicatrized; and he found the foot in the vagina. He attended the parturition of this infant in December, 1824. (*Lond. Med. and Phys. Journ.* 1825).

The fœtal extremities are sometimes luxated during intra-uterine life. M. Chaussier saw a fœtus whose two legs, knees, feet, and three fingers of the left hand were luxated. MM. Dupuytren and Billard describe spontaneous luxations of the thigh bone in very young infants. (*Mem. sur un déplacement originel ou congenital des femures*. Par M. Baron Dupuytren—*Repertoire du Anatomie*, t. 2).

M. Chaussier has also described fractures of most of the bones of the fœtus during intra-uterine life. M. Devergie reported to the Royal Academy of Medicine, in Feb. 1825, a case of intra-uterine fracture which occurred at the sixth month, in consequence of the woman having fallen on her abdomen against the corner of a table. The pain was at first excessively acute, but gradually abated. She was delivered at the full time, of a healthy infant, which presented a large tumour in the region of the left clavicle. It died on the eighth day after birth, and, on examining the body, the clavicle was found fractured; the broken pieces rested on each other, and were united by a large callus, which formed the tumour already described. (*Archives Gen. de Med.* 1825, t. vii). This case proves that the clavicle of a fœtus in the womb, at the sixth month of pregnancy, may be fractured by a fall or blow on the abdomen of the mother, and that it may be consolidated before parturition.

The following case is related in a German journal, by Dr. Carus, and published in the *Archives Generales de Medecine*, 1828:—A young woman, aged 25 years, of a good

constitution, and in the sixth month of pregnancy, fell upon the abdomen, and she felt the infant violently shaken, but its movements very soon ceased. She was delivered at the full time of a very feeble infant, which appeared to be dying, and on whose right leg was a wound nine lines in length. The edges of this wound were pale and flaccid—it extended from one ankle to the other—and affected the skin and muscles. The tibia was fractured, its body was separated from the inferior epiphysis, and the periosteum was destroyed. The whole of the diseased parts presented a most unfavourable aspect. Attempts were made to adjust the fracture, but the wound sphacelated, and necrosis supervened. The disease extended rapidly, and the infant died on the third day. It is therefore evident, from this case, that a disease may be inflicted on the fœtus while in utero, which may speedily destroy life after birth.

The preceding observations also attest the fact, that blows or injuries inflicted on the abdomen of a pregnant woman may fracture the bones of the infant in her womb from the sixth to the ninth month of its existence, which is a point of importance in medico-legal inquiries. If this fact is true, and none can doubt the proofs of it, it is reasonable to conclude that blows or falls on the abdomen may be inflicted on the head of the fœtus in the womb, and may fracture the skull, cause concussion or compression of the brain, and death. It is only a few months ago since my valued and experienced friend, Dr. Blicke, of Walthamstow, requested the opinions of Dr. Merriman, Dr. Blundell, and myself, on this point, at one of the Courts in Westminster. None of us could speak from personal observation, as we had not met a case of intra-uterine fracture.

It is scarcely necessary to observe, after the foregoing remarks, that fractures of the bones of the infant may occur during parturition, either by malformations or contractions of the maternal pelvis, or by the rudeness of the obstetrician, whether male or female.

Deformities of the joints are also observed in infants at birth, as noticed on a former occasion. In fine, inflammation and supuration of the joints of the extremities have been observed in new-born infants. There is an interesting case in my Journal, which I shall read to you.—(*See Lond. Med. and Surg. Journ.*, edited by Dr. Ryan, vol. vi, No. 138, Sept. 1834.—*Observations on Acute Arthritis in New-born Infants*—Thesis sustained by Jules Teilhard Terrise before the Faculty of Medicine of Paris, Dec. 5th, 1833, translated by Alexander Thomson, M.B. of St. John's College, Cambridge).

The following is the substance of M. Terrise's thesis. The author remarks that he could not find any account of acute arthritis in the annals of medicine from the earliest period to 1833, but that the experienced

M. Baron had informed him that he had occasionally observed the disease. M. Terrie observed in the body of a very young infant inflammation of the hip, knee, and shoulder joints, with pus between the adjacent muscles. There was no symptom of these diseases during life.* In an infant of four days old there was pus in the hip, knee, ankle, and wrist joints. The shoulder joint was inflamed in an infant of six days of age, and purulent matter between the adjacent dorsal muscles. I have repeatedly observed suppuration in the elbow, wrist, knee, and ankle joints in very young infants, which supervened immediately after malignant small pox, and you have seen a remarkable case this day at the Free Hospital. My friend, Mr. Appleton, of Holborn, requested me, some time since, to visit a case in Baldwin's Gardens, in which the elbow, wrist, knee, and ankle joints contained a white ill-conditioned pus.

Diseases of the Lymphatic System.—These maladies are rarely observed in infants at birth, but are developed occasionally at the eighth month of life. The mesenteric glands are the first affected of the lymphatic system. It is easy to account for this fact—infants are almost invariably overfed, or have improper aliment. Irritation in the duodenum is the consequence, and this is transmitted from the orifices of the lacteals in the duodenum to the mesenteric glands. These become inflamed, enlarged, and impervious, a sufficient quantity of chyle or nutrition is not conveyed into the thoracic duct or circulation, the whole body and extremities emaciate, though the appetite is great or voracious, and the abdomen becomes tumefied. Scrofulous and rachitic infants are most subject to this disease, which is technically denominated *tabes mesenterica*. The history of this complaint does not apply to new-born infants in general. The glands of the neck are next most frequently affected, and then those of the tracheæ and roots of the lungs.

M. Billard has found tubercles in different parts of the bodies of infants. Thus he observed tuberculous granulations in the peritoneum of an infant that died four days after birth; and in two others the mesenteric glands were enlarged. In four infants there were tuberculous granulations in the liver and spleen, and in two of these in the lungs. It is very important to state that this industrious pathologist also observed tubercles in the lungs of infants which were born dead or before the full time of uterine gestation. M. Husson has also reported two cases to the Royal Academy of Medicine; the first infant was born dead at the seventh month, and the other survived for eight days: the first presented pulmonary tubercles softened, and some in a state of suppuration, though the mother was not phthisical; and the liver of the second was tuberculous.

M. Billard observed pulmonary tubercles, in 1826, in four infants who died from the first to the fifth month. M. Baron had predicted the disease in one of them. According to these writers, the symptoms of phthisis in adults were absent. Pulmonary tubercles in infants are transparent, small, round, and disseminated on the surface, tissue, and root of the lungs. These observations prove that phthisis may attack infants in the uterus, a fact contrary to the opinions of many modern writers.

Scrofulous or glandular enlargements may appear in infants from the first to the seventh year, and in children from this period to puberty; but they rarely occur afterwards. The disease most commonly attacks infants of a lax habit, with smooth soft skin, and fair hair, a peculiar fulness and rosy appearance of the face, large eyes and upper lip, and a delicate complexion. It also attacks children predisposed to rachitism, in whom the head, abdomen, and joints are remarkably large. The exciting causes of glandular enlargement are cold and variable climates, crude and indigestible food, bad water, damp and low situations, hereditary predisposition, syphilis, and debility, however induced.

The indications of treatment are to improve the general health by tonics, chalybeates, iodine, nutritious aliment, animal and vegetable jellies, pure or sea air, living on the sea-side, wearing flannel next the skin, &c. I have found the greatest benefit from the use of hydriodate of potass used internally, and applied to enlarged glands, or to the abdomen when tumefied. To infants from a year to five years old, I exhibit from three to six grains of hydriodate of potass to the ounce of distilled water, in the dose of a tea-spoonful three times a-day, sweetened at the time of taking. The ointment may be composed of six or ten grains of the hydriodate, or ioduret of lead, to one ounce of lard, and a drachm may be rubbed over the affected part morning and evening, unless it reddens the skin, when it should be discontinued until this appearance has ceased. These medicines, with the preceding, have the most beneficial effects in every form of scrofula, mesenteric disease, enlargement of the glands in the neck, white swelling, and inflammation of the joints in scrofulous subjects. I have seen numerous successful cases in my hospital, dispensary, and private practice, and I am convinced that no one depreciates iodine or its preparations, who has used them with genuine, or tried them fairly. The students of my class have ample opportunities of observing multiplied proofs of this statement. I have fully expatiated on the use of iodine in my edition of Hooper's Physician's Vademecum and Formulary of Hospitals.

Diseases of the Organs of the Senses.—Development and Diseases of the Eyes.—These organs are scarcely capable of performing

their functions, in infants born before the end of the sixth month of pregnancy, and some authors say not until the seventh, eighth, or ninth month. The eyelids are generally agglutinated until the sixth or seventh month, and the sclerotic tunic is very thin and transparent. The cornea is not fully developed at an earlier period. It is at first in contact with the anterior surface of the crystalline lens, and is separated from it, by the secretion of the aqueous humour. The iris is usually covered by the *membrana pupillaris* until the seventh month, when this membrane ruptures in the centre, and retracts towards the circumference, on account of the arrangement of its vessels, which offer opposite arches, which are not adherent at their convexities or contiguous parts. When the pupil dilates, the aqueous humour which was situated behind the iris escapes in front of this membrane, and forms the anterior chamber. The vitreous humour, which is at first red, gradually loses its colour and becomes transparent. The lens is at first fluid, and by degrees becomes thick and lenticular.

The permanent occlusion of the iris, eyelids, and congenital cataract, require operations which ought not to be performed in the early months of life, and these are described in the surgical works. There are numerous vices of conformation of the globe of the eye, as when the organ is too prominent or diminished in size, or when united to its fellow, forming one body on the median line, and termed *cyclopsy*, or *monopsy*, which is irredeemable.

In some cases the axis of vision is imperfect at birth, or the newly-born infant fixes its eyes on brilliant objects, looks obliquely, and acquires squinting or strabismus. This disease, however, often depends on imperfection of the organization of the brain, or the muscles of the eyes, and in such cases is generally incurable. It may, however, be acquired after birth, by placing the cols or beds of infants obliquely towards the light, and then a change of position, and the use of goggles so constructed as to admit light in an opposite direction to that to which the eye is directed, or in the axis of vision, may sometimes effect a cure.

Ophthalmia of New-born Infants—(O. Neophytorum).—The commonest disease of the eye in new-born infants is conjunctivitis. It is to be recollected, that the tunica conjunctiva is a mucous membrane, which lines the eyelids, and is reflected over the sclerotic tunic, and according to most modern anatomists over the cornea. When any part of the conjunctiva is inflamed the disease may affect the whole extent of the membrane, and consequently that portion over the globe of the eye. In mild cases, conjunctivitis is limited, but in severe examples, it becomes extensive and may destroy all the tissues that compose the organ of vision, both in infants and adults. This result very rarely

happens in the simple or mild forms of the disease.

The symptoms of this species are more or less redness and tumefaction of the eyelids, intolerance of light, and the infant turns its head into the opposite light, and cries when the lids are examined. The pain is caused by the irritation of light, or the mechanical friction of the globe of the eye upon the inflamed conjunctiva. On separating the eyelids, we find the inner surface more or less inflamed, and the globe of the eye unaffected, unless the disease is severe. Such is the first degree of ophthalmia of new-born infants, and it supervenes from the first to the sixth day after birth.

The causes are exposure to the light of a fire, candle, or the sun, when brilliant; cold or damp atmosphere; mechanical injuries; the passage of soap lather or ardent spirit into the eyes, when the new-born infant is being washed. The disease is also induced by removing the infant from the chamber of the mother in cold weather, into the lobby, drawing-room, &c.

Treatment.—When the disease is slight, the application of cold water or rose water, by means of a thin fold of muslin, with a slight aperient, and darkness of the apartment, will be effectual. It is the practice, at the hospital for infants, at Vienna, to apply thin folds of muslin wetted with cold water constantly over the eye or eyes. It is to be borne in mind, that in treating diseases of the eye, lotions are applied externally to the lids, either hot or cold, and also directly to the affected part. Thus, cold lotions or cataplasms are applied to the lids internally, while a lotion is directly applied to the conjunctiva by being dropped into the eye. Leeches are seldom necessary, unless when the inflammation is severe. In such cases, one small or middle sized leech may be applied to the external angle of each eye, according to M. Baron of Paris; or to each upper eyelid, if we follow the practice of Mr. Lawrence, who states that he has repeatedly observed severe collapse produced by the application of a single leech. He further advises, when the inflammation is subdued, a solution composed of two, three, or four grains of alum to each ounce of rose water as an astringent, and this is to be injected between the eyelids three or four times a day, so as to remove all secretion, and constrict the affected blood vessels; to which I add a few drops of the sedative solution of opium. The bowels ought to be regulated with castor oil, magnesia, manna, rhubarb, &c. according to the age and strength of the infant.

When this disease attacks infants, from one to seven years of age, it may be necessary to scarify the lower eyelid, and to apply counter-irritation by means of blisters, or antimonial ointment, behind the ears, or to the nape of the neck. It is now considered bad practice to apply leeches round the eyes,

or to the temples, or counter-irritants on the temples, in cases of infantile or adult ophthalmia.

When the disease becomes subacute, a stronger solution of alum, or the compound solution of this medicine of our pharmacopœia, properly diluted, is of essential service. Some strongly advise two or three grains of sulphate of zinc to each ounce of distilled rose water, and others recommend a solution of the sulphate of copper, more especially when the surface of the eyelids is granulated. This last remedy is necessary in cases of children from the seventh to the fourteenth year, or of adults, but scarcely ever, according to my observations, in cases of infants from birth to the seventh year.

Catarrhal Ophthalmia.—This differs in no respect from simple conjunctivitis, unless that it is more severe, and the eye is chemosed or blood-shot. The cause is cold, and as the disease is often common among children at certain seasons, and also among adults, it is held by some writers to be contagious.

The treatment is the same as in the last form, but more active. Some practitioners apply a weak solution of nitrate of silver, (one or two grains to the ounce of water) and others a much stronger ointment, ten grains to a drachm of lard, introduced between the eyelids, on the globe of the eye. This practice is seldom necessary, according to my experience.

Purulent Ophthalmia.—When the preceding diseases are violent and terminate in suppuration, conjunctivitis has been termed purulent, or Egyptian ophthalmia. In this species there is a copious discharge of a thick, yellow, muco-purulent fluid, which distends the eyelids, agglutinates them, but when they are separated with the fingers, flows abundantly over the cheek. The eyelids become so swelled and distended in the course of one day, that they cannot be opened unless by considerable force. On separating them to allow the matter to escape, and wiping off any that remains on the eyelids and globe of the eye, we often observe œdema of the subjacent cellular membrane, and the cornea buried in the folds of the distended conjunctiva.

This extensive disease produces most agonizing pain in adults, and is so severe as often to destroy new-born infants.

The causes of this disease in new-born infants, are acrid discharges of the mother, such as the purulent form of leucorrhœa, or gonorrhœa, either of which may come in contact with the infant's eyes, during its passage into the world. The disease, however, may appear in a mild form, independently of these causes. It is important to state, that it often destroys vision, and sometimes life. When it arises from the preceding causes, the symptoms are as follow: the inflammation becomes violent, the sclerotic tunic is injected with blood, chemosed,

or to use a popular term, blood-shot, the external and internal surfaces of the eyelids become vividly inflamed, there is an abundant secretion of pus from the conjunctiva covering the globe and lids of the eye, the latter are agglutinated, and the purulent matter accumulates behind them, so that on separating them, it flows over the cheek, and the infant cannot open its eyes. If we inspect the conjunctiva we find it intensely inflamed, the folds of this membrane, which exist between the globe of the eye and inner surface of the eyelids are swollen, and present on their surface small granulations, and when the infant cries the lids are everted, and a temporary ectropium is produced. During the progress of this kind of inflammation, the suppuration becomes most abundant, it varies in colour and consistency, it is generally thick, and of a yellowish white colour; but it may be mixed with blood, or in some cases a sanguineous exhalation takes place, when the pus is wiped off, or removed. In the last stage of the disease the purulent matter may assume a greenish yellow colour; and if jaundice exists at the same time, it may be perfectly yellow.

Every one who knows the anatomy of the eye, and who is acquainted with the science of surgery, is aware that palpebral inflammation (that of the eyelids) may readily pass to the globe of the organ of vision, and cause destruction of its tissues, and often complete loss of sight.

The most common effect of purulent or gonorrhœal ophthalmia is opacity of the cornea; and ramollissement, ulceration, perforation, &c., are fortunately of comparatively rare occurrence; when the primary disease is treated judiciously, they rarely occur; as the inflammation diminishes, the purulent secretion and tumefaction of the eyelids gradually cease, and the opacity of the cornea is generally, but not always, removable. But when the inflammation advances, the cornea may be destroyed, and all the ravages already described may be produced. In such cases, the pupil will be more or less deformed, according to its adhesion with adjacent organs.

The prognosis must be arrived at, after due consideration of the progress and intensity of the inflammation. The disease may continue for a few days, or for weeks, or months.

It is necessary to observe, that opacity and ramollissement of the cornea are not always caused by purulent, or rather puriform ophthalmia; and that these states may also be induced by gastro-intestinal irritation. This fact is proved by the observation of M. Magendie, that a dog fed on sugar, suffered from ulceration and perforation of the cornea.

I shall briefly examine the results of the extension of purulent ophthalmia. The contiguity of the cornea to the conjunctiva, and

the adhesion between these parts, render it clear that the diseases of the latter may readily extend to the former, and thus, inflammation of the cornea (keratitis or corneitis) is one of the most common consequences of conjunctivitis; and opacity, nebula, or pearl, ramollissement, or perforation, may be the usual result.

Opacity occurs in such cases, in the same manner as in adults, in consequence of the effusion of coagulable lymph or puriform matter between the layers of the cornea, or the conjunctiva which covers that part of the eye. This opacity may be more or less extensive; it may be a small speck, or cover the whole cornea, but it is fortunate that in either form it is generally removed in cases of young infants, after the cessation of the inflammation, by appropriate means which will be hereafter described.

Ramollissement, or softening of the cornea is much more serious, and is of occasional occurrence. When it commences, the cornea loses its clearness and polish; it presents one or many points of a greyish or brown colour, and these are distinguished by a line of demarcation from the sound parts. The centre of the ramollissized or softened part is speedily perforated, and a communication is established between the atmosphere and the anterior chamber of the eye, and as soon as the artificial aperture is made, there is an effusion of the aqueous fluid. This aperture is generally opposite to the pupil, and is sometimes so large as to allow the escape of the crystalline lens and vitreous humour, whose coverings are previously destroyed by inflammation and ulceration. Under such circumstances, the lens and humours, or fluids of the eye being expelled, the eye diminishes in size, and vision is completely and irremediably destroyed. It sometimes happens, however, that after the perforation of the cornea, the iris protrudes, or is prolapsed, so as to prevent the expulsion of the lens and vitreous humour; but in such case, unless the protruded part be restored to its natural situation, imperfect vision or total blindness will follow.

Protrusion or prolapsus of the iris is a common disease when the cornea is perforated by wounds, as I shall notice hereafter; as when children wound the eye with sharp instruments, such as penknives, scissors, nails, &c.

Ulceration differs but slightly from ramollissement; it generally occurs in the centre of the opaque part, and its edges are tumefied.

These general observations having been premised, it remains to notice the treatment of purulent, Egyptian, leucorrhœal, and gonorrhœal ophthalmia, which, pathologically speaking, are the same disease; and then I shall notice the symptoms and treatment of those morbid alterations caused by it.

Treatment.—Antiphlogistic remedies must

be vigorously employed; venesection, leeching, cupping in grown children, purgatives, tartarized antimony in nauseating doses, the oleum terebinthinæ, and blisters. The local remedies are, strong solutions of the liquor plumbi subacetatis, nitrate of silver, sulphates of zinc and copper, the wine of opium in former pharmacopœias, the ointment of nitrate of silver, or the black ointment of Mr. Guthrie, and lastly, the application of the unmixed nitrate or lunar caustic.

In cases of infants or children, there is generally more or less gastro-intestinal irritation or inflammation, and repeated doses of tartarized antimony, or of oil of turpentine, are contra-indicated, though highly efficacious in cases of adults. Mr. Travers proposed the first remedy, and Mr. Hugh Carmichael, the second. In cases of adults, Dr. Vetch bled to the amount of fifty or sixty ounces; but fifty of his patients out of six hundred and thirty-six, lost the sight of both eyes, and forty more became blind of one eye. Mr. Lawrence advised bleeding in gonorrhœal ophthalmia, while blood could be got from a vein, (on the Venereal Diseases of the Eye, 1829), a practice which few, if any, I apprehend, would be so rash as to follow, and which the adviser has since thought fit to retract. (A Treatise on Diseases of the Eye, 1834). The received opinion at present is, that the most copious depletion will not prevent the destruction of vision, and that local bleeding is much more efficacious, as the disease is local, and seldom excites constitutional disturbance. Dr. O'Halleron, who had vast opportunities of treating the disease in the army, declares that bleeding is unnecessary, and that he has cured hundreds of cases with the stimulant treatment, and always with the greatest success. He was the first who applied strong solutions of sulphate of copper and nitrate of silver. Dr. Ridgeway, also an army surgeon, was the first to recommend very strong solutions of the last remedy. It is now used in this form by Mr. Guthrie, and also in ointment, at the Royal Westminster Ophthalmic Hospital. This ointment is the following:—

R. Argenti nitratis, gr. x;
Unguenti cetacei, 3j;
Liq. plumbi acet., m. x.

Fiat unguentum in usum.

The eyelids are separated, so as to allow the purulent matter to escape, and any that may remain is removed with a dosil of lint. A piece of ointment, varying from the size of a pin's head to that of a garden pea, is introduced on a probe between the eyelids, which close, and are then rubbed with the finger for a few seconds. The remedy is reapplied every second or third day. The application is not so painful as is generally supposed; but I do not think it necessary in a majority of cases of infants. The solutions used at the above hospital, vary in

strength from one grain to twelve in an ounce of distilled water.

Mr. Walker, of Manchester, applies nitrate of silver to the inner surface of the eyelids with great advantage. (The principles of Ophthalmic Surgery, &c., 1834). "The pain," says this able writer, in his admirable manual, "is not so severe as many persons may suppose, and soon subsides. It is in truth no caustic for destruction of surface, or at all events very slight, and consequently no cicatrization ever results from its use. Little else need be done. Attention to cleanliness, and the frequent washing out of the matter from the surface of the eye, with a solution of alum or sulphate of copper, with attention to the general health, as may be required, constitute the essential points." I entirely assent to the advice of this author so far as lotions are concerned, but I entirely differ from him and others, who use too strong an ointment of nitrate of silver, or the lunar caustic, indiscriminately, more especially in cases of children—I might almost say in adults; for you have all seen a patient whose vision was destroyed by this remedy, and who attended the Royal Westminster Ophthalmic Hospital, St. George's Hospital, and Mr. Stevenson's Eye Dispensary, for two years and seven months, without any relief. This man was led to the Free Hospital. Both corneæ were of a horny colour, with enlarged vessels traversing from both sides of the sclerotic tunic, the eyelids were covered with villousities, or what some term granulations. His general health was duly attended to, and he was ordered the following lotion:—

Rx. Liq. alum. c. Ph. Lond., ʒij—iv;
Aqua rosæ desill., ʒvj—viij;
Liquoris opii sedativ., ʒss—j.

This remedy was prescribed with a view of diminishing the size of the vessels which were in a state of chronic inflammation, and likewise to promote absorption of the effused lymph which obscured the corneæ. It produced the desired effect after some weeks, and the patient is now able to see his way, and to read the names on the sign boards as he walks along the streets.

He continues an out patient of mine, as he is subject to conjunctivitis from exposure to cold, and any member of the profession may see him and hear his own statement on my days of attendance at the hospital. I mention this case to prove that violent stimulants applied to the eye may do great mischief, and that a milder plan of treatment, which is generally adopted by the profession, is sometimes, I should say generally, more beneficial.

In purulent, leucorrhœal, or gonorrhœal ophthalmia of infants, when the cornea becomes opaque or ulcerated, Mr. Walker advises the application of the pure nitrate of silver. He conceives that we never need allow any case to get worse under this treatment efficiently employed. It would, in

my opinion, be unnecessary to use it in a mild case. According to my experience, astringent and less stimulant applications are generally successful. There are but few cases which require the use of the nitrate of silver alone or diluted.

Strumous Ophthalmia.—This term is applied to conjunctivitis in strumous or scrofulous habits. It is very common in infants, children, and young persons, and frequently observed in adults.

The symptoms are great intolerance of light, the infant or child closing the eyes firmly and turning from the light, copious lachrymation, more or less tumefaction of the eyelids, sometimes of the face and glands of the neck; and on examining the eye, we observe phlyctenulæ or small pustules on the margins of the cornea. The intolerance of light is so great, that some have supposed the retina must be affected, or that there is retinitis combined with this disease. It is not difficult to disprove this opinion. The infant is observed to open its eyes during twilight, and sometimes during sunshine, when its back is towards the light, which it could not do had it laboured under retinitis. This form of disease is often complicated with eruptions about the eyes, on the cheeks, forehead, and chin, which form scabs or crusts, or that disease which the older dermatologists termed *crusta lactea*, and the moderns, *porrigo larvalis*.

The causes of this form of ophthalmia are a peculiar diathesis or state of constitution, bad living, clothing, want of cleanliness, exposure to cold, &c.

The indications of treatment are to improve the general health, as in scrofula, by mild aperients, tonics, quinine, carbonate of iron, pure air, warm clothing, sea air, &c., and nutritious aliment; by alteratives, as the mild preparations of mercury, hydrargyrum cum creta, with rhubarb, carbonate of iron, quinine, &c., with leeches and blisters behind the ears, or to the nape of the neck, and other antiphlogistic measures. The method I adopt in such cases is, first to regulate the bowels and abdominal secretions, and to apply a lotion of the liquor plumbi acetatis, diluted with rose water, to which is added the sedative solution of opium.

It is seldom necessary to apply any remedy to the *porrigo* or *crusta lactea*, except ablation with white and not yellow soap and water; and when the scabs are removed, the ulcerated surface may be sprinkled with flour or hair powder. It often happens that the whole face and forehead may be covered as if with a mask, formed by one mass of scab; and parents are generally alarmed lest their infants should be marked. This disease, however, never causes marks or deformities, and generally disappears during the use of the remedies already mentioned. It is sometimes extremely obstinate, but its treatment in such cases will be stated, when I describe diseases of the skin.

Pustular Ophthalmia.—This disease is nothing but conjunctival inflammation, accompanied by pustules round the margin of the cornea, or on the inner surface of the eyelids. It is most common to infants, children, and young persons.

The treatment is the same as in the last disease, with the addition of applying nitrate of silver, or stimulant lotions.

Erysipelatous or Edematous Ophthalmia.—This term is applied when conjunctivitis is followed by a serous effusion into the cellular tissue beneath the affected part; and the causes are the same as in the disease from which it derives its name.

Treatment.—When the inflammation is severe, antiphlogistic measures will be necessary, with warm fomentations, blisters, and other counter-irritants. When the disease becomes chronic, the remedies already enumerated for the treatment of conjunctivitis will be necessary, and also those medicines which excite absorption.

Variolous, Morbillous, and Scarlatinous Ophthalmia.—It often happens during exanthematous eruptions, such as small pox, measles, and scarlatina, that the conjunctiva becomes inflamed, and that the cornea or other tissues of the eye may become affected.

The treatment must be modified according to the species of disease, in the manner already mentioned. When pustules form on the cornea in small pox, the sense of vision is often destroyed; and this proves the vast superiority of vaccination.

Chronic Diseases of the Conjunctiva.—The chronic diseases of the conjunctiva are granulations, ulcers, fungus, chemosis, ecchymosis, pterygium, pannus, xerosis, or xeroma.

Granulations of the Conjunctiva are caused by inflammation, and often follow purulent and other forms of ophthalmia. They consist in a number of small soft elevations, or fleshy growths, similar to those observed on ulcers, and by their pressure on the cornea, inflame it and cause opacity or ulceration of that tissue.

The chief object to be accomplished, is the removal of these growths by means of astrigent and stimulating lotions, such as solutions of alum, zinc, &c.; and if these fail, some practitioners strongly advise the application of nitrate of silver, or sulphate of copper every day, or other day, until the conjunctiva regains its natural smoothness. According to my experience, which has been very extensive, the disease will generally yield to the astrigent solutions, and the more powerful caustics are unnecessary in the majority of instances. These will also excite the absorption of the opacity of the cornea. Fungous growths, and ulcers of the conjunctiva, disappear by the same treatment.

Chemosis and Ecchymosis of the Conjunctiva.—The first term is applied when the conjunctiva is blood-shot or highly vascular, and the second, when it is partially so. Both

are symptoms of some form of ophthalmia, and will be removed by antiphlogistic measures.

Pterygium is a vascular membrane or fleshy growth from the conjunctiva, of a triangular form, the apex extending and adhering to some part of the cornea. It may gradually develop, unaccompanied by inflammation, but generally succeeds purulent, or some severe ophthalmia.

It may be removed by the use of nitrate of silver or sulphate of copper; but it sometimes requires excision. This is effected by seizing it with fine forceps, and excising it with a pair of scissors, and then applying cold, and other antiphlogistic measures.

Pannus.—This disease consists in the expansion of a highly vascular membrane over the conjunctiva and cornea, which is caused by some form of inflammation. Astringent and stimulant collyria usually remove it; and if these fail, solutions of nitrate of silver or sulphate of copper may become necessary.

Xerosis—Xeroma Conjunctiva, is that condition of disease in which the affected tissue loses its character of mucous membrane, and assumes the appearance of common integument. It is of very rare occurrence. I have seen one example only, in which both eyelids partially adhered to the globe, and the eyes remained permanently opened.

—o—

CLINICAL REMARKS

ON

CASES IN THE NORTH LONDON HOSPITAL,
BY MR. COOPER.

—

Suppuration under the Dura Mater, following Contused Wound of the Scalp—Autopsy—Compound and Comminuted Fracture of the Olecranon—Fracture of the Thigh—Amputation of the Arm—Condition of the Amputated Limb, on Dissection.

GENTLEMEN—In this Clinical Lecture I will first bring under your consideration some particulars of the case of James Sadler, a hackney coachman, aged 51, who was admitted on Saturday the 31st of October, on account of a wound of the occiput, occasioned by a fall on the pavement from the box of his coach. The wound was of the contused lacerated description, attended with a good deal of swelling from extravasation of blood in the adjoining cellular tissue, a large branch of the occipital artery having been divided. The pericranium was not detached. The man had been stunned by the fall, but quickly recovered, and was not sick, a consideration proving that the blow was not a severe one.

On his arrival at the hospital, he was perfectly sensible, and his pulse natural.

Mr. Quain saw him directly after his admission. The wound was dressed, and in the evening, the patient finding himself well

enough, went home. He took five grains of calomel and a drachm of the pulvis jalapæ comp. and was directed to restrict himself to a low diet, and keep himself as quiet as possible.

On Nov. 2nd, the patient came to the hospital again; his bowels had well opened—the swelling had subsided, and the wound was looking favourably.

On his coming to the hospital, on the morning of the 7th, a week from the period of the accident, he complained of being generally unwell, and of pains and stiffness in his joints, especially those of the upper extremities. The wound in the head had undergone a change for the worse; on inquiry it was found he had had a rigor, followed by pyrexia, which had been going on for three or four days. It was, I think, the neglect of himself during those days, that gave an opportunity to the disease to reach a stage which afterwards proved fatal. He was now taken into the house, put on low diet, and the wound was poulticed. The pulse was but little disturbed, and the bowels were opened.

On the 8th, the pain and stiffness in his wrists and shoulders were diminished. He walked about the ward, and conversed cheerfully with the patients; he also requested to be allowed meat, but this was refused. On the 9th he was much better, had passed a good night; his bowels were open. At five in the afternoon he took his tea and was in excellent spirits. At seven he was seized with another rigor, and felt very unwell, but would not permit the house-surgeon to be sent for, observing that he should soon be better. On the 10th his pulse was 120 and full; there was slight difficulty of speech, no stertor, his pupils active, but a degree of stupor about him. On the 12th I saw him, and considered it to be a case threatening suppuration beneath the cranium. He was bled to $\frac{3}{4}$ xvi, and a purgative consisting of eight grains of calomel, and the senna mixture given him. As the foregoing quantity of blood did not affect the pulse, the bleeding was carried to $\frac{3}{4}$ xxiv. The medicine operated freely, but the man became more and more insensible, and died at 8 o'clock next morning. The blood taken away presented a buffy and cupped appearance. On examining the body 24 hours after death, the following appearances presented themselves. The pericranium was uninjured and adherent to the skull. On opening the cranium, a quantity of turbid serum escaped. The dura mater was evidently less closely attached to the part of the inner table below the external wound than elsewhere. Beneath the dura mater, the whole surface of the right hemisphere was covered with a thick coating of yellow pus, and the left hemisphere presented appearances of increased vascularity and turgescence. No lesion was detected in the viscera of the abdomen or thorax.

Remarks.—Gentlemen, this case appears

to me full of instruction. A man meets with a contused wound of the scalp, from a fall, which stuns him for a few minutes; he soon recovers his senses; the wound is dressed; he takes a cathartic, and returns to his home, where he probably soon resumes his usual diet and mode of living. He remains free from any serious indisposition, however, for about a week, when he is attacked with shiverings, pains in his limbs, and other febrile disturbance, for which he seeks no surgical aid for three days. On being now received into the hospital, and kept quiet and on low diet, he at first gets better, but dies in the course of three or four days, from the effects of inflammation of the dura mater, with suppuration under it, and an effusion of turbid fluid between it and the cranium.

I believe this patient only came under my observation on the 12th of November, when I found him affected with a degree of stupor and an impediment of speech, proving that effusion of fluid, on or within the brain had already commenced. Gentlemen, I also pointed out to you at the time, the unhealthy, unfavourable appearance of the external wound, the surface of which was pale and covered with a scanty quantity of ichorous matter. It seems, however, that the pericranium had not separated from the bone, and the wound was not surrounded by puffy œdematous swelling—two circumstances which are particularly noticed by Pott, as indicative of suppuration on the dura mater beneath the injury. In the case before us the pus was not directly under the cranium, but on the surface of the right hemisphere, beneath the dura mater. The dura mater, however, was loosened from the inner table, and a turbid serous fluid had accumulated between them. Had the man lived a little while longer, probably pus would have been deposited also in this situation, and the œdematous swelling of the scalp and a detachment of the pericranium from the part of the skull near the wound would have ensued. The case is practically instructive, as exemplifying the necessity of rigorous antiphlogistic treatment of every patient who meets with a contused wound of the scalp, and any degree of concussion of the brain, sufficient to stun him, though only in a slight and transient way. If you refer to the writings of Pott, you will find many instances of persons who had had what could not be called severe knocks on the head, such as were scarcely forcible enough to stun them, and who found themselves well enough to neglect the aid of surgery, and returned to their usual avocations and modes of life. In particular, they neglected to avail themselves of venesection, active calomel purgatives, low diet, and a perfectly quiet regimen. Some of them even enjoyed themselves for three or four weeks, and were then attacked with rigor, pain in the head, and general uneasiness in their limbs, fol-

lowed by heat and dryness of the skin, thirst, and an accelerated full pulse. At the same time, if there was a wound on the head, its appearance suddenly changed, the granulations losing their healthy vermilion colour, the surrounding part of the scalp becoming œdematous, and the pericranium detached. Some degree of delirium may come on, and then, if the disease increases, symptoms of pressure from effusion within the skull, the consequence of inflammation having continued too long unsubdued. In our case, the particular symptoms of such pressure, from effusion, were the stupor and difficulty of speech. The great practical inference from the history and observations now delivered, is, that whenever you are called to a patient who has received a blow on the head, though it may be only such as stuns the individual for a short period, you must urge the prudence of his being freely bled without delay,* of his taking brisk cathartic medicines two or three times a week, and of confining himself to a very low diet, and quiet regimen. Should these precautions fail to arrest inflammation of the membranes of the brain, which will sometimes begin three or four weeks after the accident, ushered in by an attack of severe shivering, you should then endeavour to check the progress of the inflammation by bleeding, calomel, tartarized antimony, cold evaporating lotions applied to the scalp, and leeches, followed by blistering.

Compound and Comminuted Fracture of the Olecranon—Fracture of the Thigh. Amputation of the Arm.

The next case, gentlemen, is that of Charles Hussey, on which I made some clinical remarks about three weeks ago*,

* The following is the case, as given by Mr. Cooper on the occasion:—Charles Hussey, aged 36, a slater, was admitted October the 15th. He had fallen from a ladder, at the height of a third story of a house, in consequence of one of the steps breaking as he was ascending. The femur was broken transversely, about the junction of its middle with its lower third. There was also a compound and comminuted fracture of the olecranon of the left arm. With the point of the finger, some fragments of bone could be felt within the wound, and one small piece was so loose, that it was taken out. The extremity of the olecranon was retracted by the triceps. The patient complained of pain in his side and back, where he had received some severe contusions. The thigh was put up with a long splint, in the straight position, and the elbow was extended by means of a splint in front of the joint, the arm having been previously bandaged from the fingers upwards. As there was a good deal of blood oozing from the wound, the sides of it were not brought

concluding with stating my opinion, that it was exceeding doubtful whether the arm could be ultimately saved. Indeed, on the 20th of October, five days after the accident, I had proposed amputation, considering it then would have afforded the best chance of saving the man's life. I deemed it right, however, to have a consultation with Messrs. Liston and Quain, and the result was a decision to endeavour to save the limb. The bandage having been removed, a considerable quantity of sanious matter flowed out of the original wound. Fomentations and poultices were applied, and the limb laid on a pillow.

Oct. 22nd.—I made an incision over the elbow, and let out about half a pint of reddish brown matter. On the 23rd, his pulse was 116. Another considerable abscess over the triceps muscle was opened. The broken femur, which had been put up in long splints in the extended position, was this day also examined, and the bandages and splints re-adjusted. On the 24th, the pulse had fallen to 100. The fore arm was placed in a lower position, in order to prevent the pus from gravitating towards the shoulder. The patient was allowed two glasses of port wine and some beef tea. In the evening, the skin was hot, but moist; the pulse 120. On the 25th the bowels were opened with castor oil. Copious discharge from the arm. Rests pretty well at night, without an anodyne. On the 29th, the report is, he went on favourably until yesterday. The sub-sultus tendinum and delirium had subsided. The pulse had gone down to 96, and become soft. The tongue had been clean and moist, and the skin natural. But on the night of

together till the next day; a cold evaporating lotion was applied.

October 16. This morning a considerable swelling has extended up the limb, with ecchymosis over the olecranon; the bandage was therefore slackened. The man has passed a quiet night.

17. Febrile excitement increased; pulse 120. Some calomel and antimonial powder were prescribed, followed by the senna mixture, and afterwards by the camphor mixture, with small doses of tartarized antimony and nitrous spirit of ether every three hours. The patient is not quite rational; raises his arm from the pillow; pulse 135, but compressible; bowels very freely opened; the patient's manner anxious and quick, and countenance much changed for the worse: he is constantly moving the injured arm: eight leeches applied to the elbow.

18. Arm much swollen and discoloured; cuticle separating over the triceps; copious effusion of serum in the cellular tissue, up to the shoulder.

Extensive ecchymosis over the glutei muscles, forming a very dark coloured swelling. Leeches repeated. Pulse, 135; tendency to delirium at times.

the 28th, about 12 o'clock, he became exceedingly restless, threw the fractured limb off the bed, and removed his shirt, talking at the same time in the wildest manner. The night nurse neglected to inform the house-surgeon of these unfavourable circumstances.

Next morning the patient had less delirium, but was still somewhat incoherent; his pulse was 136. I directed a grain of the muriate of morphia to be given immediately, and suggested that benefit might result from keeping the patient under the influence of this medicine. On the 30th, his tongue was white, pulse less frequent. As his bowels had not been opened for two days, some aperient medicine was given. From this date, notwithstanding the good derived from morphia, and supporting the patient with wine, beef tea, &c., the case proceeded from bad to worse. Generally delirium every night; the hand œdematous, the fore arm and arm, nearly up to the armpit, in an erysipelatous state, with matter diffused under the integuments, and, as I apprehended, the synovial membrane of the fractured joint full of pus. Under these circumstances, with a pulse rarely under 130, and sometimes about 150, I took the earliest opportunity, as soon as the redness and swelling of the upper part of the arm had somewhat abated, to remove the limb. The mode of operating which I selected is not that most commonly practised in this metropolis, but which has the advantage of admitting of being done very quickly. The method was that first recommended and practised by Langenbeck, and subsequently by Graefe and Mr. Liston. I first made an external flap, by introducing the point of a narrow smallish amputating knife into the centre of the posterior part of the limb, till it touched the bone. I then inclined the handle towards the patient's side, and made the point pass closely round the humerus to its fore part, when I pushed it through the biceps and centre of the front of the limb, and completed the external flap by cutting downwards and outwards. I took especial care not to make the flap more than two inches and a half in length. Then, introducing the knife at the upper and posterior angle of the wound, I passed it round the bone to the front angle of the first wound, and, by cutting downwards, completed the inner flap. A sweep of the knife round the bone now divided the fibres of the brachialis and triceps closely adherent to the humerus, and the bone was then sawn through. Had I not practised this method of operating, I should have practised that which Dupuytren generally selected, and which consists in making a circular incision at once through the integuments, biceps, and great part of the triceps, without any dissection of the integuments from the fascia, and after having retracted the divided integuments and loose muscles, in cutting through

the muscular fibres closely attached to the bone, and separating them from it a little way upwards. In this way you may save abundance of soft parts to cover the end of the bone, and perform the operation with great expedition, and perhaps with as little suffering to the patient, as the removal of a limb in any way permits. At all events you thus save him from the torture attending the dissection of the skin from the fascia—by far the most severe proceeding in ordinary amputations.

I chose, in the case before us, to try the lateral flap amputation, that it might not be supposed, after what I have written in favour of the circular incision, that I am prejudiced and unwilling to ascertain in the field of experience how far the commendations bestowed by Langenbeck, Graefe, and others on this mode of amputating with lateral flaps, are well founded. Even Velpeau, who disapproves of it, allows that it possesses the recommendations of quickness and facility; but he maintains that the stump is very subject to inflammation from the flaps slipping and moving about, and that if supuration occur, the bone may protrude at one of the angles of the wound. The common fault in this operation is certainly that of making the flaps too long, when some of Velpeau's apprehensions are not unlikely to be fulfilled. This fault I have avoided. The stump, which was closed with a single stitch, and covered with linen dipped in cold water, had an excellent appearance directly after the operation; but some little disturbance of the flaps was produced in about two hours after, in taking up the small arteries, which then began to bleed, and the flaps did not unite. Indeed, no union could have been expected, with inflammation in the limb, reaching nearly to the shoulder, and a pulse between 130 and 140. During the operation the pulse had fallen to 120, and the patient went on favourably till two or three days ago, when in consequence of an attack of erysipelatous inflammation about the stump and breast, the constitution became again severely disturbed, delirium coming on, and the pulse rising to 150. From this state the patient is again recovering, the delirium having left him, and the pulse subsiding. On the 21st of November, an incision was made in the erysipelatous swelling over the pectoral muscle, and the inflamed skin had been bathed with the strong nitrate of silver wash. The patient had also taken occasionally five grains of calomel with the muriate of morphia.

On the 22nd.—The man sleeps a good deal, through the influence of the morphia, but his pulse keeps at 140. In consequence of ulceration having begun over the sacrum, he has been placed on the hydrostatic bed. The erysipelas of the arm and shoulder is subsiding. The incision and the nitrate of silver have had an excellent effect. On the 24th, the fracture of the thigh was united.

On the 30th, the report states the patient is going on favourably; and the stump promises to be an excellent one, without any protrusion of bone, though suppuration occurred.

Condition of the Amputated Limb.—The subcutaneous and intermuscular tissue was gorged with serum, and thickened and indurated; several large abscesses around the joint, and an extensive one on the dorsum of the hand and part of the fore arm. In the joint, a quantity of purulent fluid, with some coagulable lymph, amongst the fractured pieces of the olecranon. The cartilages of the articular surfaces of the three bones were completely absorbed.

Foreign Medicine.

Cholera in Italy.

M. BONAFONS addressed to the Academy an authentic note on the sanitary state of Italy; and the letters from Dr. Contu, of Turin, relative to the cholera at Piémont, and the employment of sulphate of quinine by the endermic method. The following is his account of Turin:—

	New Cases.	Deaths.
October 22	—	1
— 23	1	—
— 24	3	—

Genoa was perfectly free from disease; and at Livourne and Venice, the cholera was considered as having terminated. The following is from Milan, dated October 28:—“Several letters from Venice assure us of the healthy state of that city. Professor Hildebrande is on the spot; and he declares that no case now exists, either in the city or its environs. Navigation will, therefore, probably be set free.”

Amputation of the Neck of the Uterus.

M. Lisfranc exhibited to the Academy the neck of a womb, which he had just amputated in the presence of M. Magendie. The disease had been of eight years' standing. All the ordinary means had failed, and the constitution of the patient began to give way. The part which had been taken away presented all the characters of cancer; and the section had been made at a considerable distance from the body of the organ. The patient was going on well.

Polypus of the Uterus.

M. Lisfranc presented two polypi, each as VOL. VIII.

large as a fist. The patient had suffered for ten years. The weakness was extreme, the complexion yellow, and the discharge abundant. The disease had been taken for an enormous cancer of the womb. In the middle of the vagina there was a soft fungous tumour, bleeding at the slightest touch; and the finger could only with great difficulty be carried round it. It could be pushed up only in a slight degree. M. Lisfranc introduced the index and middle fingers, depressed the tumour, touched it alternately with both hands, and ascertained the existence of a polypus. He did not venture to affirm there were two.

In the operation the hooks always tore through the tissues which they laid hold of, and it was impossible to implant them in the neck of the womb, which M. Lisfranc has done so often without the least ill effects. The operator introduced, therefore, the index and middle finger of the right hand, but found it difficult to reach the pedicles of the tumours; and the uterus could be drawn down to only a very slight extent. He succeeded, however, in bringing to the exterior of the vagina great part, first of the anterior tumour, and then of the posterior. He then introduced deeply into the vagina, along his fore-finger, a pair of scissors with curved blades; and by a quick section, the patient was freed from these two tumours, which were to a great extent degenerated. Only a few drops of blood were lost. The patient experienced no ill effects.—*Lancette Francaise.*

Cantharides and Cantharidin.

M. Tommaso Palviri, a physician at Alba in Italy, has made some experiments with these substances, on the lower animals and on man, both in the healthy and diseased states.

1. *The Lower Animals.*—Two rabbits were killed, the first in two hours, by two grains of cantharidin in a little ball; the second in half an hour, by a grain and a half dissolved in milk. A third took the same dose, with fifteen drops of cherry-laurel water. Death ensued instantaneously, though the same animal had supported twenty drops of cherry-laurel water, five days before.

Two dogs of the same age and size took, the one ten grains of powdered cantharides, the other twelve in boluses. The first died

quickly, and the stomach was found not inflamed. The other was killed six hours after the dose, and the substance was found undigested, and the stomach of a rosy tint. These substances, then, act only by absorption.

2. *Man in Health.*—The author has twice taken fasting a grain of cantharidin. It produced a general rigor, with a sensation of coldness down the spinal column, pale skin, a feeling of heaviness in the head, and the pulse diminished in frequency by five pulsations. There was a copious secretion of urine at the end of four hours. A fortnight afterwards he took in the morning two grains in four doses. At the second dose he felt a heavy pain in the head; at the third, a little vertigo, with pale skin, and perspiration. He could scarcely maintain himself erect. The pulse fell seven beats. The urine produced a burning sensation, and was more abundant than the fluid swallowed. After dinner he took some alcohol, and then ten drops of liquid ammonia in water. The vertigo disappeared. The superabundant flow of urine ceased in the night; and on the morrow nothing but an unaccustomed weakness remained.

3. *Man in Disease.*—In a pleurisy occurring in a miserable constitution, with sanguinolent expectoration, after two bleedings had been practised, three grains of powdered cantharides were given in solution in the day, and the dose was augmented daily up to ten grains. Continual perspirations were produced, with copious urine, good expectoration, and absence of pain. A cure took place after the disease had continued sixteen days, and eighty-five grains of the medicine had been taken.

In a case of inflammation of the heart, with a suspicion of aneurism, a hundred and twelve grains were given in twenty days, with great relief. The urine was at first scalding; but after the drink was augmented, it became copious and cloudy.

Six other cases are mentioned, but not detailed. 1. Morbid pulsations in the ear, after a disease. 2. Continued fever of a malignant character. 3. Pains in the kidneys. 4. Anasarca. 5. Swelling of the thigh. 6. Inflammation of the womb and peritoneum. The author has also tried this agent in cystitis and gonorrhœa, but with little success; not

having been able to increase the doses.—*Lancette Francaise.*

Aceto-Spirituos Tincture of Cantharides as a Vesicatory.

Mr. D. S. Young, after repeated trials of this tincture, is led to regard it as admirably adapted to supersede the use of emplastrum lyttæ. The manner in which he has prepared it was by digesting four ounces of coarsely powdered Spanish flies in three ounces of rectified spirits, mixed with nine ounces of concentrated acetic acid, in a wide-mouthed glass-stopper bottle for five days, exposed to the sun. The mixture was then strained through flannel, yielding eight ounces of the aceto-spirituos tincture. To Mr. Young's commendations of this tincture are added those of Messrs. Twining and Stewart, of the General Hospital, Calcutta. From the reports of these gentlemen, the medicine acts as a *rubefacient* if quickly brushed once over the skin: and when the skin is freely wetted with the tincture, and rubbed for the space of three minutes, a perfect *vesicatory* is usually formed in about two or three hours. The blister has been in all cases more complete, and contained more serum than that produced in twelve hours by the emplastr. lyttæ. The remedy can be more exactly confined to the part which we desire to affect, and the margin of the vesication is well defined; the whole of the cuticle is more generally removed than by the common blistering plaster, and a more prompt and more free suppuration usually takes place. The pain produced by the application of this tincture is more severe, but much more transient than that caused in any given time by emplastrum lyttæ, but at the time it is rubbed on the skin, no pain is produced. In only one of sixteen cases, did any irritation of the urinary passages occur, and that was in a paralytic patient in whom a blister was produced from the occiput to the sacrum. This irritation of the urinary passages was, however, described rather as ardor urinæ than strangury, and the inconvenience caused by it was neither severe nor of long duration. In this case it would have been hardly possible to confine a long blister so exactly to the part. A perfect vesication was produced in two hours, the margins of which were distinct and well de-

fined, and its effects had not spread beyond the part required to be blistered. Mr. Twining has, in two cases of indolent ulcers, with thickened, raised, and inverted edges, applied this tincture with the best effect. The chronic disease of the edges of these ulcers was subdued by the second application, and the sores quickly put on a healing aspect.—*Abridged from the Transactions of the Calcutta Medical and Physical Society.*

Rupees found in a Man's Stomach.

A man came into the hospital for a complaint supposed to be what is vernacularly called *durd-i-sool*, which is characterized by agonizing pain at the pit of the stomach, recurring in paroxysms, only to be alleviated by strong external pressure. He used to have always beside him a pointed stick, on which he leant, or pretended to lean very forcibly during each attack, but as no unequivocal signs of concomitant constitutional disturbance could be observed, he was regarded as an impostor. Diarrhœa occasionally teased the man, and at such times he seemed free from the spasmodic affection. His constitution appearing to suffer from these attacks, and no relief being afforded by medicinal treatment, he was permitted to remain altogether in the hospital. At length he sunk under this bowel complaint, and on opening the abdomen, the stomach was found to be greatly elongated, contracted in its calibre, thickened in its coats, and altered in its colour. A large indurated moveable mass was felt within it, which was at first conjectured to be a scirrhus tumour or a bone, when the native doctor, who was assisting the surgeon in the examination, exclaimed that he had once heard that the deceased had swallowed fifteen rupees. On laying the stomach open, nine pieces of silver were found placed *en rouleau* at the pylorus, close to which a circular ulceration, with dense indurated edges, had been excavated. When proceeding to open the intestines in order to search for the other six rupees, a convict stated that the deceased had, at successive times, passed that number by stool, but how long ago he had swallowed the fifteen pieces he could not tell. From the date, however, obtained, it is probable they were taken into the stomach at least six years previous to his death.—*Abridged*

from the Transactions of the Calcutta Medical and Physical Society.

Fungus Hæmatodes.

Dr. Smith, professor of surgery in the University of Maryland, has observed in fungus hæmatodes, "one trait," he says, which "so far as he knows, has not been pointed out by authors, and that is an occasional disposition to recede from its first locality, and transfer itself to some other part, sometimes very remote from that first affected, which may then resume its healthy condition." Whence he infers "a very important principle relative to this disease, viz. that the nutritive functions have a control over the morbid excrescence, greater than has been supposed to exist." "And," he adds, "if it be established that this power exists, it is obvious that we may hope to excite and direct it by remedies, so as frequently to effect the complete dispersion of the disease."

As the grounds of these views, he relates the case of a poor woman labouring under bleeding fungus, located in the vagina, upon the recto-vaginal septum, and exhibiting strongly every trait of the disease. Although a doubtful opinion was expressed regarding the ultimate result of an operation, the patient was so anxious that the disease should be removed by the knife, that the operation was performed, during which, it was found necessary to extirpate a considerable portion of the recto-vaginal septum. The patient soon recovered from the immediate effects of the operation; but after the lapse of a few weeks the disease reappeared in the same parts. The case was then considered hopeless, and a palliative treatment only advised. The glands of the groin soon became affected and considerably enlarged.

Some time elapsed before Dr. Smith had an opportunity of seeing the patient, but when he was at length permitted an examination, he was surprised to find that almost every trace of the disease had spontaneously disappeared from its original locality, and also from the glands of the groin. Several small tumours had recently appeared in and around the mammae, exhibiting all the characteristic marks of incipient fungus. They had an elastic pulpy feel, and were affected with but little irritation. After another considerable interval of time, the

patient was again examined, when the tumours situated on the breasts were found to have completely disappeared, and the disease to have begun to manifest itself in the glands of the iliac region within the abdomen. In this last locality the disease continued to progress until it terminated the life of the patient. Immediately before, the disease had recommenced its ravages in the vagina and had extended to the uterus. On a *post mortem* examination, the disease, which was manifestly the medullary fungus, was found to have involved the iliac glands on both sides, and to have extensively affected those of the mesentery.

Dr. Smith has previously related a case of fungus hæmotodes in the Baltimore Medical and Surgical Journal, which he had successfully treated by preparations of iodine and mercury, generally and locally applied, with spare diet and repose.—*Condensed from the North American Archives of Medical and Surgical Science.*

Anæmia cured by Preparations of Iron.

Dr. Geddings says that he has seen the treatment which the first view of the symptoms of this disease would seem to indicate: viz. the repeated bleedings, the diligent use of antimonials, cathartics, and mercurials so frequently adopted, without any other effect than an exasperation of all the symptoms, that he determined on trying an opposite mode of practice. Influenced by this determination he has, notwithstanding the general commotion of the vascular system, the violent throbbing of the vessels about the neck, the hurried and embarrassed respiration, the frequent and *shattered pulse*, and the occasional intense heat of the skin, which frequently attend this disease, had recourse to a combination of corroborants and alteratives, with the most decided advantage. Two cases are detailed to exemplify the particular mode of treatment and its result. The first is the case of a young sailor, in whom anæmia succeeded intermittent fever. After trying the purgative plan, with blisters to the abdomen, and afterwards the use of quinine on blistered surfaces, without any benefit, ten grains of the prussiate of iron was given three times a day for five days, when the improvement of the patient was obvious. The dose of the iron was then in-

creased to sixteen grains thrice a day, and ointment composed of iodine 3ss., hydriodate of potass, ʒj, and strong mercurial ointment, ʒj, was rubbed upon the abdomen daily. After a fortnight's perseverance in the treatment, he was perfectly cured; but still directed to continue the use of iron, taking the muriated tincture instead of the prussiate. The second case is that of a sailor, 18 years of age, who, from his earliest youth, had been annually subject to intermittent fever. In this instance, the carbonate of iron, in doses of ten grains thrice a day, was administered at the commencement, together with the nightly use of alterative pills, and a generous diet, with porter. In ten days there was a marked improvement; the tinctura ferri muriatis was substituted for the carbonate of iron on the 26th day of treatment, and in a fortnight from this time he is reported to have been far advanced in convalescence.—*Condensed from the North American Archives of Medical and Surgical Science.*

Poisoning from Ergot.

Dr. Hulse, of Pensacola, describes the case of a lady who, with a delicate constitution and peculiar idiosyncrasy against all narcotics, was delivered, after six hours' labour, of a healthy boy at six o'clock in the morning; profuse hæmorrhage immediately succeeded, and on trying to withdraw the placenta, it was found to be attached, and an effort to introduce the hand produced fainting. A drachm of the ergot of rye was directed to be infused in eight ounces of boiling water, and one half of the infusion ordered to be given immediately, the remainder in five minutes afterwards. A few contractions of the uterus followed, and the hæmorrhage ceased. The patient was supported in her exhausted state, with a few drops of the tincture of camphor given occasionally. In this condition she continued until eleven o'clock the next morning. During the interval she took a few drops of acetum opii, and slept about an hour. Ergot was now given in doses as above every half hour, until she had taken twelve ounces of the infusion. The uterus, which had been inactive for many hours, gave two or three strong contractions soon after the first dose, and then relapsed into a state of quiescence.

On introducing the hand, the placenta was found detached near the os externum, and was brought away without causing pain. At this juncture "the patient was in a state approaching insensibility; the pulse was full, about 65, and the limbs covered with a cold sweat; wine and water was ordered. Shortly the palpebræ began to swell, as also the lips and fauces, the tears flowed copiously, the schneiderian membrane seemed much stimulated, and there was coryza, great difficulty of breathing through the nose, and injections of the vessels of the conjunctiva. The lips and palpebræ began to puff as if stung by a bee, and gradually assumed a livid appearance. The power of deglutition was now nearly lost; the voice became feeble; she said her jaws were fixed, and shortly after, it was with the greatest difficulty that an answer of yes or no could be elicited. Previous to arriving at this point, she had complained of pain in every nerve, and a sensation of emptiness in the head."

Five grain doses of carbonate of ammonia in water were given every half hour, and friction used over the whole body and limbs, with the strongest liniment of ammonia; after the third dose, the symptoms had so far subsided as to render it unnecessary to continue the remedies. On recovering the power of speech, she said that her head had appeared to be quite empty, and that the sense of hearing had become so heightened, that every word spoken in the lowest tone reverberated through the head, and passed through every nerve in the body. The symptoms all disappeared in a few hours, except the redness and tumefaction of the palpebræ, which remained in a slight degree the following morning. As the pulse rose, and the patient recovered, there was a general perspiration, the matter of which emitted the peculiar factor of ergot.—*Condensed from the North American Archives of Medical and Surgical Science.*

Diabetes Mellitus cured by Tincture of Cantharides.

A boy aged 17, suffering under diabetes mellitus, came in April, 1831, under the care of Dr. Wilmot Hall, of Baltimore. When he first presented himself, his appearance was that of one who had suffered for some

considerable time from the disease. Within nine hours he passed a gallon of pale straw-coloured urine, sweet to the taste; his pulse was 84; his appetite irregular; digestion imperfect; he seemed to labour under no important pulmonary affection, and his alvine dejections evinced the presence of bile. Sulphate of quinine and phosphate of iron were, in the first instance, freely used for some time without any apparent benefit. With the exception of a little bread, he was not allowed anything but strictly animal food. Finding no abatement of the diabetic symptom, he was ordered twenty drops of the tincture of cantharides thrice a day, with directions to increase five or ten drops each dose, unless strangury was induced. On the 19th of May he had passed only a pint of urine during the night. He was now prohibited the use of bread, and confined to animal food exclusively. He, however, occasionally obtained bread by stealth, and on such occasions always found that the quantity of water was considerably augmented, so that at last he was led to refrain from it entirely. At this time he took two hundred and seventy drops of the tincture thrice a day, and was ordered to persevere in the regular increase of the dose. On the 9th of June he was taking the tincture in doses of two hundred drops; the urine passed during the night was four ounces; there was a slight strangury, and the dose of tincture was therefore diminished. On the 12th of June he took three hundred and fifty drops at each dose, when his health was much improved, his strength allowing him to take exercise, without aggravation of the diabetes. He persevered in the use of the medicine until the dose reached four hundred and twenty-five drops, when after suffering from severe strangury, he was ordered to discontinue the tincture, and pronounced to be cured.—*Abridged from the North American Archives of Medical and Surgical Science.*

Iodine in Hydrocele.

Mr. Martin, of the Native Hospital of Calcutta, having experienced many inconveniences from Sir James Earl's mode of treating hydrocele by port wine injections, determined, in 1802, to substitute a solution of the tincture of iodine for the wine and water previously used, and he has now

published the result of his trial in 162 cases which have fallen under his care during the last three years. A detail of the first case in which this experiment was made will exhibit the mode of his procedure, and remove the necessity of repeating others in illustration. "The operation was performed in the ordinary way; but in place of the warm solution of wine, two common urethra syringes-full were injected of a solution of tincture of iodine, in the proportion of two drachms to six of water, of the ordinary temperature. The patient was placed in the recumbent position, on account of rapid faintness, the canula withdrawn, and the *injection retained*; the scrotum being moved about freely for a minute, so as to bring the injection in contact with the whole of the vaginal cavity. The pain appeared rather more severe than from the common injection, but on the fifth day after the operation he demanded his discharge, scarcely any treatment having been requisite while in the hospital. Mr. Martin states, that out of the great number of cases which he has treated in this manner, he has only met with one in which symptoms of a dangerous tendency supervened: a few leeches, with an evaporating lotion to the scrotum, and a gentle purgative, removed these. One case of ten years' standing is described, in which the tumour reached to near the knees, and contained the enormous quantity of *ninety-two ounces* of greenish offensive serum. By the iodine injection the patient was "quite well in eight days." The advantages of this practice are thus described:—1st. The operation with the solution of tincture of iodine would seem free from the danger of infiltration. 2nd. It is more certain in its effects than any former injection. 3rd. The cure is effected in a shorter time. 4th. It is much easier of performance. 5th. No serum has on any occasion been "reproduced a few days after the operation," demanding a second tapping. 6th. The care in after treatment, on which "so much depends," with the wine solution, would not seem here to be requisite.—*Abridged from the Trans. of the Calcutta Med. and Phys. Society.*

Acute Hydrarthrosis. By Baron Larrey.

A man fifty years of age sprained his knee severely. A dropsy of that joint was the

consequence. It formed a very large tumour, and was evidently the result of acute inflammation of the synovial membrane, brought on by the violence of the injury.

M. Larrey applied four moxas to the tumour, and enveloped the limb in an immovable apparatus. This apparatus consists of several pretty long compresses, wetted with a mixture of white of eggs, vinegar, and camphorated spirit. By their application a kind of permanent compression was maintained over the whole tumour, and the moxas did not suppurate at all. This was just what was wished. In a fortnight's time the compression was made stronger by the renewal of the same apparatus, and the tumour had already begun to diminish. In another fortnight the absorption of the synovia was complete, and the patient appeared perfectly cured.

There are two important points of practice to be attended to in the management of this affection: the equal and firm compression of the tumour, by means of an immovable apparatus, and the absolute repose of the joint. These two are the most powerful and proper methods of effecting a cure. It may be said, it is very difficult to admit the utility of moxas in acute arthritis, with hypersecretion of synovia; but supposing that the latter remedy has not contributed to the cure, neither can it be said to have done much mischief. In cases, indeed, of indolent hydrarthrosis, the application of moxas before compression, appears to us of very great advantage. The practice in question is not that which is generally followed in similar cases. The usual plan is to treat the inflammation of the synovial membrane, first by antiphlogistics general and local, especially the repeated application of leeches, emollient cataplasms, rest, &c. Then, when the acute inflammatory state is subdued, recourse is had to blisters; and sometimes moxas are likewise added, when the absorption is slow in taking place. Allowing, however, that the principle which directs practitioners in this mode of procedure is in itself just, we must nevertheless observe that its execution is defective. We have had occasion to remark, a great number of times, both in the hospitals and in private practice, that the application of leeches around articulations inflamed from injury, such as a sprain for example, is rather

hurtful than advantageous. The bites of these animals almost always produce an increase of inflammation, an augmented flow of blood, great swelling, and sometimes erysipelas, which greatly aggravates the malady, and retards its cure. It is also, as we think, doubtful whether the emollient applications, of which such general use is made in these cases, are really beneficial.

A principal point in the circumstances in question, is to prevent the effusion of fluid in the injured articulation, and to stifle, by that means, the violent inflammation which would not fail to supervene. In order to fulfil this important indication, we know no better method than compression, assisted by the continual moistening of the bandages with cold water. If traumatic inflammation should already have taken place, we should like best to employ cupping for the local abstraction of blood. We may afterwards have recourse to compression, assisted by the cold water. It is well known in the present day, that among other advantages, methodical compression exercises an incontestable antiphlogistic influence, by the active opposition which it offers to the secretion of fluid in the part, and by that kind of torpor which it induces in the tissues submitted to its influence.—*Lancette Francaise*.

Aconitum Napellus in Rheumatism.

By Dr. Chaudru.

The case which we are about to relate, in conjunction with those already published, is calculated to induce perseverance in experimenting on the employment of *aconitum napellus* in rheumatic affections.

M. B., 54 years of age, stout in person, and of a strong constitution, was attacked for the first time, at the age of nineteen years, with an intense articular rheumatism. Since that period he has experienced very frequent paroxysms, and sometimes of a very serious character. Extensive use was made of a series of different agents;—general and local bleeding, revulsives, sudorifics, opiates, emetics, purgatives, &c. As a last resource, the patient had, for a long time, been in the habit of constantly using *Sibie's* purgative pills, of which he took more than a hundred boxes, that is, fifteen hundred pills. They sometimes produced considerable hyperca-

tharsis, and substituted a diarrhoea for an habitual and sometimes obstinate constipation. Under this influence, M. B. was less frequently subject to rheumatic relapses. Indeed he was often the subject of tenesmus, and felt himself in imminent danger of an enteritis and its consequences. When once the attack of rheumatism seized him, although not intense in its character, it was very long in continuance—lasting eighteen days at least, sometimes a month, and even two occasionally, whatever were the remedial means adopted. This, as is well known, is the usual period of a rheumatic affection.

On the 19th of September, 1835, being at Talence in rainy weather, M. B. felt an attack, and hastened to employ his usual remedy, *Sibie's* pills. The malady however increased. It was confined at first to the right hand, the wrist being red and swollen, with impossibility of motion; but the next day it extended, almost simultaneously, to all the articulations both superior and inferior, except those of the hip. It had not spared even the vertebral articulations, so that the trunk was constantly kept in a state of forced extension, as in *opisthotonos*. All these parts were the seat of violent pain, augmented by the slightest movement. The pulse was full, strong, and frequent; the skin hot; the tongue white and moist; thirst ardent; no pain in the head.

The treatment adopted consisted in emollient narcotic fomentations, with the continued applications of flannels steeped in the same liquid; infusion of *linden*, with the addition of some drops of acetate of ammonia in each cup; pills of the alcoholic extract of *aconitum napellus*, and abstinence. These means were exclusively and perseveringly employed from the 20th to the 28th of September. The *aconite*, administered at first in the dose of two grains, was gradually increased to twelve, and was then taken in doses successively decreasing. From the 22nd there was a notable improvement. The pains were less severe, the joints less swollen, red, and hot. Some motions could be performed, though with difficulty, such as raising the hand to the head. The pulse was more natural, and some sleep was obtained. This plain and progressive improvement allowed the patient to take a bath on the 27th. On

the 28th he rose, and walked about; the inflammation had disappeared, except in the joints of the left great toe.

Notwithstanding the greatest attention during the course of the disease, we could not observe any crisis, either by the skin or the kidneys. The light diaphoresis, which was constantly present, is abundantly explained by the frequently repeated tepid drinks, the weight of the bed-clothes, and the smallness of the patient's chamber. The urine, scanty rather than abundant, was red and loaded with sediment during the first period of the disease, but afterwards regained its limpidity. The alvine secretions were solicited by emollient injections.

There was one phenomenon which struck me, from the administration of the first pills of the extract of aconite, and which, if it had become serious, would have determined me to discontinue the medicine. I refer to a particular state of somnolency, numbness, and torpor, which the patient experienced for more than twenty minutes, every time that he dosed. It was like that which happens to every one in a state of health, after a long sleep, when he requires to be shaken in order to be roused. As the first pills contained a preparation of opium, though in very small proportion, I remained in doubt respecting the cause of the phenomenon just described. I struck out that substance from the formula, leaving only the aconite and an inert powder; but the same phenomenon was observed, and continued during the administration of the medicine.

The patient, as well as myself, was agreeably surprised at so quick a recovery, after so frightful an attack, especially when it is remembered that such attacks occurred so frequently, that our patient might be said to have a rheumatismal diathesis. We do not think it necessary to inquire whether the cure could be attributed to anything else than the aconite. The acetate of ammonia was employed only in doses of five or six drops in each cup of infusion; and beside, no crisis took place by the skin. The preparation of opium was employed only in the first sixteen pills, to the amount of forty-eight grains. The aconite alone, therefore, was given in active doses.

If it were necessary to confirm the authen-

ticity of the case we have just reported, we might state that M. Guitrac, whose testimony is of great value in matters of science, knew the patient, and saw him once with us. We conclude in his words:—"If the alcoholic extract of *aconitum napellus* be not a specific in rheumatismal affections, it may at least be regarded as a very valuable medicine in their treatment. Every practitioner, therefore, should have it at hand."—*Lancette Francaise*.

—0—

REMARKS ON ERYSIPELAS.

To the Editor of the *London Medical and Surgical Journal*.

SIR—In reading the clinical remarks of Mr. Liston upon the second case of erysipelas recorded in your journal of the 21st inst., I perceive he makes no allusion to the application of cold, either in the treatment of the patient under consideration, or in recommendation of its use and eligibility in similar circumstances. For the principle of the practice which I am about to advocate, I am indebted to the influence of a remark made to me by Sir Benjamin (then Mr. Brodie) many years since, upon the supervention of erysipelas, consequent upon an operation of removing a large tumour from the breast of a lady, who consulted me upon the nature of a tumour I considered scirrhus, and recommended its removal. I recommended the case to Sir Benjamin Brodie, who advised excision; the operation was most skilfully performed by him; the edges of the wound intimately approximated, and every thing proceeded most favourably until the fourth day, when erysipelatous inflammation supervened.

A novice in practice, impressed with the instruction I had imbibed from the prevailing theory of the day, as to the treatment of erysipelas, no sooner did the disease manifest itself, than I lent it a helping hand, by giving cinchona bark (quinine not then being in vogue), ammonia, &c.; the mischief progressed, the operator was called upon; feeling confident in the notions I had received, I made known my treatment. His remark was, "I see no reason, sir, why a different treatment should be here adopted than under ordinary circumstances of inflammatory action—purge freely, give diaphoretic salines, and foment and poultice the wound, first dividing the recently formed adhesions, to remove tension. This advice came too late; too severe a degree of inflammation was established to be arrested, the mischief extended, the symptomatic fever raged, the brain suffered, and death ensued. In this case, from subsequent experience and observation, I think the lancet was prejudicially spared, as also the cold

evaporative lotion—as in my future practice amid a multitude of most severe cases both of idiopathic and symptomatic erysipelas, I have never failed in one—my treatment having been decidedly generally and locally antiphlogistic, where temperament and constitution would admit, but invariably topical bleeding* and cold lotions, consisting of Spr. Vini Rect., Liq. Ammon. Acet., Aquæ Rosæ, partes æquales—under every circumstances; modifying the general antiphlogistic treatment, according to existing circumstances; as to the idea of repelling inflammatory disease from an external surface, and giving it a greater tendency to attack any internal subjacent part, is a proposition I consider untenable upon every rational principle, it being an acknowledged fact that caloric evolves, to unite with a body of a lower temperature; it may as well be argued that a heated bar of iron, would have its temperature condensed and concentrated by plunging it into a hillock of snow—the rationale is, the colder body borrows, or extracts from its heated neighbour the difference of degree of caloric, until a mean temperature is produced—inflammation is heat—the antagonist of heat, is cold; the habitation of life is on fire, whether its walls or interior, it matters not, the destructive element must be checked—seek out, and remove the cause, and simultaneously attack its localities. I am Sir, your very obedient servant,

JOHN LANGLEY.

**The London Medical
AND
Surgical Journal.**

Saturday, December 19th, 1835.

— — —
**THE PROFESSORSHIP OF SURGERY IN
THE UNIVERSITY OF EDINBURGH.**

THE vacant chair of Surgery in the University of Edinburgh is, we understand, to be offered to Sir Charles Bell. In this event, the Town Council will evince a judgment in the choice of a professor, which it were to be wished they had more frequently exercised—the consecrated seats of the Cullens,

* An objection has obtained, that leech bites have a tendency to increase the irritation of the part sought to be relieved—the punctures of half a dozen may do so, but twenty or thirty so far relieve the local congestion and tension, that their greater advantage overcomes the lesser evil; the same opinion might apply with equal force to scarifications.

the Monros, the Blacks, and the Gregories, having been of late years too often occupied by individuals previously unheard of; so that if they have been respectably filled, which we admit has generally been the case, the thanks are due to fortune and not to the Town-Council of the good city of Edinburgh.

If Sir Charles Bell accepts the proffered honour, he will, no doubt, raise the Edinburgh School of Surgery to a high degree of eminence. We may add that he will find a field well worthy of his transcendent abilities. The *pures* in our part of the world have taken it into their heads that Edinburgh surgery is a hundred years behind London surgery; but we can assure them from an extensive and impartial comparison, derived from our personal experience, that they labour under a grievous mistake, and that their Northern brethren, so far from being behind, are very considerably in advance of them. The Edinburgh surgeons are for the most part better anatomists, better pathologists, quite as good operators, and incomparably more learned men than those of the English metropolis. That they are better anatomists is an opinion in which perhaps not many will agree with us, yet we are perfectly convinced of its accuracy. There is a material difference in the method of studying anatomy in the two schools; in London the student attains a very exact knowledge of mere structural anatomy; but this knowledge is generally too little blended with physiology and pathology, and, thus deprived of the relations which give it real value and applicability, it very speedily evaporates; there is nothing to render its hold on the memory permanent, the most trivial and the most important facts presenting themselves with equal claims to attention; accordingly it too frequently happens that the student, after he has been ten years in practice, is extremely innocent of all anatomy whatsoever: in Edinburgh, on the other

hand, anatomy is taught chiefly with reference to physiology and the practice of surgery; so that the student is enabled to discriminate what is worth remembering, while his reason and observation come to the aid of his memory in the retention of those facts which have any important bearing.

Anatomy presents itself to the London and Edinburgh student under aspects entirely different; a great number of Edinburgh students, though diligent, would be rejected on anatomy by the London College of Surgeons, and a still greater number of London students, though equally diligent, would be rejected by the College in Edinburgh.

That the Edinburgh surgeons should be better pathologists than those of London, is very easily accounted for by the joint cultivation of physic and surgery in the Northern metropolis, where most of the physicians would be ashamed of themselves, and very justly so, if they were not found "good at need" in the capacity of surgeons, and where almost all the surgeons, even those connected with hospitals, are general practitioners, and in the constant exercise of every branch of their profession.

That the Edinburgh surgeons should be better educated men than those of London, is just as easily accounted for by the fact that a great many of them are actually doctors of medicine, and that almost all have enjoyed, to a greater or less extent, the advantages of an academical education.

But to return from this digression on the comparative merits of London and Edinburgh surgery.

If Sir Charles Bell accepts the chair of surgery, *Edinburgh* will make a great acquisition; but will such an event speak well for the encouragement given to professional talent in *London*?

Will it be creditable, we ask, to the state of the profession, or to the discernment of the public in this metropolis, that one of the most distinguished

surgeons, and, beyond all rivalry, the greatest physiologist of the age, should, after twenty years' residence in London, have found so little inducement to remain there as to accept an academical situation in Edinburgh? We answer *no*, it would not be creditable. The truth is, that every man of high talent and unblemished character, must feel chagrined at being thrown into the background by a set of shallow coxcombs and unblushing knaves—at finding experimentally that "the race is not to the swift, nor the battle to the strong"—that distinguished talents are of little avail, and that an honourable character, so far from being an advantage, is a direct drawback, by preventing him who bears it from descending to the mean artifices, the vile sycophancy, and the disgraceful humbug by which the "heads of the profession" too often attain to a "bad eminence."

Again, does it speak well for the public spirit of the largest and wealthiest metropolis in Europe, that it has no academical honours to confer, and that it has no better distinction to offer to the most meritorious members of a learned profession, than the presidency of one of two corporations—it were profane to call them colleges—a connexion with which, in any capacity, is derogatory to the character of a gentleman?

We say a connexion in *any* capacity; since to be of the number of the rulers is to fraternize with bullies and rogues; to be of the number of the ruled is to bend the neck to a slavish subserviency; and to be the ostensible head of so despicable a body, is, in reality, to be "the great toe of an *unpopular* assembly"—it is to stand forth as the type of its aggregate vices; of the insolence of the bullies, the dishonesty of the rogues, and the meanness and pusillanimity of those who quietly allow themselves to be browbeaten and cheated.

Such are now the honours to which each *legitimate* son of Æsculapius

(pure to wit, all the rest are bastards), may, by a remote possibility attain; but we hope most sincerely that many years will not elapse ere a London University, rich in its endowments, and patriotic in its spirit, will hold out stronger inducements to exertion, and nobler rewards to merit.

LONDON MEDICAL SOCIETY.

Monday, December 14, 1835.

DR. WHITING, PRESIDENT.

THE Society was occupied this evening with the discussion of a case that had now terminated, and which in its progress, had been related to the Society last Session. A variety of opinions were expressed, as to the proper name of the disease; but as we cannot give the case in full, we have thought it the most proper proceeding to merely notice the discussion in this manner.

—o—

WESTERN MEDICAL ASSOCIATION.

Thursday, December 10, 1835.

DR. RYAN, PRESIDENT, IN THE CHAIR.

The Poor Law Amendment Bill.

MR. VERRAL's paper on the Poor Law Amendment Bill having given rise to an animated discussion at a previous meeting of the Association, it was then agreed that a petition should be presented to Parliament on the subject. The petition was laid before the Association this evening, as drawn by a committee appointed for that purpose, and after some observations from Drs. Ryan and Epps, Mr. Verral and other gentlemen, the following petition was agreed to.

The humble petition of the Western Medical Association, to the Honourable House of Commons in Parliament assembled,

Sheweth—That your petitioners are members of a Society, entitled "The Western Medical Association," established for the purpose of improving themselves in the science of medicine, and of exalting the character of the medical profession.

That your petitioners have beheld with considerable alarm the proceedings under the *New Poor Law Act*, in reference both to the mode of employment and the remuneration of the medical officers connected with the various parishes in England.

That your petitioners are satisfied that every candid mind must acknowledge that the remuneration of medical men under the old system was of a most inadequate character; a character changed most considerably for the worse under the *regulations* of the Poor Law Commissioners.

That your petitioners are further convinced that, in regard to the method adopted

in obtaining medical assistance, the power placed in the hands of guardians in distributing parishes and districts, is at once unjust to the profession, and injurious to the poor.

That in regard to the profession, your petitioners are convinced they are unjust, inasmuch as they arbitrarily dispose of that practice which a practitioner may have obtained by his industry, skill, and attention; inasmuch as they introduce a comparative stranger, upon no other reason than a difference in *pecuniary bidding* for services to be rendered, into the midst of a practice and the connexion of the original and established practitioner.

That your petitioners are satisfied that, in regard to the *poor*, the regulations are injurious, as placing them at the mercy of a stranger, who may obtain the power over their sick persons by bidding a few pounds lower than that of a man, who, from a long experience, knows the relationship between the kind-hearted medical practitioner and his afflicted brethren of the human race; and who knows, also, that there are many attentions which no pecuniary aid can ever compensate. And that further, the universal enforcement of the system of *tender* must induce a perpetual ill-will among medical men, a destruction of the professional character, and finally, establish an amount of remuneration totally inadequate to the services required.

That your petitioners feel convinced that individuals who will thus consent to undervalue professional services must have motives of no superior character; that their chief hope must be, that, by a limited supply of inferior medicines and of inferior attention, they may be enabled to render the contract not so great a loss; encouraged at the same time by the hope, that, patronized by the guardians, they may be enabled to worm their way into the bosom of respectable families, and thereby to supplant men more talented, or at least better acquainted with the wants of a district than a stranger can possibly be.

That your petitioners therefore pray your honourable House to take this matter into your serious consideration; a desire they the more willingly express, being convinced that it is the wish of your honourable House, both that every possible emendation should be made in the *New Poor Law Act*, and also that the education of the members of the medical profession should be as perfect as possible; an education involving a very considerable expense, which ought to be regarded in estimating the value of the services tendered, so as to ensure an adequate remuneration.

And your petitioners further add, that they will be happy to prove the truth of the allegations in this, their petition, before a Committee of your honourable House.

And your petitioners, &c.

WESTMINSTER MEDICAL SOCIETY.

Saturday, Dec. 12, 1835.

RICHARD QUAIN, ESQ. in the Chair.

*Eczema—Hæmoptysis—Death of Mr. Mart.
—Favourable Report respecting Mineral
Magnetism.*

DR. ADDISON, in consequence of the case of eczema related last week, placed before the Society, some very beautiful models representing the ordinary species of that disease. He was glad to see the attention of the Society directed to cutaneous diseases, as there was no class of maladies so little understood, or on which a wrong diagnosis respecting could more affect the reputation of the medical practitioner. With respect to Mr. Thomson's case, he still thought Bateman had described two instances in which precisely similar symptoms occurred, except that the form of the exfoliation was not so exquisite, and there was vesication; and he (Dr. A.) had no doubt that the disease might appear merely inflammatory with imperceptible vesication. Mr. T.'s case was evidently eczema rubrum. The cause of the exfoliation being so exquisite, he considered to arise from the imperfect manifestation of the vesicular eruption, which allowed the deposition of fluid between the cuticle and cutis vera, so that the former was consequently raised. Now, Dr. Copland had mentioned the presence of gastro-enterite in eczema; but was the gastro-enterite dependent on eczema, or was it merely a sequela to it? It was difficult to suppose the first, because eczema often arose from local irritation; but as we often meet with gastro-enterite in that disease, it is probably a sequela to it; besides, liquor arsenicales and other irritants were given with good effect in eczema; which if it were dependent on gastro-enterite would not be the case.

Dr. Johnson believed the novelty of Mr. Thomson's case consisted in the periodicity, not the recurrence of the attacks. He wished to inquire, did the cases referred to by Dr. Addison exhibit that peculiarity?

Dr. Addison remarked that the statements of patients could not always be relied on; he could not say the attack took place exactly at the seventh week; but he believed that was about the usual time. Dr. Bateman in one of his cases mentions that the attack recurred regularly once a month for a considerable time.

Mr. H. Thomson brought the case forward as showing a variety of the disease. Had a young member of the profession expected to find that variety described in authors, he believed he would have failed to recognize it.

Mr. Salmon understood there was some vesication in Mr. Thomson's case, about the shoulders.

Mr. Thomson remarked there was slight vesication in the second attack, but it was so exceedingly minute, as to be detected with the greatest difficulty.

Dr. Addison said it often required a mi-

croscope to detect the vesication in this disease. With respect to the prescription which had led to some conversation at the last meeting, he was sure that a decomposition must have taken place; but whether the arseniate of quinine which was formed, was less valuable as a medicine than the simple quinine was another question. He thought the clearer we steered from unchemical preparations the better.

Mr. Salmon, when connected with the General Dispensary, had always been able to detect the slight unevenness of the surface, by passing his fingers over it, covered with flour or pure magnesia.

Dr. Johnson was not an advocate for unchemical compounds, but as we find many medicines which are called unchemical, very serviceable in practice; for example, the tartrate of antimony and the sulphate of magnesia were a good illustration. While on his legs he begged to ask the Society, in how short a time hæmoptysis proves fatal? the Society had just lost another valuable member, Mr. Mart, besides Sir D. Barry, from that disease. That gentleman had been subject for the last two months to a dry cough, and had resided in the country, coming to town occasionally on business. Dr. J. did not see him during that time. He was called to see him yesterday morning, in consequence of an attack of hæmoptysis, but he could not attend sooner than 5 o'clock P. M. Mr. Lambert was called in and bled him; the blood coughed up at that period did not exceed a tea-cupful. Dr. J. visited him at five in the evening. The blood that had been abstracted was cupped; the hæmoptysis since the morning had not been violent, the sputa only being slightly tinged with blood. The pulse was a little accelerated; the blood thrown up became a little more florid; and the cough more frequent. Dr. J. feared another attack, and did not apply the stethoscope. The bowels had been moved, and 1 grain of the superacetate of lead, and $\frac{1}{2}$ grain of opium were ordered to be given. Almost directly afterward hæmorrhage followed, and he died at 9 o'clock. The body had not been examined; but he should endeavour to get permission so to do.

Dr. Addison said, without an autopsic examination no certain opinion could be given. Aneurism might have existed. He remembered a case at Guy's hospital, in which the patient suddenly threw up a large quantity of blood whilst on the close stool, and died. He was supposed to have had hæmoptysis. On examination, however, it was found death resulted from the bursting of an aneurismal tumour.

Dr. Johnson was induced to believe Mr. Mart's case was not one of aneurism, from the fact of the first attack not proving fatal.

Mr. Thomson related a case, in which a patient had sudden hæmoptysis in the morning, but lived till 7 P. M., when he suddenly vomited a large quantity of blood, and died. On examination, it was found an immense

vomica had partially burst in the morning; and that in the evening more blood having accumulated was thrown up, and proved fatal. The lungs were much diseased. He thought it was probable that Dr. Johnson would find a large vomica in Mr. Mart's case.

Several other cases were related; but as no post-mortem examinations were allowed, they were not considered satisfactory.

Mr. Horne saw Mr. Mart about a month ago, when he stated to the patient's friends that the disease would shortly end fatally. He was then informed that Dr. Clarke had given the same opinion.

Mr. Lambert replied, Dr. Clarke had never given that opinion; but Mr. Davidson immediately rose and confirmed the statement of Mr. Horne. In answer to a question by Mr. Horne, Mr. Lambert replied that he had never thought Mr. Mart's lungs were much affected, for he had only a slight cough.

A conversation now ensued, with respect to the names of Messrs. Watkins and Hill having been mentioned to forward the views of Dr. Schmidt, in which it was stated by a member that that firm had authorized him to contradict the statement that had been made, they never having had anything to do with the matter.

Dr. Schmidt was allowed to explain, that the offer of competition was made to Messrs. Watkins and Hill, through a Mr. Wilkinson of Pall-Mall; and that the reward of 100*l.* was offered by a gentleman near Manchester, if they could produce magnets of equal power with Dr. S.'s. They tried and failed; attributing their failure to the inferiority of the English steel to that of the German.

Mr. Hale Thomson now was called on for the report of those cases in which Dr. Schmidt had tried the effect of his magnets. He could not as yet assert that any benefit had resulted from such application; but he believed he could positively assert, in opposition to the opinion expressed by Dr. Ritchie, that a decided physiological effect could be produced by the application of the magnet as recommended by Dr. Schmidt. Dr. S. had selected four cases of amaurosis as fair ones for the trial; lachrymation was distinctly produced in every case by the application of the instrument, with great mobility of the iris. In addition to this fact he would mention the case of a boy who was received that afternoon into the Westminster Hospital, with permanent dilatation of the pupils from concussion of the brain. The magnet was applied for three minutes, and the iris contracted. The experiment was repeated, and a further contraction took place, which was permanent. These experiments were conducted in the presence of Mr. Soden, the House Surgeon, who agreed with Mr. Thomson as to the result.

Dr. Webster had witnessed the application in the cases of amaurosis mentioned by Mr. Thomson. In one of these cases, that of a woman, she expressed herself as having been benefitted. The other three had as yet re-

ceived no relief; but, on the contrary, complained of their vision being rather more clouded.

Mr. Holt mentioned the case of his daughter, who had been deaf for some time. Dr. Schmidt's magnets were applied five times, and the results were decidedly beneficial, the hearing having improved.

Further reports were requested by the Society, which then adjourned.

Hospital Reports.

NORTH LONDON HOSPITAL.

Case of Dyspepsia, Scrofula, and Phthisis, with Clinical Remarks by Dr. Elliotson.

E. G., aged 29, was admitted on the 8th of September; the report states that "he was first affected with scrofula 17 years ago; it had made dreadful ravages in his arms and legs; the left elbow-joint is stiffened, and pieces of bone have been constantly coming away; one piece, he says, was three inches long. In consequence of his great suffering he has taken opium for the last three years, to relieve the pain. He believes none of his relations have been affected with scrofula. A few months since, he had an attack of diarrhoea, which was followed by ascites; there is now evident fluctuation." Now, this was a case in which generous diet was indicated, animal food, as much as was convenient to the stomach, and malt drinks. Conjoined with these, we gave the carbonate of iron; iodine also was likely to do good; we therefore gave him one of its mildest preparations, the hydriodate of potash. Had he pursued this plan of treatment for six or eight months, according to my wishes, there is no doubt he would have been very much relieved, for he was evidently improving when he left, having a desire to go home.

The next two cases were still more unsatisfactory, for the patients died: they were cases of phthisis. Both the patients came in with excavations in their lungs; in one case, that of a young man, aged 29, the excavation was slight, and there was sub-mucous r le. In that of the woman, aged 36, large excavations were detected by the stethoscope. Now, some people affirm that they can cure consumption: I cannot; I have tried every thing that has been recommended, but without success. When the disease is threatened, I believe we can do good, by strengthening the system. Wearing flannels, the use of the shower bath, living regularly and uniformly as regards diet, and proper exercise in the fresh air, I believe have saved many patients who have been threatened with phthisis; but when the tuberculous matter is formed, we can only relieve suffering. In all cases where there is new formations, there is no

remedy in medicine, whether those new formations be of a strumous melanotic or scirrhus character. We may prevent the condition that gives rise to them; but when they are once formed, we cannot remove them. In spite of all care, when phthisis has once come, it will go on. We can relieve some of the sufferings, such as the cough, the night sweatings, and the ulcers, by inhalation; but we have no power over the tuberculous deposit. In the case of the woman, I endeavoured to afford her some relief, by ordering her to inhale creosote; she was, however, so weak she had scarcely strength to use it. I contented myself with allowing her anything she might fancy, with small doses of opium to relieve her cough and procure sleep.

Inhaling is sometimes attended with benefit; laudanum, or the tincture of hyoscyamus mixed in warm water, and the steam drawn into the lungs, have been sometimes attended with good effects: iodine in solution has been also recommended; but it is a very acrid substance, and the use of it is frequently followed by hæmorrhage: I doubt if it is a good application either for the ulceration or the system of the patient. I have seen benefit result from the use of chlorine, but more from that of creosote; of course there must be no inflammation when that medicine is used. I have certainly seen, in cases in which I have employed it, an improvement in the expectoration; the cough has become easier, and patients have lived longer than I expected they would have done; of course I cannot say that those who have inhaled creosote have lived longer than they otherwise would have done, for these sort of cases are so uncertain; but the young man, whose case we have mentioned, inhaled the creosote, and he certainly lived longer than I expected he would have done from the state in which he was when admitted. The way in which I order creosote to be inhaled is by putting a few drops of it in cold water, and when it is going to be used to agitate it, and inhale through the liquid; a drop was generally added every time he used it.

Now we will shew the lungs of this patient: there was pectoriloquy and cavernous respiration under both clavicles; you see the right lung is one mass of tuberculous deposit; the ulceration is greatest at the upper part; it began there first, and of course is more advanced; you perceive the upper part is a complete sac, the middle part is less ulcerated, and the lower one still less. Here is the left lung; the upper part contains a larger cavity; you will remember there was pectoriloquy on this side too. It is usual for the left lung to be more diseased than the right, but the contrary occurs in this case. There is no tuberculous matter at the lower part of the left lung. The heart is small in this case, as it generally is in phthisical patients; by accident it may

be larger, but it is generally smaller than natural.

Anasarca Phlogistica.—Phlebitis—Application of the Nitrate of Silver.

Mary Anne Cates, aged 18, was admitted November the 10th, under the care of Dr. Elliottson. She is a housemaid, and has had amenorrhœa for nine months, during which time she has suffered from headach and debility. Six months ago she was bled, and took medicines for the suppressed menstruation, but was not relieved. A fortnight ago, her feet and ankles began to swell, next day the swelling extended up to the knees; the face and arms became œdematous, and the abdomen began to enlarge. At the present time her feet and ankles are swelled, and pit on pressure; there is slight erythema there, her face is pale and œdematous, arms and hands swollen, the abdomen is enlarged, and painful on pressure, the skin natural. She complains of pain in the loins, shooting pains in the head, worse at night, urine almost suppressed the last fortnight; what little there was, was high coloured. She has taken some drops the last three days, which last night occasioned a copious flow of urine. Bowels regular; auscultation detects a bellows sound synchronous with the pulse; she has shortness of breath after running up stairs, or making exertion of any sort. She was bled to ℥ xvj. , and half an ounce of cream of tartar, with ten grains of the powder jalap, were ordered every morning.

11th. Pulse 108, weaker; urine scanty, neutral, albuminous; blood not buffed, or cupped; the headach has left her; her legs are not so hot at night; the eruption is not so vivid; has still pain in the abdomen.

12th. Œdema of face much subsided; pain in the abdomen gone; pulse 88; œdema of the right hand and arm has subsided, from the serum running away at the puncture made at the venesection; that of the left hand and arm also nearly gone; complains of some headach.

14th. Her foot and arm are very painful.

15th. Had a shivering fit, which lasted from 1 to 3 P. M., succeeded by heat; complains of pains all over her, but chiefly in the loins; has great thirst; pulse 100, full; tongue dry, reddish at the tip; lips dry; teeth loose; bowels still relaxed.

16th. Erysipelas has taken place in the forearm; the solution of nitrate of silver was applied to the inflamed surface.

18th. She is very irritable; the tongue and lips dry; the arm quite raw.

19th. Tongue dry; skin hot, and dry; pulse rapid; there is evident phlebitis; the nitrate of silver solution was applied in the course of the vein, and the ung. hydrarg. fort. ℥ j rubbed into the thighs every hour; symptoms of gastritis have also come on, for which twenty leeches and a blister were afterwards applied.

20th. The phlebitis is spreading; the caustic solution repeated; inflammation has spread along the vein to the axilla; constitutional symptoms, much as yesterday; pulse hard, 108; gastritis much relieved; the solution of the nitrate of silver applied to the arm as high up as the axilla; she is evidently sinking fast, her pulse is vernicular, tongue dry, skin still hot; is in no pain, but has great difficulty of breathing; no power to expectorate. Died this afternoon.

Autopsy.—The cephalic vein was distended with pus and coagulated fibrine, the coats of the vein were indurated from the bend of the elbow, to its junction with the axillary vein; the surrounding subcutaneous cellular tissue was healthy, except being œdematous. The synovial membrane of the shoulder joint contained pus and synovia. The heart was healthy, but contained some clots; the stomach contained a greyish gelatinous mucus; there was redness at the cardiac orifice, continuous with a similar state of the mucous membrane of the œsophagus, which presented several detached patches of redness, and also contained a greyish gelatinous mucus, similar to that found in the stomach; this mucus was of the consistence of mucilage; the spleen was enlarged and congested; the intestines, liver, and lungs, healthy throughout; the kidneys were large, and had assumed appearances of the commencement of granulation. There was erysipelas in the ward.

Dr. Elliotson remarked of this case, that it is evident that in inflammation of a vein, that other veins, situated in different parts of the body, suffer under the same affection; the inflammation is not continuous, but the parts seem to suffer from sympathy; he had seen cases in which distant veins from the original seat of the disease, had become affected, in which there was no line of continuity. If then, you are successful in subduing inflammation in one vein, there may be such irritations in other veins, that the patient sinks. With regard to the application of the caustic, he considered it in sub-phlebitis, an excellent application; a friend of his had applied it with the best effect in a case which did not, however, arise from the absorption of a morbid poison. It did not in the above case succeed; but there was no room for antiphlogistic treatment, and it is probable no other remedy would have been successful.

Efficacy of Hydriodate of Potass in Caries Ossium.

William M— was admitted November the 10th, under the care of Dr. Elliotson. He is a carman, of moderate habits, never addicted to drinking; has generally enjoyed good health. He was kicked by a horse nine years ago, from which accident he felt little inconvenience, except two black eyes, until four years afterwards, when he felt a gnawing pain in the bones of his head, which continued for several hours together, and has

lasted until the present time. Five pieces of bone have been discharged from his nose, which circumstance has caused some degree of disfigurement in that organ. He now complains of violent pains in his head, commencing in the forehead, and sometimes extending to the occiput: in other respects his health is good; tongue clean; pulse 92, moderately full; appetite good; no thirst; bowels open.

Four grains of the hydriodate of potass in solution, were ordered three times a day.

17th. Much easier, better altogether.

18th. Has now no pain; from this time he continued quite easy, and was discharged on the 1st of December, quite relieved.

Dr. Elliotson remarked that this was a case proving the efficacy of hydriodate of potass in caries of the bones of the head.—It was a good example also of the evil resulting from injuries, which at the time they were received seemed of no consequence, but after a long time, break out in a serious disease. He had often seen affections of a like nature in old people, resulting from injuries they had received when young. With respect to the remedy, it was also of great benefit in perioritis, instances of which had been seen in the hospital. Sarsaparilla would never have done so much good. It would have been interesting to watch this patient for two or three months, but that would have been impossible in an hospital; he was, however, told to return if he felt at all ill.

Sedatives in Delirium.

E. J., aged 40, was admitted Nov. 18, under the care of Dr. Elliotson; he is a chair maker, strong and muscular, formerly of intemperate habits, drinking considerable quantities of rum; he has generally enjoyed a good state of health; but about six months since, he caught cold and suffered under a disease of the chest. He entirely recovered from this illness in a few days, and resumed his work. About a fortnight ago he again caught cold, and was seized with a violent pain in the chest, difficulty of breathing, cough, and fever. He was attended by a surgeon who bled him three times, and gave him medicines, by which means his health became considerably improved. Last week his head became confused, and his intellects were impaired—he was in a state of delirium when he was admitted into the hospital. A strait jacket was employed in consequence of his violence, half a grain of the muriate of morphia was given him.

Nov. 20th. He is much better; perfectly rational; the skin is moist and of a natural temperature; tongue clean; appetite improved; he has, however, great thirst; pulse 80, moderately full; bowels open yesterday. He complains of a slight pain across the forehead, and his voice is very hoarse; there is a troublesome cough; no morbid signs on auscultation. He only took two doses of the

medicine, and was quite relieved and left the hospital.

Dr. Elliotson said, this was a case proving the efficacy of narcotics in delirium arising from weakness, and which is often seen in persons of intemperate habits. It is necessary before administering narcotics in cases of delirium, to carefully observe if there be any flush in the face, or suffusion of the eyes; if there be, it will be necessary to bleed. This man only took two doses of the medicine. It was not only in such cases as this that the sedative plan of treatment was of benefit, but it was exceedingly useful in cases of partial insanity, unattended by inflammation. A case had been recorded in one of the journals (see Dr. Ryan's Journal, vol. 7, p. 381,) in which he (Dr. E.) had employed sedatives with success in a case of monomania. Dr. Seymour had recorded many others. Acetate of morphia is generally preferred by that gentleman, but the muriate is as good. Bleeding and mercury would have been the practice in former times. This man had been bled three times, before his admission, for another disease.

—o—

PROFESSORSHIP OF SURGERY IN THE UNIVERSITY OF EDINBURGH.

Sir Charles Bell is elected, we believe, to the office of surgeon in the University of Edinburgh. An erroneous report has been going the round of the profession, that Mr. Liston was a candidate. Now, the fact is this: Mr. L. said from the beginning, that no appointment could be offered to him which could induce him to leave London; but, of course, he could not but feel flattered that his return to Edinburgh should be desired. He could not feel any objection to be nominated as a candidate for the vacant office, but, as to accepting the appointment, he never had the slightest intention of doing so.

BOOKS.

A Treatise on the Diseases of the Eye and its Appendages. By Richard Middlemore, M.R.C.S., Surgeon to the Birmingham Eye Infirmary. 2 vols. 8vo. London. 1835.

Rudiments of Physiology, in Three Parts. Part I. On Organism.—Part II. On Life, as manifested in Irritation.—Part III. On Life, as manifested in Sensation and Thought. By John Fletcher, M.D., F.R.C.S.E. Part I. 8vo. pp. 156. Edinburgh. 1835.

A Synoptical Chart of Diseases of the Eye, their Classification, Seat, Symptoms, Causes, and Treatment. By John Harrison Curtis, Esq., &c. &c.

A very correct and useful chart for students and junior practitioners.

Portrait of Professor Tiedemann.

This is an excellent likeness.

On the Perforation and Division of Permanent Stricture of the Urethra by the Lanced Stilettes, with Observations on the Nature and Treatment of Spasmodic and inflammatory Stricture, and various other Urethral Affections. By R. A. Stafford, Surgeon to the Marylebone Infirmary, &c. Third Edition, 8vo. pp. 322. Longman and Co.

The British Medical Almanack, with Supplement, for 1836; containing a Chronological History of Medicine, from the German of Hecker; a complete Account of all the Medical Institutions in England, Scotland, Dublin, and Paris, with Lists of all their Medical Officers the Subjects of Medical and Scientific Prizes, &c. The Supplement contains Dr. Grant's Classification of the Animal Kingdom; Species of Men; Statistics; Weight of the Human Body at all Ages; Laws of Human Mortality, deduced from the latest Observations in England, Belgium, France, and Sweden; Comparative Mortality in all the English Counties; Mortality and Sickness in the English and French Armies; the Proportion of Sickness at every Age; Statistics of the English Hospitals; Cholera; Bills of Mortality; Laws of Disease; Magendie's Formulary of New Medicines, with additions; Creosote; Tests of the Urine; Hydrometer; Auscultation; Percussion; Physical Signs of Thoracic Diseases; Antidotes of Poisons; the Anatomy Act, &c. &c. 1835.

Manual of Practical Midwifery; containing a description of Natural and Difficult Labours, with their Management. Intended chiefly as a Book of Reference for Students and Junior Practitioners. Illustrated by fifteen Engravings. By James Reid, M.D., Member of the Royal College of Surgeons in London and Edinburgh. 12mo. pp. 245. London: Churchill. 1836.

Nouvelles Recherches sur le Rhumatisme Articulaire Aigu en General et Specialement sur la loi de coincidence de la Pericardite, et de l'Endocardite avec cet Maladie, ainsi que sur l'efficacite de la formule des emissions sanguines coup sur coup dans son traitement. Par J. Bouillaud, Professeur de Clinique Medicale à la Faculté de Médecine de Paris. 8vo. pp. 162. Paris and London. J. B. Bailliere.

The Obstetrician's Vademecum; or Aphorisms on Natural and Difficult Parturition; the application and use of Instruments in Preternatural Labours; on Labours complicated with Hæmorrhage, Convulsions, &c., &c. By Thomas Denman, M.D., Licentiate in Midwifery of the College of Surgeons, London, and Hon. Member of the Royal Medical Society at Edinburgh. Considerably augmented and arranged according to the present state of Obstetrics, by Michael Ryan, M.D., Member of the Royal College of Physicians, London, &c., &c. Ninth Edition. Illustrated with Seventeen Plates. 12mo. pp. 231. London: E. Cox. 1836.

By JAMES MANBY GULLY, M.D.

LECTURE XXVIII.

*Treatment of Chronic Duodenitis and Enteritis,
and of Hypochondriacism.*

FOR chronic duodenitis the treatment is the same as when the irritation predominates in the pyloric region. I suppose the disease to commence with jaundice, as it commonly does, for the majority of the attacks of jaundice are owing to duodenites, which prevent the bile from descending into the digestive canal, and thus cause its absorption.

When an individual is affected with jaundice, whether there be pain of the right side or not, he always presents the signs of gastro duodenitis — loss of appetite, dry tongue, tension of the hypochondrium, great thirst, &c. A few leeches applied to the region of the pylorus and duodenum do away with these symptoms, and mild drinks finish the cure, provided the disease occupies the first portion of the duodenum, constituting pyloro-duodenitis, and it be recent.

When the duodenitis is of longer standing, or has been treated by one of those administrators of emetics who maintain that gastric disorder is an entity, the specific for which is tartar emetic, it is not so readily cured: there is a tendency to organic change of the liver, and general gastro-enteritis. In such case you should practise bleedings, especially if there be congestion of the liver and the patients be plethoric, great feeders, with broad face and capacious bellies, and daily consumers of huge quantities of food. You first of all bleed, and then apply from thirty to fifty leeches to the right hypochondrium, with emollient poultices, giving at the same time mild and cooling drinks. Have no care of the precept laid down by Hippocrates, not to withdraw wine from those who are in the habit of having it—de-

prive them of it without any pity: they grumble at first, but in a day or two are glad to console themselves with a glass of cold water. If you do not treat them thus, the inflammation seizes on many organs, and you can no longer arrest it. In its highest degree you give them no food at all, but merely saccharine and mucilagino-saccharine drinks. On the reappearance of appetite, and disappearance of the fever, you allow them to have thin arrow root, sago, and similar mild aliments, and two or three hours after ingestion you give them small quantities of some cold saccharine fluid. If they become weak, and these aliments pass rapidly through them, you give them something more substantial. If after long use of aqueous fluids and light food they are no longer able to tolerate them, and are rather capable of digesting meat without bread, you must allow them to take it. Be not exclusive in diet: watery aliments suit strong persons who have not been debilitated, but if you have to deal with weak, flaccid, and asthenic individuals, you cannot always succeed with such aliments, for they surcharge the stomach: you must give more nutritious matters, such as rice cakes, strong soups, eggs—eggs, by the way, are unfit for excitable persons, being almost as irritating as wine—a few mouthfuls of fresh fish or white meat, without allowing to drink at the time, but ordering a small quantity of cold drink two or three hours afterwards. After supporting this diet for some time, you may give them greater latitude.

Green vegetable diet has been too much bepraised as that which is appropriate to duodenitis: it only agrees with strong, full-blooded, and inflammatory subjects. Such persons you may keep on this diet for two or three months, if the disease be of long standing, and we have Van Swieten's authority for this: but give none of your depuratory juices, water cress, horse radish, and such like—it is all quackery. When you have to deal with persons that are always pale, constipated, with colourless motions and no bile, and a tendency to dropsical disease, such diet is improper, it would not be digested. You must then study what best agrees with them, and act accordingly:

in the event of your giving meat, correct it with cold and refreshing drinks.

Generally speaking, these diseases are desperate affairs, for they remain in a state of fixity, the liver having ceased to secrete. Yet I have known persons who, after secreting bile as pale as possible, at length had it as best coloured as the most healthy; and I conducted them to this state by a gradual passage from the lightest to the strongest food. Be not, therefore, too rash in losing all hope of such patients, unless indeed they be inveterate spirit drinkers. Spirits have not only a stimulating effect, but a specific action on the nervous system, which they seem to penetrate, and upon which they produce a modification different from inflammation, for they destroy its vitality, and sometimes give it a species of stimulation that is accompanied with a debility and convulsive agitation of the muscles, that has been called delirium tremens, against which opium is commonly used: of this we shall have occasion to speak hereafter.

I cannot imagine how some persons reconcile themselves to the use of purgatives, calomel, jalap, bitters, &c., with the intent of re-establishing the secretion of the liver. I never saw a patient completely cured by such means. I am aware that purgatives do very well for some individuals, and that they give temporary relief—their constipation ceases, and the appetite returns. But all this is factitious: patients so treated, become tributary to the apothecary, and drag on a miserable existence. In the winter they take pills, and in summer they go to watering places: after eight, ten, or fifteen years they die by consumption or dropsy. *Thus it is that the rich gluttons of England live and die; they are first sick from intemperance, and then they are finished off by purgatives.* If you would have a complete cure, you should make these robust, constipated persons stay by antiphlogistic regimen; apply forty to sixty leeches over the liver if they be males, and twenty to thirty if females; take all stimulants from them, and put them on vegetable diet. If the constipation embarrasses you, either make them drink cold fluids after meals, as before directed, or give slightly purgative clysters: vegetables and ripe fruit will also assist in relaxing the bowels; if the patient is firm to your directions, his bowels will at length open without any artificial means: in this manner I have cured persons that have been constipated for a dozen years. When they have colicky pains, give emollient clysters. Should they have contracted the habit of taking purgatives, gradually withdraw them, and substitute vegetable diet; in this manner I have made many recover who digested artificially by means of purgatives and medicinal waters.

The treatment of chronic enteritis is pretty nearly the same, only that you have the advantage of a sound stomach and duodenum, of the patient not suffering during the first

digestion, and that you have only borborygmi and lancinating pains. If the patient be not broken, and has no large mesenteric masses in the belly, the antiphlogistic treatment may be perfectly successful; but you must place him on diet just as severe as if he had a more serious complaint. Soups are best for him: you have greater latitude as regards the stomach, but for this very reason you should lay down your rules with greater severity.

The nervous sensibility being exalted, you give opium internally in fractional doses, or by the endermic method on the various abdominal regions.

When the disease is far advanced, and there are large and indurated ganglions, probably contractions, ulcerations about the ileo-cæcal region, &c., the case is serious: you must then insist on antiphlogistic regimen for a longer period, and have recourse to exutories.

Treatment of the Neuropathic State consequent on Gastro-enteritis.—I have already stated that this neuropathic condition is frequently conjoined with chronic phlegmasia of the upper portion of the digestive canal, but scarcely ever with that of the lower portion or colon alone, and that this is owing to the greater influence excited by the upper portions over the sensitive centres.

In the first place, this neuropathic state requires the treatment peculiar to its cause, or to partial gastritis, for it seldom attends on general gastritis, which is much too serious to have it alone for a consequence. In fact, the state in question does not indicate any serious disease: hypochondriacs are not confined to bed, and can go about as they please, whereas general gastritis allows of no such thing. The remedy for the neuropathic condition is therefore that of partial gastritis; but are there no others? The empirical physician, who never reasons, may certainly agree in saying it is proper to nourish the patient with feculent and gelatinous substances, apply leeches from time to time to the affected part, &c.; but he would moreover give something else for the nervous symptoms, and what would that be? why, opium, assafoetida, valerian, camphor, musk, in short, antispasmodics, which have a diametrically opposite action to that of emollients, which prevent the cure and give rise to a series of perturbative movements, by which those of the original disease are masked; the patients fancy themselves freed from the disease, but after some time it reappears in a more acute form, and forces him to have recourse to antiphlogistics, after which, he again flies to antispasmodics, and so he goes on, until the disorganization is consummated. Thus it is that the diseases in question are perpetuated, and ultimately prove fatal. Treated in this manner, they represent to you what emetics in gastric disorder represent in a much shorter space of time.

What had we better do? Persuade the patient that when the internal irritation is subdued, the neuropathic condition will cease, and then, if it has not altogether disappeared by the use of antiphlogistics, we must try to get rid of it by other means. I have already pointed out opium and other narcotics introduced by the skin in preference: but the principal remedy, that which stands in place of all others, is distraction, dissipation, open air, travelling, and mineral waters.

To some persons exercise is hurtful, those, for instance, whose circulation is in bad condition, who are subject to congestions of the liver and stomach, or other viscera; when such persons walk, run, or use their limbs, the heart becomes violently agitated, and congestions of the vena cava and the whole abdomen supervene. You must, therefore, in prescribing exercise, think of something else than revulsion, than making the muscles act, exciting the transpiration, and begetting cheerfulness: you must think of the circulation itself, ascertain the effect of walking on the patient, whether it does not render the heart turgid, unequal, and palpitating in action; you must examine the epigastrium and its arteries—an examination that is the more necessary, as many neuropathic patients have really excessive irritability of the heart. More than this: the neuropathic state is frequently caused by a supernormal action of the heart, that drives the blood with too great violence, or by an enfeebled heart, that allows the blood to accumulate in it. We are not acquainted with the secret of the circulation, nor with that of the connexion of the nervous with the sanguineous system, the visceral arteries are surrounded with such a number of nerves, as to be enclosed as it were in a sheath: now, when the heart is strongly agitated, and drives the blood into those arteries, we behold a source of irritation that is not commonly looked to, but which certainly merits close attention. After antiphlogistics have produced their effects, sedatives of the circulation are soon found, such as digitalis, acetate of lead, opium, narcotine, morphia, hydrocyanic acid, or even cold, when the season allows of it; for I am not exclusive in my method, nor do I refuse any remedy: indeed, I am incapable of looking into any question in an exclusive manner: one disease brings all others to my mind. Here then I terminate what I had to say on the chronic phlegmasia of the digestive canal.

Reply to some General Objections.—In this I purpose to glance over some attacks that have been made against me in a Medical Journal.* As this is a serious question, as

indeed all questions are that refer to disease and the preservation of man's life, I think it important to shew you, at least, once in a way the flimsy manner in which my ideas are attacked, and the unfairness with which they are perverted.

"Doubtlessly," says the journalist, "it is a great and happy idea to make physiology the basis of medicine, and on this score the leader of the physiological school has right to claim the laudation of his contemporaries." "*Doubtless it is a happy idea,*" &c. Here is the passport, the flattery, the honey on the vessel's brim. Now look to the bit-
ters. "But has not this idea been strongly abused by the attempt to refer to irritation or inflammation, all the modifications, all the pathological alterations of which our organs are susceptible?" This is false; I do not refer all these alterations to irritation and inflammation, but I do so in great part, because they, in fact, do depend thereon.

"Physiological physicians have placed themselves out of the range of a great number of facts that may be observed, by recognizing in all disease one sole cause, one effect, and, consequently, only one series of therapeutical agents." This again is false; the physiological doctrine is not confined to one only series of therapeutical means. It admits them all, but assigns to each its just value. Its principles are such as can be applied to every kind of treatment. It retreats from no fact, and rather searches out the most extraordinary, in order to submit them to the trial of its principles, or for the purpose of making trial of itself—meantime, it does not leave them isolated, it brings them together into certain groups of ideas, and this it is by which they are characterized.

"What medical man would be induced to believe that a pseudo-membranous inflammation is an inflammation arrived at the maximum of intensity, when he beholds the most irritating medicines, such as concentrated acids, conquer a disease which antiphlogistics aggravate, or, at least, against which they are powerless?" Here you have an insidious phrase: if you desire to serve an apprenticeship to sophistry, you have here the opportunity. They first of all take phlegmasia in general, without making any distinction: yet it must be particularized. Would you study false membranes on the exterior of the body, or at the apertures of the mucous membranes? Now, I affirm it as a fact, having myself done it, that the formation of such in those parts may be arrested by means of antiphlogistics: I therefore give a formal denial to the contrary assertion. In the next place, it is false to say that the formation of false membranes can be so readily stopped by concentrated acids as is asserted. This you may certify by reading

* Most probably the "*Revue Medicale*" is the journal alluded to: it is the organ of those who profess to follow the Hippocratic mode of studying disease, though articles

from time to time appear in it that do but little honour to the name of the father of medicine.—J. M. G.

M. Bretonneau's work, where you will see how patients die by dozens with false membranes developed in the bronchi and digestive passages, at the very time when concentrated acids were being applied. This proposition is, therefore, without foundation. Moreover, concentrated acids are not applicable to any internal viscus.

"Is it possible to consider dysentery as a superacute enteritis, when we see it yield so rapidly to narcotics?" Neither is there more truth in this—they exasperate it. Besides, in the superacute degree, dysentery is commonly accompanied with gastro-enteritis (formerly called essential fever), a fact attested by all the monographs of dysentery. Dysentery is not a *superacute entity*—they have positively dared to print these words; it very often is so, and all the *classiques* believe it. Now, never does opium succeed in any superacute affection: never can a physician who pretends to be an honest man, and who cares for the lives of his fellow-men, bring himself to treat a superacute dysentery with narcotics. We must retrograde far beyond Pinel, if we would erase dysentery from the list of inflammatory diseases, among which he placed it. The observation above can, therefore, only apply to that dysentery which has lost its inflammatory character, and to which I also apply opium. But I do more than these superficial men: I regulate the diet so as to protect the diseased parts from exposure to the irritation of masses of fecal matter. This they know to be my method, but they have a party to uphold, and are only anxious to make dupes at the expense of truth.

"Were lead colic connected with a phlogosed condition of the digestive passages, would it be so readily or so radically cured by the operation of drastic purgatives?" I never said that this disease should always be treated by bleedings: we shall see that there are cases wherein inflammation exists, and others where it does not. But their aim is to make persons believe that I have only a way of viewing and only a medication for use: in short, they aim at overthrowing my system of teaching.

"If we apply to the diseases of the stomach, we shall not be surprised to find described under the name of gastritis a host of varied affections connected with the most opposite modifications of the gastric mucous membrane, and one sole medication opposed to lesions which observation has taught us to combat by the most diverse means." Here is a phrase for common-place people, a phrase that signifies nothing. What are these "most opposite modifications?" What do they mean by the "host of varied affections?" Do they count them by hundreds or thousands? And as for my "one sole medication," is it true that I prescribe

one only? Have I not given an account of the success that is obtainable by using all remedies whatever. They would have you understand that there are more than I have mentioned: but I have mentioned in this course, as well as in my writings, strong food, alcoholic liquors, bitters, narcotics, antispasmodics, purgatives, and sudorifics. All these are substances which irritate the intestinal canal, and I pointed out the cases in which they succeed, those in which they are only palliatives, and those in which they cannot be tolerated. Long enough I have been in the habit of making these distinctions, and it can scarcely be said that I have always remained by one series of means.

"We have never seen the antiphlogistic treatment conquer so rapidly as tartar emetic, that group of symptoms that has been designated by the name of gastric disorder (*embarras gastrique*), and which certainly does not suppose the existence of an inflammation of the stomach." You have never seen: yes, but others than you have seen the antiphlogistic treatment act quite as rapidly as tartar emetic. For my part I have employed both, and during twenty-seven years that I have been in the habit of treating a hundred cases daily, you may imagine that I have had time enough to see a good number of cases of gastric disorder to prescribe plenty of tartar emetic. I no longer do so, though formerly I did: I have cured with tartar emetic cases of gastric irritation which were not inflammatory, but which might become so. I have seen a still greater number exasperated by this remedy, and after hundreds of such proofs, I was obliged to give it up. I have not said that an irritation of the intestinal canal cannot yield to stimulants: I have only maintained that there is no security against attacking the group of symptoms called gastric disorder by emetics, not only on account of the too ordinary danger of aggravating the disease, but because sudden accidents may follow upon its use, for instance, when the digestive organs are on the eve of a perforation, which an emetic might produce instantaneously, or when, with a tendency to apoplexy, hemorrhagic effusion is suddenly hastened, &c. &c.

You see, then, to what all these objections, all these studied phrases are reducible; they are false imputations, perverted facts, assertions that cannot bear discussion. And who emits them? persons who have not sufficient conscientiousness and lack the necessary attention for keeping pace with the progress of science, or who disfigure it in order to serve the purposes of certain coteries. Suffice it for me that I have once convinced you; henceforth I shall not turn aside to notice any of these stupid decriers.

LECTURES
ON THE
PHYSICAL EDUCATION AND DIS-
EASES OF INFANTS,
FROM BIRTH TO PUBERTY.

BY DR. RYAN.

*Delivered at the Medical School, Westminster
Dispensary, Gerrard Street, Soho;*

Session 1834-35.

LECTURE LV.

Diseases of the Eye, concluded.—Blepharitis—Inflammation of the Eyelids—Ophthalmia Tarsi—Edema Tarsi—Tinea Tarsi—Lippitudo—Hordeolum—Chalazion—Syphilitic, Scrofulous, and Cancerous Ulceration.—Ectropium—Encanthis—Entropium—Trichiasis—Distichiasis—Ancyloblepharon—Congenital Vices of Conformation—Corneitis, and other diseases of the Cornea.

Diseases of the Palpebræ or Eyelids—Blepharitis.—This is rarely a primary disease, but is generally caused by purulent ophthalmia, inflammation of the lachrymal sac, external injury, erysipelatous inflammation of the head or face, exposure to cold, smoke, dust, lime, bites of insects, and other external agents. When idiopathic, it seldom extends to the globe of the eye, as we frequently observe in adults. It is sometimes accompanied by œdema, and it may terminate in suppuration or abscess in the lid. It often becoms chronic in scrofulous persons, and occasionally destroys the eyelashes.

The *treatment* in such cases, consists in the application of leeches, cold and saturnine lotions, purgations, and low diet. When suppuration is inevitable, it ought to be encouraged by poultices, fomentations, and the purulent matter evacuated as soon as possible. If the disease becomes chronic, it may be combatted by ointments of ioduret of lead, hydriodate of potass, calamine ointment, the ointment of the nitrate of mercury, or of the red oxide of mercury, formerly called red precipitate.

Edema Palpebrarum is a symptom of the former disease, and also of anasarca consequent to scarlatina. It disappears when these diseases are removed.

Ophthalmia Tarsi—*Psorophthalmia*—*Tarsitis*.—This species of inflammation affects the tarsus, Meibomian glands, conjunctiva, palpebralis, and ciliary margins. The symptoms are intolerance of light, lachrymation, and great itching of the lids. This disease is very common in delicate and scrofulous infants, especially during cold weather.

The *treatment* is antiphlogistic in the acute form of the disease, but it is generally so slight, that this is seldom required. The application of the saturnine lotion, with or without the sedative solution of opium, purgatives, and exclusion of light, are in

most cases sufficient for its removal. When it becomes chronic, it will be necessary to employ weak solutions of zinc, sulphate of copper, nitrate of silver, or oxy muriate of mercury, and the ointments of ioduret of lead, hydriodate of potass with opium, red oxide of mercury, &c. The ioduretted preparations are extremely efficacious in strumous habits, and the general health ought to be improved by mild purgatives, tonics, quinine, carbonate of iron, &c.

Tinea Tarsi.—This term has been employed when the edges of the tarsus are inflamed, and the ciliary margins covered with pustules. In some cases there are numerous pustules round the eye, and more especially when there is porrigo favosa of the forehead and face.

The indications of *treatment* are to improve the general health by mild and occasional purgatives, such as hydr. c. creta, rhubarb, carb. ferri, &c., and to apply saturnine lotions, with the sedative solution of opium, and the other means advised for the disease last mentioned. We observe a vast number of diseases of the external surface of the eye in children at the Free Hospital, Westminster, and Western Dispensaries; and they generally yield very speedily to the methods now recommended, as all of you have observed. The children of the poor are peculiarly predisposed to ophthalmic diseases, on account of inattention to cleanliness, the want of proper aliment, and other comforts of life.

Lippitudo—*Tylosis*.—This is an aggravated form of the last disease, and presents ulceration and induration of the edges of the eyelids, so as to cause the cilia, or lashes to fall out—*ptilosis*. This disease is also very often observed in adults, and generally continues for life. It requires more stimulating *treatment* than *tinea tarsi*, and the same remedies in larger quantities are employed. The following preparations may be used with advantage:—ung. hydr. nit. dil., ung. plumbi iodureti, ung. argenti nitratis, ung. hydr. nitr. oxid., with solutions of nitrate of silver, sulphate of copper, zinc, and acetate of lead, &c. The proportions of these unguents and solutions will be found in my translation of the New Practical Formulary of Hospitals.

Hordeolum—*Stye*.—This is an inflammation of the ciliary margin, which generally terminates in suppuration. In the acute stage, cold lotions, and poultices of bread and water will often remove it, but when it contains matter, this should be evacuated by means of a slight puncture made with a lancet. When the abscess becomes chronic, the matter may be absorbed by a lotion of ioduret of lead, or hydriodate of potass. Some advise nitrate of silver to be applied, with a view of causing sloughing, but this is seldom necessary.

Chalazion—*Grando*.—This term is applied to a small hard tumour on or near the edge

of the lid, which former writers compared to a hailstone. It may contain fluid or a caseous substance, and is caused by an obstruction of one of the Meibomian ducts. It is most frequently observed in adults, and is generally situated under the skin of the upper eyelid. It projects more or less, feels hard, and sometimes inflames, suppurates, or may be absorbed.

I have found the preparations of iodine cause its removal by exciting absorption, and I have also known it to suppurate or remain indolent, when it was necessary to excise it, the lid being first everted. When several small ones appear, they are called *milium* and *phlyctenula*, from their resemblance to millet seeds, and are treated with the same means as those just mentioned.

Tumours of the Eyelids.—Besides the tumours already described, there may be others, which are incysted or fleshy. These may be absorbed or removed by everting the lid, transfixing the tumour with a hook, and excising it with a curved scissors.

Encanthis or enlargement of the caruncula lachrymalis is generally removed by nitrate of silver, or by excision.

Epicanthis is a fold of skin which covers the internal canthus. It is often congenital or accidental, and may be easily excised.

Navi-materni are sometimes situated on the eyelids, and may be removed when small, by vaccination or pressure; when large, a seton double ligature passed through them, as stated on a former occasion, very generally cures them.

Syphilitic Ulceration.—This appears on the eyelids of infants in a short time after birth, and speedily assumes the character of such sores. If mistaken, its true nature will be discovered by the appearance of a copper-coloured, or some form of cutaneous eruption.

It will be necessary to exhibit mercury to the mother, and to apply the black lotion, composed of calomel and lime water, and sometimes the nitrate of silver or sulphate of copper.

Cancerous Ulceration of the eyelids is seldom observed in infants. When it appears as a primary disease in adults, it commences in the form of a hard tubercle, accompanied by lancinating pain, and may terminate in ulceration, which will extend to the globe of the eye, unless the diseased portion is completely excised.

Scrofulous Ulceration is best treated with the internal and external use of iodine: the ioduret of iron is an excellent tonic, and that of lead, a valuable topical application. The general health ought to be improved by the means proper for scrofula.

Ectropium—Eversion of the Eyelid.—This disease most commonly affects the lower lid, and is often caused by purulent ophthalmia in infants, when this is succeeded by ulceration of the lids. The exposure of the in-

ternal surface of the eyelid to the air, and to external irritations, is speedily followed by inflammation and thickening of the conjunctiva, which puts on a fleshy appearance, and is termed *ectropium sarcomatosum*.

The mode of *treatment* in the early stage of this disease is to invert the lid, and retain it in its ordinary situation by small straps of soap or court plaister, and then to apply cold lotions and other antiphlogistic means, if necessary. But this plan will not succeed when the disease is chronic, the conjunctiva thickened, or when there is loss of substance of the exterior covering of the lid. In such cases, the application of the ung. argent. nitratis, the ung. hyd. nitr. oxid, with stimulating or caustic solutions, are to be tried. When these fail, a portion of the morbid growth ought to be removed by excision with a pair of scissors; and sometimes a triangular portion of the lid is excised and the edges approximated by means of sutures. But these operations are rarely necessary when the former measures have been judiciously employed.

There is another malposition of the eyelids which is productive of worse consequences, than the present one, and which I have next to describe.

Entropium—Inversion of the Eyelids.—Inversion of either eyelid causes direct mechanical injury by pressure, and the presence of the eye-lashes, against the globe of the eye, inducing inflammation, opacity, or ulceration of the cornea.

The indication of *treatment* is to restore the eyelid to its natural situation, and this is effected by one of two methods. The first is to apply some caustic to the external surface of the lid, form an eschar of such a size that, when it heals, the cicatrix will draw the inverted lid into its proper place. The second plan is to excise a portion of the eyelid with a pair of scissors or scalpel, and place the edges of the wound in contact by means of sutures. In some cases, a part of the orbicularis has been removed; and when all these methods fail, the ciliary margin must be excised, so as to remove the roots of the cilia. The incision is made within a line or two of the margin of the lid, so as to take away all that portion which presses on the eye and keeps up irritation.

Trichiasis—Inversion of the Cilia.—This disease consists in the inversion of the eye-lashes without that of the lid. It produces all the diseases caused by entropium. It affects infants as well as adults. It may happen that only a few hairs are inverted, and in such cases they may be plucked out with a forceps or tweezers. When the whole eyelashes are inverted, the ciliary margin must be excised, so as to remove the roots of the hairs.

Distichiasis.—This disease consists in a second row, or a part of one, in addition to the natural cilia, and requires the same treatment as in the last-mentioned disease.

Ancyloblepharon.—Adhesion of the *Eyelids* to each other.—*Symblepharon*.—Adhesion of the lids to the globe of the eye are sometimes congenital diseases, especially the first; but the second is generally caused by lime, mortar, red hot iron, or strong acids applied to the eye, which may be followed by adhesive inflammation.

The treatment consists in removing inflammation by ordinary means in the second form, and by dropping almond oil into the eye, or by introducing spermaceti ointment to prevent the disposition to adhesion. The adhesion has likewise been incised both between the lids and these with the eye; and in the first case, adhesive straps are applied to separate the lids, and gold beaters' leaf introduced between them, for the same purpose. It is not difficult to keep the lids separated after the operation, as I once observed in a case in which I operated successfully. Sir James Murray, of Dublin, also attests this fact in the case of a girl whose eyelids adhered in consequence of a burn, and were separated by him, with the pleasing effect of restoring her vision.

The eyelids may be destroyed by burns and other serious injuries. In a case of this kind, Mr. Walker, of Manchester, intended to form an artificial eyelid, but the patient was considered a bad subject for the operation.

Congenital absence of the eyelids, or of a portion, has been described by authors, as I mentioned in a former lecture. When the lid is slit like a harelip, the disease is termed *coloboma palpebræ*. Deficiency or malformation of the eyelids is of extremely rare occurrence, and is generally observed in monsters, which are born dead or nonviable.

Ptosis.—Falling of the upper eyelid is occasionally observed in children, arising from relaxation of the integuments, or paralysis, consequent to hydrocephalus. It is generally cured in such cases by removing the disease which has caused it. When ordinary remedies fail, a piece of the lid is excised, and the edges of the wound brought in apposition by sutures, and then antiphlogistic measures are necessary.

Lagophthalmos, or shortening of the upper eyelid, may be congenital, or caused by burns, wounds, &c. In such cases, the lids remain open, and no operation can remedy the defect.

These general observations having been premised, let us now examine the diseases caused by conjunctivitis.

Corneitis.—Inflammation of the Cornea.—This is a rare disease, unless when the conjunctiva or sclerotica is affected.

The symptoms of corneitis are, a dull, hazy appearance of the affected tissue; red or pink vessels appear in the form of a zone, intolerance of light, and sometimes an infinite number of small ulcers. Coagulable lymph is effused, and opacity between the

external layer and the rest of the cornea, or deeper seated, is very rapidly produced.

The usual causes are conjunctivitis, exposure to cold, injuries applied to the cornea, as when pieces of metal, or certain sharp instruments are projected against it.

Treatment.—The exciting cause, whatever it may be, ought to be removed, if possible.

When a scale of iron, or any foreign body is imbedded in the cornea, it ought to be removed as soon as possible, with the point of a lancet or a cataract needle. Cold applications, especially those composed of the diluted solution of acetate of lead, from ʒss—3ij—iij, in six ounces of water, may be placed and constantly renewed over the eyelids, or directed over the affected parts.

Abscess of the Cornea.—This is an occasional consequence of corneitis, and pus is deposited in the lamellated tissue of the affected organ, more especially in children or adults of a scrofulous habit. In most cases the matter is absorbed, or it excites ulceration, and escapes externally or internally into the anterior chamber, when the disease is termed *hypopyon*. The matter sometimes presents at some portion of the margin of the cornea, and this form is designated *onyx* or *unguis*.

The indications of treatment are to reduce the inflammation, excite the absorption of the matter, if possible, or to evacuate it by means of one or more punctures, and then apply cold, astringent, and absorbent lotions, as in cases of opacity.

Ulceration of the Cornea.—This disease is the consequence of inflammation. When the ulcer is superficial, it may disappear of itself, or require astringent and stimulant lotions, as solutions of alum, zinc, compound solutions of alum properly diluted, or even nitrate of silver, in solution or ointment. The last remedy ought not to be resorted to, unless in severe forms of the disease, as the former ones are usually successful.

The bowels ought to be purged by appropriate medicines, the age and strength of the infant or child being duly estimated. In severe cases, leeches, sometimes venesection, and counter-irritation must be employed. Some authors advise the use of mercury urged to produce ptyalism, but this, in my opinion, is seldom necessary.

When the disease assumes a chronic form, astringent and stimulant lotions, or collyria, are indicated: the compound solution of alum (ʒj to ʒiv of rose water), or the liquor plumbi acetatis, ʒj to ʒiij of the same fluid, with ten or twenty drops of an aqueous solution of morphia, or the sedative solution of opium.

The general health ought to be attended to, and restored by aperients and tonics. The disease is very tedious and troublesome in scrofulous subjects, and may require the external and internal use of iodine, or its preparations, alone or combined with the sedatives just mentioned.

When inflammation exists at the same time, the treatment for conjunctivitis, or catarrhal ophthalmia is necessary.

In those cases in which the ulceration advances and perforates the cornea, the aqueous humour will escape, and the iris protrude, which acting as a foreign body, will excite inflammation, lymph will be thrown out, and adhesion between the iris and cornea may be the result. When the iris is prolapsed (*prolapsus iridis*), the strangulated portion will become agglutinated to the sides of the aperture of the cornea, the further evacuation of the aqueous humour will be prevented, and that fluid will again distend the anterior chamber. The adhesion between the protruded iris and perforated cornea, will inevitably cause deformed pupil, and, more or less imperfection of vision.

The treatment in such cases consists in touching the protruded portion of the iris with nitrate of silver, formed into a pencil shape, every day, or according to some to excise the projecting part with a scissors, and thus to remove it as a foreign body and a source of irritation.

Astringent lotions may be advantageously applied at the same time, and the bowels ought to be properly regulated. The ulcer generally heals in a few days, but as the iris is adherent to the cornea, the pupil becomes more or less deformed, and vision may be slightly or greatly affected.

In some cases of wounds of the cornea and iris, in which the latter protruded, I have returned it with a fine probe, ordered the patient to recline on the back for several hours, applied cold water to the eye, and advised the integuments round the affected organ to be rubbed with strong solution of the extract of belladonna, (℞i—ij—iij to the ℥j of water), with a view of dilating the pupil, acting upon the fibres of the iris, and thereby causing the part lately protruded to maintain its ordinary position, which it is most likely to do when the patient reposes entirely on the back. The cold lotion assiduously applied to the wound in the cornea, favours its union by the first intention, which often takes place very speedily; the aqueous humour is secreted, fills the anterior chamber between the cornea and iris, and prevents the latter from being displaced or protruded. It is also worthy of mention that infantile iritis caused by wounds, is seldom so violent as that of adults; and speedily yields to antiphlogistic measures.

Opacity of the Cornea—Pearl—Nebula—Albugo—Leucoma.—These species of disease are usually caused by corneitis or conjunctivitis, as already mentioned. It often happens, however, that obscurations do not always follow inflammation. In some cases there are no specks whatever, but in most instances there may be one or more. When these occur, there is more or less inflammation, of the eyelids and the enlarged vessels act as irritants; or there are enlarged ves-

sels running from the sclerotic to the speck on the cornea, which are excited by the movements of the lids. The cause in other examples is inversion of the edges of the lids (entropium) or of the cilia or eye-lashes (trichiasis).

The indications of treatment are to remove all causes of irritation, to reduce chronic inflammation, to constrict the enlarged vessels by astringent, and slightly astringent lotions, such as the solution of alum, or nitrate of silver, or oxy muriate of mercury, in the proportion of two grains to each ounce of rose water. Great advantage will also be derived from the alternate use of the liquor plumbi acetatis, in the proportion of half a drachm to three ounces of rose water, with thirty drops of the sedative solution of opium, or a proper quantity of morphia. I have also observed very good effects produced by the ioduret of lead, and protoioduret of mercury, in the proportion of two or three grains of the first, and from a grain to a grain and a half of the second to each ounce of rose water; but either quantity of these medicines may gradually be increased. These preparations possess the power of increasing absorption, and consequently of removing the speck or specks, termed opacity, or pearl.

It is essential to know, that a long use of the nitrate of silver may tinge the conjunctiva of a dark olive hue, but this is of very rare occurrence; perhaps it happens once in three hundred cases. A tint is also caused by a long use of the preparations of lead in ulceration of the cornea. The lead undergoes a chemical change, becomes deposited in the excavation of the cornea, which adheres permanently to its tissue. This disease was noticed about the same time, by Dr. Jacob of Dublin (Dublin Hospital Reports, vol. v), and Mr. Windsor of Manchester (Lancet, Dec. 1830).

Dry collyria, or powders, are sometimes blown into the eye by means of a quill, for the purpose of exciting absorption of opacities, &c. The medicines generally employed are calomel, sugar, calamine, &c.; but these are rarely if ever used in this country. They are still applied in veterinary practice, and sometimes by continental surgeons, more especially when there is superficial cloudiness, technically termed *nebula*; but I have usually succeeded in removing this species with the remedies just mentioned. When the opacity is deep seated between the layers of the cornea, the disease is termed *albugo* or *leucoma*, and is seldom relieved by any means, more especially if the speck becomes of a pearly whiteness.

It often happens that a part or the whole of the lucid cornea becomes white or opaque, after purulent Egyptian, and gonorrhoeal ophthalmia, and in such cases vision is inevitably destroyed. If the pearly whiteness be over the axis of vision, it has been proposed to make an *artificial pupil*, but when

the pearl or leucoma is extensive, the lucid cornea cannot be distinguished from the sclerotic tunic or white of the eye.

It was formerly the practice to apply blisters and setons, issues and counter-irritation behind the ear, or to the nape of the neck, remedies now seldom employed, as they are too violent in cases of children.

Chronic Corneitis—Vascular Cornea.—Chronic inflammation of the cornea is a very common disease from birth to puberty. It is generally followed by some one of the forms of opacity just described. There are straggling enlarged vessels traversing the cornea and terminating in the opacity, which they supply with lymph.

The same treatment as in the last disease is to be employed; and if this fail, the enlarged vessels may be divided with a cataract knife, or partially excised with a scissors, having been previously raised with an eye forceps. I once restored the sight of a young lady by this method, and the history of the case will be found in the Dublin Medical Transactions, 1828, vol. 4.

Staphyloma of the Cornea.—This disease consists in a projection of the cornea in a conical or spherical form, with opacity and loss of vision. It is a very common occurrence after purulent ophthalmia in infants and adults. It is scarcely necessary to remind the anatomist and pathologist that the displacement of the cornea may cause displacements of the other tissues of the eye. We observe, accordingly, that the iris is often in contact with the cornea, the anterior chamber is obliterated, and the posterior is enlarged. On inspecting the eye, we find the cornea more or less opaque, the iris in contact with it, the posterior chamber enlarged, and sometimes extended into the vitreous humour.

When the cornea projects so as to prevent the closure of the eyelids, great irritation of the eye and its coverings will be induced, and an operation will be necessary in extreme cases. It often happens, however, that staphyloma does not protrude beyond the eyelids in children and adults, and no operation is necessary.

Treatment.—When the operation is deemed advisable, it is performed as follows:—a cataract knife is passed transversely through the cornea, a little anterior to its union with the sclerotic, and the edge is brought downwards and outwards. A flap is thus formed, which is raised with a forceps, and excised with an eye scissors. As soon as the cornea is excised, the aqueous humour escapes, and the eye collapses. Cold applications are now constantly placed over the eyelids, and are composed of water or the saturnine lotion, and a bandage or roller is passed round the head, without compressing the eye. The great object now is to prevent inflammation, for should this disease supervene, the original complaint may return.

The patient should be kept in a dark room, the sound eye closed, and bleeding, leeching, cold applications, purgatives, and diaphoretics employed, if necessary.

Should inflammation supervene in despite of these remedies, and the eye become distended again, it will be advisable to puncture it with a lancet, and this generally affords great relief.

The progress of staphyloma is so slow in some cases, that it has been advised to arrest it by applying nitrate of silver. This form of the disease has been designated *partial staphyloma*. It must be obvious to the pathologist that the disease cannot be arrested by the use of caustic; and I may add, nor by any other means, in many cases.

Conical Cornea.—This disease bears some resemblance to staphyloma. It consists in a projection of the centre of the cornea in the form of a cone; and injures vision by producing short-sightedness. It seems to be caused by the absorption of the centre of the cornea, induced by the pressure of some part of the globe of the eye. It is an incurable affection. When it occurs in children from the age of seven to fourteen years, the defective vision may be in some measure remedied by the use of concave spectacles. It has been proposed, but is seldom followed, to extract the lens so as to diminish the excessive rays of light, but the operation is perhaps never performed at present.

Fungosities of the cornea are occasionally met with, and may be removed by the preparations of iodine and mercury, with the astringent lotions advised for opacities. When these fail, the fungous growths are seized with a fine forceps, and removed with a pair of scissors. Some surgeons strongly advise the application of the nitrate of silver to repress them when they begin to reappear.

Wounds of the Cornea.—These are inflicted with sharp instruments, and are easily cured in most cases, provided the iris is not injured. I have treated cases caused by wounds with scissors, penknives, nails, sharp pieces of wood, &c. They readily yield to the antiphlogistic treatment, but are mostly followed by more or less opacity, which is to be treated in the manner mentioned when describing that disease.

The treatment consists in leeching, purgation, cold applications, and keeping the eyelids closed by means of soap or court plaster, which will keep them quiet, and prevent friction on the injured part. In this, as in all the forms of ophthalmia, the other eye ought to be covered, and the room darkened for one, two, three, or more days.

Such is a brief account of the commonest diseases of the eye, in infants and children. All the other tissues which compose the organ of vision, are liable to diseases; and these are described in monographic treatises, manuals, and surgical works. When I state

that some works on diseases of the eye occupy 1,600 pages* octavo, I need scarcely observe, that it is impossible in a course of lectures on diseases of children, to do ample justice to the subject.

Organs of Sense—the Vices of Conformation and Congenital Diseases of the Auditory, Olfactory, Gustatory, and Palpatory.—The vices of conformation of the organs now mentioned, have been described on former occasions, when the subject of occlusion and absence of parts were under consideration. The organs are rarely affected with disease during the intra-uterine life of the fœtus.

Cases of congenital deafness or dumbness, are of very rare occurrence, and seldom admit of cure, though infants so affected may be instructed, and even educated, in asylums devoted to them exclusively. Aural surgery is in a most deplorable state of imperfection in this kingdom; there is not even one good or extensive work on the subject. Some few of our treatises are scientific on certain parts of the diseases of the ear, but most of them are erroneous and empirical. We must therefore refer to the standard works on medicine and surgery for information concerning diseases of the organ of hearing. Diseases of the organ of taste are rarely observed in children, except those already described.

Vices of Conformation, and Diseases of the Organ of Palpation or Touch.—The vices of conformation of the skin, were described in a preceding lecture. The congenital diseases are exceedingly numerous, and require to be fully described, as many of them not only appear on the premature and full grown infant at birth, but also during childhood, adolescence, manhood, and old age. I shall therefore occupy several lectures, in placing before you the nosologies of all former and recent writers; and attempt to give a complete history of the nature and treatment of cutaneous diseases. I shall lay all authors, both ancient and modern, on the subject, under contribution, arrange their facts and conclusions, and add the result of my own observations, during several years as physician to three of the largest dispensaries in the metropolis. But as diseases of the skin form a part of my course of lectures on the Principles and Practice of Medicine, I shall describe them in that department of science.

I have now concluded the history of vices of conformation, of the congenital and other diseases of infants, and think it right to direct your attention to their importance in the practice of medicine. The account I have given abundantly proves, that infants may be born so deformed, or diseased as to be incapable of surviving but for a short time, and of never arriving at maturity. This is so important a fact, in trials concerning prolicide, that I shall submit a tabular view

of congenital diseases in favour and against viability, the knowledge of which may save persons accused of this crime, when the infant was so constituted that it could not possibly survive, or arrive at the adult age.

M. Billard gives the following table of congenital diseases in favour and against infantile viability, which I consider correct, and of great importance in medico-legal inquiries concerning prolicide:—

1. *Vices of Conformation, and Diseases necessarily mortal.*

Absence of the skin, with want of the parietes of the splanchnic cavities (eventration).

Obliteration, division, or duplicity of the œsophagus.

Ulcers and gelatiniform ramollissement of this organ before birth.

Obliteration of the stomach.

Its gelatiniform ramollissement developed before birth.

Obliteration, division of the superior parts, or the middle or inferior third of the digestive canal.

General ramollissement of the intestinal mucous membrane, developed before birth.

Dropsy of one or both kidneys.

Obliteration and cohesion of the rectum to the bladder.

Malformation of the nasal fossæ, with monopsy.

Hernia of the abdominal organs into the thorax.

Inflammation of the pleura, lungs, bronchiæ, developed before birth, or during parturition.

Inability to dilate the cavity of the thorax, in consequence of the feebleness of the infant.

Congestion of the lungs and of the heart, at the moment of birth.

A single heart, with one auricle and ventricle.

Division of the heart into two parts, by a complete septum.

Pericarditis developed during intra-uterine life.

Accephaly and anencephaly.

Vices of conformation of the spinal marrow.

Hydrocephalus, with considerable deformation of the cranium.

Encephalocele with hydrocephalus.

Apoplexy, complicated or not with fracture of the cranium, occurring before or during parturition.

Ramollissement of the brain.

Hydrorachis, with ulceration of the tumour.

2. *Diseases which are not necessarily mortal, but prevent the development of independent life.*

Ecchymoses, contusions, sanguineous tumours, cynopathy.

Nævi materni inordinately developed.

Cutaneous inflammations.

Adherence of the lips.

Excessive length of the tongue.

* Middlemore on Diseases of the Eyes.

Extreme shortness of the pharynx.

Simple œsophagitis.

Follicular ulcers of the stomach.

Simple contractions of the intestines.

Imperforation of the anus.

Intestinal hæmorrhage.

Calculus nephritis.

Peritonitis with or without dropsy.

Vices of conformation, or depression of the thoracic parietes.

Communications more or less considerable, either between the auricles or ventricles of the heart.

Hydrocephalus more or less advanced, without separation of the bones of the cranium.

Imperforation or absence of the vagina.

Accumulation of mucus in the bronchiæ.

3. *Diseases which do not oppose viability.*

Simple absence of the skin.

Cutaneous excrescences.

Excessive development of the capillary system.

Albinism.

Stationary nævi materni.

Harelip and cleft palate.

Transposition of the stomach and abdominal viscera.

Absence of one kidney.

Hypospadias, epispadias, and pleurospadias.

Extroversion of the bladder.

Umbilical and inguinal hernia.

Transposition of the heart.

Contractions of its orifices, anomalies of their valves.

Persistence of the foetal openings some days after birth.

Cerebral atrophy.

Hydrorachis without ulceration of the tumour.

Fractures, luxations, and divisions of members.

The following conclusions may be drawn concerning viability in relation to the pathology of new born infants.

1. That every infant which has respired, and is affected with any of the diseases in the first order of the above table, cannot be considered viable.

2. That every infant that has respired, and is affected with the diseases in the second order, is viable, but not likely to arrive at maturity.

3. That every infant that has respired, affected with any of the diseases in the third order, is evidently viable*.

I have now, gentlemen, to thank you for the great attention which you have devoted to the study of the physical education, the pathology and treatment of the diseases of our species, both at and after birth, and from the latter period, until the age of puberty. I have placed before you a brief account of the vices of conformation, mal-

formations, diseases of infants during intra-uterine existence, at and after nativity, and considered them according to the received principles of physiology, pathology, and therapeutics. I have attempted to arrange a scientific system of infantile medicine, with an ardent hope to convince the rising portion of our profession, that this class of diseases are as much entitled to their consideration as any other, and that these maladies require somewhat more extensive remedial means, than the warm bath, Godfrey's cordial, and the remainder of the anile code, which are still too much employed by a large portion of medical practitioners. I flatter myself with the hope that the precepts you have heard with such exemplary attention, will enable you individually to alleviate much human suffering, in a class of beings which require so much care in their physical and medical management. In accordance with the unanimous request of your predecessors in this school, as well as of yourselves, I have commenced, and intend to complete the publication of these lectures. I have given them exactly as delivered, with the exception of the practical formula for infants at different ages, which will appear at some future time. I may venture to state that many gentlemen in practice in different parts of this country, have, I am sure, estimated much too highly the preceding lectures. I am deeply sensible of the objection that might be made to the language in which they were published; but to critics who would urge this objection, I should reply—the language of a medical lecturer ought to be as plain and intelligible as possible, as some of his auditors have, unfortunately, received an imperfect preliminary education, and cannot understand technical terms without expletives; it is his duty to instruct every one of his pupils, and in my opinion he would violate it, if a single student did not fully comprehend his meaning, however tiresome his phraseology might be to the better educated, and older pupils of his class. Others might also object to the use of language so technical as some which was employed, and especially to terms in use in other countries, with occasional additions. To these I should reply, I see no reason why our terminology should not be as classical as that of any other country.

It also might be said, that many of the diseases of infants were treated too superficially; but those who would urge this comment ought to recollect, that medical students of the present day, attend extensive courses of lectures on practical as well as theoretical medicine, surgery, obstetrics, and therapeutics, and have little inclination and less time to be fatigued with useless repetitions. It is scarcely necessary for me to observe, that a vast number of medical, surgical, and obstetrical diseases mentioned in this course on the maladies of children, were described

* *Traite des Maladies des Enfants, &c.* 1833.

by me as regards adults; and, therefore, only required to be adapted to the early periods of human life. Moreover, my views on the former subjects are before the medical public, and are given in my other lectures.

In fine, I again offer you my best acknowledgment for your diligent attention to the study of a branch of medicine unaccountably neglected in this country; but which you will find as interesting and as important in your practice as any other.

—o—

MANUAL OF OPERATIVE MEDICINE.

BY M. MALGAIGNE.

FREELY TRANSLATED AND CONDENSED

By GREVILLE JONES, Esq.,

Lecturer on Anatomy and Physiology.

CHAP. IV.—Of Operations which especially interest the Skin and the Cellular Tissue.

THE general operations of which we have to treat in this place, relate to the following subjects:—1, Abscesses; 2, Cysts, with liquid contents; 3, Tumours; 4, Wounds and foreign bodies; 5, The restoration of mutilated parts; 6, Bad cicatrices.

* SECT. I.—Of Abscess.

There are four modes of opening an abscess, by caustic, puncture, seton, and incision. 1. *Caustics*.—The ancients employed the red hot iron; at present, potassa-fusa is in use. The modes of applying caustic have been before mentioned, but we may add here, the method adopted at the great hospital at Vienna. Five parts of caustic potass are beaten in a mortar, with about six of unslaked lime, added by degrees. This is moistened and formed into a paste with alcohol or eau de Cologne. A layer of this paste, about two lines thick, is placed on the part with a silver spatula moistened with alcohol. With the spatula, the extent of the cauterization is determined, for this preparation, unlike caustic potass, does not cause an eschar of greater dimensions than the application itself. In about six minutes after its application the skin becomes destroyed down to the cellular tissue, which is known to have taken place by the appearance of a grey line along the borders of the caustic. This is taken away, and the eschar washed with vinegar and water. To produce a deeper eschar, the paste may be left on for ten, fifteen, or twenty minutes. The pain is very moderate, often less than that of a blister. Besides great quickness, this method has the advantages of preventing the sore from being formed larger than we wish, and the lime, by removing any carbonic acid from the potass, renders the latter more active. 2. *By Seton*.—It is applied, as to other parts, but is fallen into disuse. 3. *By Puncture*.—A simple puncture is made in the ordinary manner. Lyon made the punctures with a red hot instrument, and emp-

tied the abscess with a syringe. In some cold abscesses, it has been advised to puncture with a trocar, and then force an injection through the canula. Recamier recommends this when the pus is fetid, and its absorption is feared. Boyer taught us to puncture large abscesses obliquely, and having evacuated the pus, to cover the opening with plaister, and again, after some days, to make a fresh puncture, and so on successively, in order to give the points time to contract and to prevent the access of air. 3. *By Incision*.—We have before sufficiently described the mode of making incisions; we shall merely notice here, some general rules:—that an abscess should be opened quickly; with one extremity of the incision at the most dependant part; in the direction of the long diameter of the abscess; in the direction of the axis of the body or some fold of the skin. When an abscess is very large, it is better to make several small incisions than one very large. It is better, when a muscle covers an abscess, to separate its fibres without cutting them across if possible.

In opening some very deep abscesses when the fluctuation is obscure, it will often be necessary to adopt the following precautions. With a convex bistoury, the parts covering the abscess may be divided layer after layer, until, with the finger, we are assured of fluctuation; or the skin may be divided, and then the remaining tissues torn through with the handle of the knife, until the abscess be arrived at. When we have divided by layers, the tissues to a considerable depth, it will be advisable to fill the wound with lint, and leave it until the abscess comes forward of itself, which our division will much facilitate, even although it should not have been made over the centre of the tumour. Dr. Graves, of Dublin, has employed this method advantageously in abscesses of the liver, and M. Dupuytren had recourse to it with success in a deep abscess of the thigh.

With regard to some particular abscesses—those of the face should generally be allowed to break themselves, to avoid cicatrices; or they may be opened with a lancet if they are too slow in coming forward. Those which occupy the thick part of the cheek, ought to be opened in the inside of the mouth. Abscesses of the parotid region should not be opened until the whole tumour is dissolved into one cavity, and a large opening should be made. If these precautions be neglected, the aponeurotic layers, which abound in this part, will keep up a tedious induration, and often give rise to numerous sinuses. In abscess of the axilla, we must bear in mind the situation of the artery near the union of the anterior third with the middle third of the axilla. To avoid all danger, M. Velpeau advises the arm to be raised as much as possible, and the abscess to be punctured from above downwards with a straight bistoury held like a pen, the inci-

sion being completed from within outwards. *Abscesses of the groin, or bubos*, may be opened either with the knife or potass. The direction of the incision ought to be perpendicular to the fold of the groin, for if made in a parallel direction, the lips of the wound are apt to curl inwards, and cicatrization is rendered difficult.

SECT. II.—Of Cysts, with Liquid Contents.

1. *Cysts of the Skin, or Sebaceous Tumours.*—*Anatomy.*—Formed by the development of the sebaceous follicles of the skin, and of variable size, these cysts, when very small, are denominated “tannes;” and their orifice is marked exteriorly, by a black point. But this orifice is often obliterated; the tumour acquires a considerable volume; it contains a viscous, transparent or whitish liquid, or a pulpy substance resembling honey, “boulle,” thick suet, &c. The parietes appear to be formed of cartilaginous layers, which have very little adhesion to the subjacent cellular tissue.

The Operative Proceedings.—Injections, sections, cauterization, (with potass when the tumour is large, with nitric acid on the point of a pen when small) incision, extirpation, excision have been proposed. The two last alone require any description here.

Extirpation.—The ordinary mode is, to make an incision along the skin with a convex bistoury, taking care not to open the cyst, if it can be avoided. Then the surrounding cellular tissue is to be separated by raising and drawing it with the fingers, or a hook, or by means of a thread which had been passed through it.

The Method of A. Cooper.—When the cyst is old and the parietes firm, this surgeon cuts through it at the same time with the skin, and empties its contents. Then detaching its parietes to a small extent from the skin, he takes the cyst between the thumb and finger of the right hand, furnished with a compress to prevent their slipping, and draws it out, favouring at the same time its extraction by tearing the cellular tissue with the thumb of the left hand. This also is the method of proceeding which M. Dupuytren follows: it gives little pain and does not occupy a minute. The wound is to be united by the first intention.

Excision—Chopart's method.—In cases, when the base of the tumour being very large, its extirpation would cause an enormous wound, we may remove the indurated portion of skin and cyst which forms the summit of the tumour, and leave the bottom of the cyst which will unite with the circumference of the integuments. A puncture is first made at the most dependent part of the tumour in order to empty it. Then the finger is to be passed into the cyst, the part which is to be removed is to be lifted up with it and cut out with the bistoury or scissors. After the operation, the bottom of the cyst exposed to the air acquires the

hardness of wax. In time some of the layers are detached, by degrees the surrounding skin becomes contracted, and by degrees the tissue of the cyst is found to have disappeared, and to have given place to a small cicatrix.

Cysts of the Cellular Tissue—Serous, Mucous, Cysts, &c—Anatomy.—These are collections of serosity, or other liquid of greater or less consistence developed in the cellular tissue, from which, frequently, they derive a true envelope: at other times the liquid is in contact with a serous surface without real walls. It is impossible, in the first instance, to distinguish the two cases, but when operating we soon discover the absence of parietes, and the difficulty, or indeed, impossibility of dissection. The methods of operating are the same as for the tumours before mentioned, with the exception of incision. But if the tumour has not parietes, extirpation even ought not to be attempted: it will be sufficient to make an incision and promote suppuration and adhesion, by the introduction of charpie or irritating injections. If the cyst have parietes, it must be separated from the surrounding parts by the fingers, scissors, or bistoury, care being taken not to open it unless its parietes be too weak to resist traction. When incision is adopted, and the tumour being very large, great irritation, or the absorption of pus, or the vitiation of the pus by the introduction of air is feared, it will be better not to evacuate the tumour completely, and to replace part of the fluid which is removed, by an injection of warm water, in order that the parietes may contract by degrees. This is the method of M. Recamier, already mentioned when speaking of abscess.

Synovial Cysts.—They are of two kinds; one a species of dropsy of the subcutaneous bursæ mucosæ, as of those on the olecranon, patella, between the hyoid bone and thyroid cartilage, &c.; the other consists in the development of the synovial bursæ of certain tendons, and are called *ganglions*. *Proper synovial cysts* are to be incised freely, or even if the dilatation be considerable, an elliptic flap of integument may be removed; then suppuration and adhesion are to be promoted by the introduction of charpie, either dry, or wetted with irritating fluids. For *ganglions*, compression is advised, or opening them with a very small incision; or rupture of the cyst, without opening the skin, by striking them with a firm body, such as a bound book, or a seal covered with linen. Sabatier applied the left thumb upon the ganglion, then with the other thumb resting on the former, he pressed forcibly until the cyst appeared hollow, and the contained tumour diffused into the cellular tissue. Slight pressure and frictions renewed for two or three days favour the absorption of fluid, and the patient is cured.

Cysts containing Hydatids.—Ought to be opened and emptied with care, and treated afterwards like cellular cysts. M. Kuhn

reckons among these cysts those which M. Dupuytren has remarked opposite the articulations of the hand and foot, and which contain little white bodies. These are frequently under the annular ligaments, above and below which they form eminences divided by the ligaments. Puncture, followed by the evacuation of fluid, and of the little white bodies, has succeeded once; in other cases the disease returned; M. Dupuytren prefers, therefore, the following procedure: one of the tumours is made to project by compression made on the other. This is incised and a director passed through it, and under the annular ligament into the other pouch, which is raised against the integuments, in order to indicate the place for a second opening. This being made, a seton is to be passed through both orifices, or separate skeins in each. The setons are to be withdrawn in thirty-six or forty-eight hours; the irritation produced will prove sufficient to bring about adhesion of the parietes of the cyst.

This operation is long and difficult; it often brings on violent inflammation, which spreads along the aponeuroses of the hand and forearm, and gives rise to numerous abscesses; we have once seen these accidents destroy a patient.

SECT. III.—Of Tumours.

Tumours are distinguished from cysts and abscesses by being always formed of solid productions. They are sometimes surrounded by a cyst; sometimes, although devoid of a cyst, insulated from the neighbouring tissues by a lax cellular tissue; at other times they are so confounded with the adjacent structures, that their precise limits cannot be determined.

1. *Of Tumours in General.*—It is often difficult to discover the intimate structure of a tumour, or even to distinguish it from cysts containing fluids. When fluctuation is obscure, recourse is had to an *exploring* puncture with the bistoury, trocar, or acupuncture needle. The bistoury is only proper when it is decided that the tumour must be removed, and the only question that remains is as to the mode of operating. The trocar, making a smaller wound, and being less liable to injure the nerves or blood-vessels, is preferable to the bistoury. The needle serves for cases in which the use of the trocar might be dangerous, as in tumours resembling aneurisms. The needle likewise serves to shew, by the extent of motion it can undergo, whether there is a free cavity in a tumour—a useful point of diagnosis, for example, in hydrocele, with thickening of the tunica vaginalis.

In employing the bistoury, it is requisite to observe the following rules:—1st. To determine on the kind of incision. The straight incision, not permitting more than a limited separation of its edges, is only convenient for small tumours placed imme-

diately under the skin, and free from adhesion; an incision in the direction of a fold of skin is convenient in extirpating encysted tumours which we fear to open, or solid tumours which it is advisable to avoid cutting, lest any portion capable of growing again should be left behind. The elliptical incision is preferable when it is proposed to remove a tumour with a flap of skin, either because this is diseased or redundant. The crucial incisions, and those in form of T or V, are indicated when it is desired to expose a large tumour without removing any portion of the skin that covers it. 2nd. Whatever incision be determined on, it should be longer than the base of the tumour, and the dissection should be made with long strokes, the edge of the knife being directed either towards the skin or the tumour, accordingly as we wish to be particularly careful of wounding one or the other. 3rd. The neighbouring muscles, tendons, vessels, or nerves, must be guarded or pushed aside by the fingers, forceps, &c. 4th. We should be well assured when the principal mass is removed, that no remains of it be left behind, especially if the tumour be of a suspicious character; anything of the kind should be removed with the knife or scissors, or destroyed by the actual cautery. 5th. When the tumour is of enormous size, a part of it only may be exposed and removed. After a few days, when the consecutive fever has ceased, we may remove a second portion, and so on, until the whole is extirpated. 6th. The wound should not be dressed until the vessels are tied, and the hæmorrhage has ceased. It is usually united by the first intention with sutures or agglutinative bandages.

2. *Of particular kinds of Tumours.*—1. *Encysted Tumours.*—Their nature may vary: their relations only are of interest to the operator. The skin and the investing cyst being cut through, the tumour is to be pressed with the fingers, in order to cause it to come out. When this occurs, it is to be seized with the fingers, or a pair of tenaculum forceps, and the cellular bands, which keep it attached to the bottom of the wound, may be divided with the bistoury held *en dedolant*.

2. *Fatty Tumours.*—These usually adhere but little to the neighbouring tissues. They present three different forms. 1. A flat tumour with a large base; the skin being cut through to the surface of the tumour, the latter is to be dissected right and left with the handle of the bistoury, or the fingers; there is seldom occasion to use the edge of the instrument. Then the tumour is to be turned out, and held with a hook, and the remaining adhesions divided with the scissors. 2. A large and projecting tumour. A flap of integument must generally be removed with the tumour, and its intimate adhesions dissected with the bistoury. 3. A pedunculated tumour. It

may be removed by dissection, the requisite quantity of skin only being left; or a ligature may be placed around it, a circular incision having previously been made through the skin. When the patient has much fear of the knife, Sabatier advises the ligature to be steeped in nitric acid and applied around the skin. This is destroyed by the caustic, without much pain, and afterwards the ligature causes none.

3. *Scirrhus and Carcinomatous Tumours.*—The knife, fire, caustics, ligature, and compression are employed in these cases. All these methods may be of use in particular instances, but we have nothing to add to the general rules before mentioned. M. Olivier advises inoculation with hospital gangrene in the centre of these tumours, and, indeed, of all others of a grave character. It is a desperate remedy adapted to desperate cases.

4. *Medullary and Hæmatoid Fungi.*—Extirpation is the only remedy: frequently, when the limbs are affected, amputation is necessary.

5. *Erectile Tumours.*—For these a variety of methods have been proposed. 1. Astringent and refrigerant applications: they are means of slight efficacy, which succeeded, however, once with Abernethy. 2. Compression: a deceptive and often dangerous method, when the tumour is large; but it may be useful with tumours that are very small, and so situated that they may be perfectly flattened. 3. Ligature. White says that he has passed a needle across a large erectile tissue, and tied the two halves with success; but this mode does not secure us from leaving behind a portion of the tumour, and may give rise to hæmorrhage, and to a recurrence of the disease. Genoul restricts the use of the ligature to cases where the base of the tumour is so small, and the neighbouring skin so lax, as to permit the tumour to be perfectly raised and insulated. Mr. Keate passes beneath the base of the tumour a straight needle, or two needles crossing each other (when it is very large), and applies the ligatures between the needles and the sound skin. 4. Caustics are advised by Wardrop. Mr. Guthrie recommends the nitrate of silver when the nævus is small and superficial. 5. The inoculation of different kinds of virus. M. Cumin advises numerous punctures with vaccine matter: M. Olivier inoculation with hospital gangrene. 6. Actual cautery. M. Maunoir has obtained by this means a perfect cure. M. Dupuytren regarded it as one of the most potent and rational methods: but the results being more serious than those which follow extirpation with the bistoury, its employment should be confined to tumours too extensive, thin, and confounded with the surrounding tissues, to allow of extirpation; and it may be employed, after extirpation, to destroy such remains of the morbid structure as may have escaped the bistoury. 7. Ligature of

the arteries. By compressing the arteries which go to these tumours we perceive them become flabby and soft, their pulsations disappear, and their volume diminishes. Hence the idea of tying all the arteries of the second order which pass to the tumour—an attempt which has not succeeded. More success has attended tying the principal trunk—as the carotid artery, for erectile tumours of the ear, orbit, &c. But, as in many cases, the tumour has reappeared, this method does not promise certain results. 8. A circular incision at the base of the tumour. This has been practised by Physick, with the view of more completely dividing the vessels. It is requisite that the incision should be made on the sound structure, should completely divide the skin and the subcutaneous cellular tissue in which the vessels are embedded. Some of these are tied, and the wound filled with charpie, to prevent immediate union. 9. Extirpation. This is effected with the bistoury used very carefully. An important precept is to remove the dissection as far as possible from the limits of the tumour, for the nearer we are to them the more vessels will require ligature, and if we cut into the tumour itself an oozing hæmorrhage will occur that can scarcely be restrained. If any part of the tumour should have escaped the bistoury, the actual cautery must be had recourse to.

All these methods may be of use: circumstances only ought to direct the surgeon's choice.

SECT. IV.—*Of Wounds and Foreign Bodies.*

Simple punctures rarely require the use of instruments; to wounds with cutting instruments the means are to be employed which we have before pointed out; lacerated wounds require no more, except the occasional removal of torn flaps which pass beyond the wound. This may be performed either with the knife or scissors.

1. *Of Wounds inflicted by the Bites of Rabid Animals.*—It is advised, in order to prevent the absorption of the virus, to wash the wound, to apply cupping glasses, to make a ligature between the wounded part and the heart, to open the veins which have their radicles near the wound, or to use cauterization. This may be performed with the actual cautery or caustics. The latter are preferred, particularly the butter of antimony. The rules for employing caustics have been already laid down; we have only to add here, that it is of the utmost importance to leave no point of the wound untouched*.

The same rules apply to the bites of venomous animals: the bite of the viper

* No security against the occurrence of hydrophobia is attained by any of these methods. Extirpation should always be performed, if possible.—T.

seldom requires cauterization. When this appears indicated, potass may be employed, or a piece of cotton imbued with alcohol, burnt on the wound.

2. *Of Wounds from Fire-arms.*—These, independent of the complications they are liable to in common with other wounds, require themselves only one operation, that of dilatation. There is a difference on this point between the French and English surgeons. The former dilate, in almost all cases, with the object of converting the contused wound into a bleeding wound, and of preventing strangulation. It is recommended to dilate as much as possible, and to carry the incisions along the whole course of the wound. But Hunter had very truly remarked that undilated wounds get well sooner than those which have been dilated, and that the incisions tend to increase the inflammation, which is the principal cause of the strangulation. We agree perfectly with the English doctrine, and confine dilatation to the following cases:—1. When the ball has traversed aponeurotic tissues, and the first signs of strangulation are manifest. 2. When it is necessary to enlarge the wound in order to extract foreign bodies, pieces of bone, or to tie vessels. It is in the latter cases only that it is necessary to make the incision along the whole course of the wound, until we arrive at the vessel to be tied, or the bone to be extracted. If the only object be the removal of incipient strangulation, it is sufficient to cut through the fibrous tissues which produce this state.

These general rules should also be observed. 1. To make the dilatation parallel to the axis of the limb, avoiding the vessels and nerves. 2. To direct the bistoury with the finger or director, and to make it cut from within outwards. 3. To enlarge the wound as much as possible on the most dependent side, in order to favour the discharge of pus. 4. If the fleshy parts are strangulated by an aponeurosis, to cut this first along, then across, or even, if necessary, in the form of a star. 5. To carry the incision the whole length of the strangulation. 6. To dress the wound simply, avoiding the reunion of the incisions by the first intention.

Dilatation is confined to wounds of the cranium or limbs. It is forbidden in penetrating wounds of the chest and abdomen.

3. *Of Foreign Bodies, with or without Wound.*—Foreign bodies are of several kinds. Some round, or of such a form that their dimensions do not materially differ, are driven by various forces into the deep parts without leaving any portion externally by which they can be laid hold of: such are balls, shot, wadding, pieces of clothing, &c. Others have an elongated form, and may often be seized by one of their extremities: such are the blade of a knife, or of a sword, a splinter, &c.

In general, it is accompanied by the

wound which permitted its introduction, but very often a ball or a needle is lost in the tissues, and remains there after the wound is closed.

1. *Of the Extraction of Balls.*—This is effected by the fingers when the ball is little engaged, which is, however, rarely the case. Many instruments have been invented for the extraction of balls more deeply seated, but they have all been superseded by the forceps. Of these, either the common dressing forceps may be used, or those used to extract polypi, or, what are better still, those invented by M. Charriere, the handles crossing one another so as to permit the branches to pass forwards in almost parallel lines. The general rules to be observed, are—1. To ascertain the situation of the ball by examining the course of the wound, by procuring information as to the position of the wounded person at the time of the injury, by sounding the wound, and examining all points of the limb to which it is presumable the ball may have been directed. 2. To make the requisite dilatations to allow the ball a free exit. 3. To divide the cellular tissue, which often embraces the ball like a cap. 4. If the ball causes a prominence at a distance from the opening of the wound, to make an incision over the situation of the former. 5. If the ball be impacted in bone it may sometimes be removed by the trepan, or if abandoned, the wound will often heal well. 6. If the ball be deeply concealed in the soft parts, so that it cannot be felt, and requires large incisions to enable us to lay hold of it, the case had better be left to nature. 7. When the ball is lodged between two tendons, it is sometimes necessary to cut one of them. 8. If lodged between two bones, as the leg, fore-arm, metacarpus, or metatarsus, the ball may be loosened and extracted with a common spatula. 9. If in making these attempts hæmorrhage be feared, the main artery of the limb should be compressed by an assistant, or with the tourniquet.

2. *Of the Extraction of other bodies which do not protrude Externally.*—Grains of powder may be extracted from the skin with the point of a needle: a tedious operation, which is only partially successful. Splinters of bone, fragments of wood or glass, portions of clothes, &c., may be drawn out with the dressing forceps, assisted by the requisite dilatations. If any foreign body be lost in the tissues after the healing of the wound, its extraction should be deferred until it forms an evident prominence at some point, which may then be opened and the forceps applied.

3. *Of the Extraction of foreign bodies which present some portions Externally.*—If the blade of a knife or sword be buried in the flesh, and the handle projects, this serves as the best instrument for drawing it forth. If the blade be broken and cannot be withdrawn with the fingers, it must be laid hold of with

strong pincers: it may be necessary to place the foot against the part where the weapon is buried, in order to enable us to employ strong tractile exertions. When a blade is broken level with a bone, and projects into a cavity, as the mouth or chest, the finger, guarded by a metallic thimble, may be introduced into the cavity, and the blade propelled from within outwards. This proceeding is only to be adopted with regard to the chest, when the wound is a penetrating one. If the blade offers no prominence externally nor internally, but produces serious inconvenience, the trephine may be used to discover it; but if no serious symptoms are present, it may be left until inflammation and suppuration have softened the tissues, and given some looseness to the foreign body.

4. *Of Wounds with loss of Substance.*—The operations for the relief of the consequences of these wounds, are detailed in the next chapter.

—o—

Foreign Medicine.

Irrregular Exanthematous Affection. By Dr. Bedor.

IN the summer of 1835, the atmosphere at Troyes was for several weeks very dry and very hot. Various exanthematous affections appeared among the children; and two cases of measles had recently occurred at Collot's boarding-school, when, on the 16th of July, a scholar ten years of age, went out for the day. On his return in the evening he was taken with a pain in the stomach, with repeated vomiting; and stated that his bowels had been frequently acted on during the afternoon, without his having committed any excess in eating. Some water holding sugar in solution was given him during the night, which was passed with agitation, and with the discharge of several loose and frothy stools, and much fetid gas. Next morning his countenance was depressed; eyes dull, but not red or watery; pain in the head; breath fetid; thirst moderate; want of appetite; tongue covered with a white coating; fauces red and hot; pulse slightly accelerated; no pain in the chest, or difficulty in breathing. Some degree of tenderness on pressure in the epigastric and hypogastric regions. Rest and abstinence were prescribed; decoction of dog-grass with mucilage; *eau sucrée, ad libitum*, and a gargle of barley water and mel rose. Two brown semi-liquid stools were passed during

the day. Some sleep, but of an agitated kind, was obtained at night.

On the 18th, he was rather better. The abdominal uneasiness disappeared, and there was observed on the skin an eruption of little punctuated spots, of a pale red colour. These increased in number, and in depth of colour, at night—the spots extending like a layer of currant juice. Contrary to what is generally observed, this eruption, which resembled scarlatina, shewed itself first in the lower extremities, then in the abdomen and loins, whence it extended over the breast and neck, and more feebly than elsewhere, over the face. The red colour was general in the evening, and the pain of the head became severe, while that of the throat persisted. Three grains of calomel were given, and sinapisms applied to the feet. An amelioration took place for a while, but was succeeded after a few days by a violent exacerbation. The eruption was not well sustained, and here and there on the skin was a furfuraceous efflorescence. The fever was greater; the head worse than usual; the speech rapid; and the mind wandering. He was now seen in consultation with Dr. Carteron and Dr. Patin, who continued his attendance on the case. Twelve leeches were applied to the occiput; one grain of calomel was given every hour, and an injection, containing an ounce and a half of castor oil and the yolk of an egg in decoction of linseed. Blisters were applied to the legs. The same gargle was continued, with decoction of marsh mallows in addition to the other drinks. The leeches bled well; but neither the injection nor the calomel had acted. The eruption was nearly effaced, having scarcely left any traces.

In the middle of the day the patient was removed to another house, which was accomplished without any fatigue; and the patient, in his lucid intervals, shewed himself satisfied with the change. The calomel was continued, and the blistered surfaces were dressed with beet root. On the 22nd, the eruption was more decided. The pulse was very quick and weak; the gums and lips were covered with sordes; the tongue yellow and dry; the countenance expressed only a stupor; and the general appearance denoted a very bad form of adynamic ty-

phus. A semi-fluid brown evacuation had been passed, containing a living worm. The room was sprinkled with a solution of chloride of lime. Next day the symptoms had increased in severity. There was a furfureous efflorescence on the skin, which was dry and burning. The patient, however, could lie on any side on which he might be placed. A hair pencil, dipped in fresh water sweetened and acidulated, was applied frequently to the inside of the mouth. It loosened and brought away by intervals some fragments of the sordes and thick mucosities which, without ceasing, accumulated there. Gangrene attacked the blistered surfaces, especially that of the left leg. Blisters appeared on the great trochanter of the right side, and towards the corresponding buttock. Pieces of ice were placed in the mouth, and received with avidity by the patient, who also took several mouthfuls of veal broth and wine and water. Plaster was applied to the right trochanter.

On the 25th, a thick crust, like the eschar of a deep burn, was taken from the mouth, drawing after it threadly mucous filaments. The extraction of the latter caused much anxiety to the little patient, but was followed by a marked improvement in his general state. Epistaxis to the amount of three or four ounces took place next day. On the 27th, the general depression and emaciation were extreme. The abdomen, which was wasted to a frightful degree, was without pain on pressure. The stools were rare, but tolerably natural. They were solicited by occasional enemata.

A hard tumour, of the size of an egg, appeared on the right side of the neck. It appeared to us to denote a critical deposition in that part. We might, I believe, attribute to it the character of what is called a complete and fortunate crisis; or, in other words, one of those sudden pathological phenomena which are sometimes observed to decide the death or the recovery of the patient, and which put an immediate stop to the struggle between the powers of nature and the destructive efforts of the disease. A very marked degree of deafness, and a purulent discharge from the ears, were observed at the same time. The auditory canals were cleansed by injections, and potato starch was added to the veal broth. The

blistered surfaces were very painful at every dressing. Opiate cerate was applied, covered with poultices.

Another cutaneous eruption appeared on the 28th. It presented the aspect and followed the course of a regular, abundant, and well-marked attack of measles. The pulmonary affection, more or less distinct, which generally appears essentially united to both scarlatina and the measles, never appeared in our young patient. The latter eruption appeared first in the inferior parts of the body, and for two days continued to spread from below upwards. On the 31st, desquamation took place; and the general state became better. Some light broths were well borne by the patient's stomach; and during the four first days of August, a diet progressively rendered more substantial, was equally well received by the digestive powers. The continual employment of the patient was to detach from the skin many portions of the epidermis, in broad leaves, several inches long. He was immersed in baths rendered gelatinous by the addition of a pound of white glue; by which his rough and parchment-like skin was softened.

The tumour in the neck verged sometimes toward suppuration, and sometimes toward resolution. The parents wished for the latter, in order to avoid a scar. A plaster of three drachms of Napolitain ointment was applied to it. At first it produced an erysipelatous redness over the side of the neck; but afterwards a very considerable reduction of the tumour. The deafness disappeared; the otorrhœa nearly so; the strength increased day by day; and the functions all assumed a satisfactory state. Thus the disease at length gave place to a convalescence which, at first uncertain and vacillating, quickly advanced towards a complete restoration to health. The following appear to me the principal conclusions to be drawn from this case.

1. Our young patient was endowed with a high degree of that inestimable vital resistance, which, Dr. Recamier has well said, is not to be measured by the apparent strength of the patient.

2. Judging from his recovery from an attack of croup, which he had when two years old, and the remarkable critical phenomena attending the typhoid exanthema-

tous fever, the diseases of this child tend more than those of many others to a salutary crisis.

3. Without wholly excluding others, affections of the nervous system, and those of the brain, are those which his constitution most dispose him to contract.

I believe it is generally admitted (as was lately observed by Professor Chomel in his Clinique) that the desquamation of the epidermis is furfuraceous in measles, and flaky in scarlatina. We have seen, however, in the present instance, that an eruption more like scarlatina than measles first appeared, and was succeeded by the latter. As a confirmation of this, a female attendant, after sitting up with him, was attacked with measles in a regular and benign form, disappearing in a few days. Nevertheless, the desquamation in our patient was by large flakes, as in scarlatina, instead of in a furfuraceous form, as is usual in measles. We also observed that the eruptions spread from below upwards; differing in this respect from the course which these cases generally follow.

In the article *Scarlatina*, in the 14th volume of the *Dictionnaire de Medecine et de Chirurgie Pratiques* (which has just appeared), it is stated that malignant scarlatina, (under which head the present case may be classed), is rare in Paris, both in private practice and in the hospitals. I intended to consult the articles *Roseola* and *Rubeola* in the same work; but though announced on the cover, they have (from some unaccountable inadvertence) been omitted in the body of the work.

It may be as well to mention here, that a younger boarder in the same school was attacked at the same time as the preceding, with a typhoid exanthematous eruption, not less irregular in its progress than that which has been just described. The principal feature in his treatment (which was conducted by Drs. Delaine and Calletot) was a general bleeding—the plan which M. Dewar recommends for scarlatina*. This other young patient also recovered perfectly.

What ought we to conclude from so striking a series of irregularities in the progress of cutaneous affections? In my opinion they confirm the observation of Professor

Broussais, that we must not trust in practice to the groups of symptoms comprised in a table, or to descriptions framed to comprehend all cases*.—*Gazette Medicale*.

Reviews.

A Practical Treatise on Midwifery, containing the result of sixteen thousand six hundred and fifty-four births, occurring in the Dublin Lying-in Hospital, during a period of seven years, commencing November, 1826. By Robert Collins, M. D. late Master of the Institution. 8vo. pp. 526. London: Longman and Co. 1835.

THIS work is a clinical report during a period of seven years, of one of the largest obstetric institutions in the world—the Dublin Lying-in Hospital. This institution was founded in 1758, about 77 years ago, by Dr. Bartholomew Moss, and has afforded relief to 131,172 poor women, an average of more than 1703 a year; but the annual admissions at present are over 2000. The chief physician is elected by a few voters, and holds his appointment for seven years, and has two assistant physicians. There is not a grosser job in the medical offices in the United Kingdom, than the appointment of Physician in Chief or Master, as he is termed, of this Hospital. The individual is invariably elected by family interest or intrigue; incompetent persons get appointed, and up to this hour, none of them was ever able to publish even so imperfect a volume as the present. The election is a farce played for the purpose of excluding talent. The best proof we can give of the evil results of it, is simply this, that Masters were appointed who did not possess the slightest claim to preferment, while the most competent have been repeatedly, or rather invariably, excluded—witness the exclusion of Dr. Montgomery and others†. We might dilate upon this topic, but we refrain from further comment, as a better order of things will be

* In translating this case, we have curtailed it very considerably, and pruned it of all its ridiculous pomposities. We hope our young friend, Dr. Bedor, (for this is evidently his first attempt), will give us next time a shorter case and more in it.

† See evidence before the Parliamentary Committee on Medical Education and Practice, in Great Britain and Ireland, 1834.

speedily established by the Medical Reform Bill.

Our author informs us in his title page, of the great number of births which took place during his Mastership; so that the casual reader will suppose that he superintended each of them, which could not be fact, nor does he assert it. We therefore think it was not the best taste to include this item in the title page. We are informed in the preface, that the author has resided in the hospital as an assistant and master for ten years, during which period, 24,119 deliveries occurred, the results of which, he almost in every instance witnessed, "being thus afforded ample opportunity of acquiring information. During the last seven years of his residence, 16,414 women gave birth to 16,654 infants." The author must, according to this statement, be most indefatigable, and have attended night and day during the above period. He apologises for the concise manner in which he has narrated the cases (and this was certainly necessary), but he preferred the simple truth, which "when unadorned is adorned the most." He has introduced several tables, which required great labour, and which afford a vast fund of practical information. These will be read with interest and advantage by every practical obstetrician. He arranges the work as follows:—

1. Natural, tedious, and difficult labours;
2. Preternatural labours;
3. Complex labours;
4. General observations on patients who died in the hospital, shewing the causes and proportions of deaths;
5. Puerperal fever;
6. Observations on still-born infants;
7. Observations on infants who died in the hospital;
8. Registry of the mortality in the early periods of infancy.

We shall select the most important facts in this work, as the observations of the author are, in general, in strict accordance with those of the highest authorities, but in some cases, as on the use of the forceps, totally at variance with them. In 16,414 deliveries, the forceps was applied 24 times, and the lever 3 times—total 27; making the average about 1 in 608 parturitions. According to this calculation, most obstetricians in private practice would require to use these instruments very seldom; and supposing, says our author, an individual to attend 4000 labours, in the course of his

life, which is a greater number than falls to the lot of most practitioners, the forceps or lever would be necessary in little more than *six cases*! Our author hazards this opinion, though he has given a table which shews the proportion of cases in which the most eminent obstetricians of the present period use this instrument; and it appears that some of them had employed it so often as 1 in every 3, 9, 12, 13, 15, 23, 31, 35, 36, 96, 98, 114, 158, 162, and 183 cases. Dr. Collins applied it in 1 in 114 cases, according to his own shewing in this table, although he concludes that in private practice the proportion ought to be 1 in 666½ cases. Now, why did he use it so often, if it be so seldom necessary as just mentioned? He surely does not mean to state, that cases requiring the use of instruments are not as frequent in private as in hospital practice. He does not state whether he used the forceps in 1 in 114 private cases, but he does state that he employed it only in 1 in 608 in his hospital practice.

Our author, however, entertains the most singular opinions on the use of instruments, which according to the best obstetric works, and to our researches and observations, we think are solely belonging to himself. His language is often vague and unmeaning, as we shall presently shew; and some of his conclusions are at variance with obstetric science, or the practice based on it.

Thus, after strongly advising the necessity of a consultation before obstetric operations, which every professor and lecturer strongly recommend, though he gives the whole credit to Dr. Labatt, and after stating that the ear must be felt before the application of the forceps—we presume the short one—he proceeds thus:—

"I have no hesitation in asserting, that to use it (the forceps) under other circumstances, is not only an abuse of the instrument, but most hazardous to the patient. It is from being thoroughly convinced of these facts by long and extensive observation, that I consider the forceps quite inapplicable where the head becomes fixed in the pelvis, (query, in the brim, cavity, or outlet?) and that the ear cannot be reached by the finger, except by violence, in consequence of disproportion existing between the head and pelvis, either owing to the former being unusually large, or the latter under size; in most instances measuring little more than three inches from pubes to sacrum (query, at brim, cavity, or outlet?), and in others less

than this. * When we consider that the blades of the *smallest* forceps used in Britain, even when completely closed, measure from $3\frac{1}{2}$ inches, to $3\frac{3}{4}$, it is clear, that were the bones of the pelvis denuded of their soft parts, there would not be space to admit of their application. The French forceps measures, when closed, on the upper side, $2\frac{1}{2}$ inches, and are about one-eighth wider on the opposite side, meeting at the points of the blades, to within one-eighth of an inch. Were we even to overlook altogether the safety of the mother, when the child's head measures $13\frac{1}{2}$, $14\frac{1}{2}$, or 15 inches in circumference, and is so compressed, as it must be, when the instrument is closed, there can be scarcely a hope of life. Of course where the pelvis is roomy, this compression of the head, so as to close the forceps, is unnecessary, and in such cases, the child is uninjured. How is it possible with the forceps to drag (*to drag!*) a child through a pelvis, where there is not space, except by *force*, to introduce (as is commonly said) a straw, or where the smallest flexible catheter cannot, in some instances, be passed into the bladder?"

What the author really means by the head being fixed in the pelvis, we cannot divine whether in the oblique, antero-posterior or bis-iliac diameters of the brim, or in the cavity or at the outlet. The head may be impacted or fixed, or arrested in its progress in every one of these positions, but to which the author refers, he leaves his readers to guess. This vague kind of writing has been long excluded from really scientific works, and most properly so, as will appear by a few remarks on the example before us. Every well educated obstetrician knows, that the infantile head may be fixed or arrested in the brim, cavity, or outlet of the maternal pelvis; and that different instruments will be required in different cases; the long forceps, lever, perforator, &c., or the short forceps and lever, &c., each of which is only applicable in particular positions of the head in the different parts of the pelvis. The subsequent part of the quotation evidently refers to disproportion between the pelvis and head, and our author concludes, as every other obstetric writer has done, that when a straw or a needle cannot be passed between the head and pelvis, the forceps is inapplicable, and craniotomy is necessary. In such cases, we feel convinced that no practitioner, but a grossly ignorant and uneducated one (and there are a vast number of such among us), would attempt to introduce the forceps, and "drag" a child through

the pelvis under such circumstances. That word *drag* has made us shudder, and reminded us of the horrible and barbarous proceedings of obstetric practitioners of the dark ages; but we do not, nor cannot believe it applicable to the practice of modern obstetricians, and much less appropriate in a Practical Treatise on Midwifery. The author ought not to have used it, and remembered the obstetric axiom—*arte non vi*.

But we beg to inquire, does it follow from the most extreme case of impacted head caused by disproportion between that part and a small pelvis, that the forceps ought not to be employed in the thousands of other instances in which there is plenty of room to apply it; and that the woman ought to be left in labour, as some were in the Dublin Lying-in Hospital, from 24 to 90 hours? The answer must be negative, according to the best obstetric writers and practitioners in existence. The table we have given attests, beyond all doubt, the correctness of this opinion.

It is to be regretted that the author did not carefully peruse some of our standard works on the use of the forceps and other instruments, before he arrived at such sweeping and untenable conclusions. It is very remarkable that all the masters of the Dublin Lying-in Hospital, for some twenty years past, have belonged to the old school of time and patience, left all to nature for 40, 60, or 90 hours, and seemed dreadfully alarmed about using the forceps. The few papers they have published—even those of Dr. Clark, Dr. Labatt, Dr. Pentland, and our author—afford too much evidence of the truth of our position. These, and many of their assistant physicians, appear to dread the use of the forceps as much as gastro-hysterotomy. In this part of the kingdom, few feel such dread, and the majority of scientific, and, consequently, judicious practitioners, do not allow the head to become impacted or arrested, or leave it so, trusting to the exhausted powers of nature for two, three, or four days; and, moreover, they have no more fear about using the forceps than feeling the pulse; and the results of their practice are as successful as in any part of the world, and much more so than in many parts. The observations of Dr. Burns are so instructive and valuable in practice, on the use of the forceps in arrest of the head, that we shall quote them fully, as we entirely agree with them, and as they

overthrow our author's conclusions. After descanting on impacted head, and advising perforation, he proceeds as follows :—

"There is another case of protracted labour requiring instrumental aid, when the head is not impacted; the pelvis may even be of ample size. It is much more frequent in its occurrence, and is known under the name of the case of arrest, or by the French writers *la tête arrêtée au passage*. The head is not fixed or jammed, the finger can more readily be passed round it, the scalp may be swelled, but it is to a less degree and firmer. The bones are nearer the perinæum, and are never so squeezed or misplaced, and the retardation appears to arise rather from the nature of the pains, or the unyielding state of the soft parts at the outlet of the pelvis, than from any great obstruction offered by the pelvis to the delivery; but I have already noticed, that a very small obstacle often decidedly impairs the actual force of the uterus: though, perhaps, not the degree of pain. Further, the head descends lower than in a case of impaction. The ear is more easily felt, not only from there being more room for the finger, but also from being farther down. It can be felt by introducing two fingers; whereas, in greater contraction, the hand sometimes must be introduced into the vagina to feel the ear fully. It is a mere case of tedious labour, but a case protracted to the utmost limits of prudence, in spite of the employment of those means which have been pointed out in the last chapter. It may arise from some slight disproportion between the size of the head and the capacity of the pelvis, or more frequently from variations and irregularities of the uterine action, which have already been fully considered, and it is much more frequent in its occurrence than the locked head. The case of impaction is clearly marked by the symptoms formerly detailed: that of arrest is ascertained by the simple condition of the head being stationary, but not jammed in the pelvis. There are many cases, then, of arrest, which are safely terminated by nature, and which are placed under the class of tedious labour; but there are many others, where it becomes prudent to accelerate delivery by artificial force, and the question for deliberation is, at what period we shall thus interfere, or, when further delay is hazardous?

"I have fully, and I hope practically, detailed and considered the causes which render labour tedious, and have pointed out the impropriety of permitting the first stage to be protracted, for thereby the uterus becomes enfeebled, and less able to accomplish the second. But when this advice has not been acted on, or when the treatment proper for the particular cases already described, has not been successful in effecting delivery, what is the consequence ultimately of delay? The uterus, by continued, but inefficient action, or unavailing contraction, becomes gradually debilitated; and when at last delivery is ef-

fected, it cannot contract with vigour and regularity, whereby hæmorrhage is occasioned, or the same event is produced by spasmodic action of the uterus. Here, then, is one very serious evil which may be anticipated. Next, there is a strong disposition given to puerperal disease, not merely to those troublesome, though less dangerous complaints, known under the name of weeds, or irregular febrile paroxysms; but also to more formidable affections, of an inflammatory nature, especially of the womb or peritonæum. Accordingly, we find that a much larger proportion of women die after protracted, than after natural labour. Here, then, is another class of evils to be apprehended. Again, although the same local mischief is not so apt to take place, that we meet with in locked head, yet the patient is not exempted from risk even of that; by continuation of labour, the soft parts at last inflame and swell, which adds not only to the difficulty of delivery, but also greatly to the danger of the case. If it be necessary to enumerate other hazards, I may set down the consequence of protracted irritation and exertion, marked by the induction of a state of fever, and at last of great exhaustion, inasmuch that the patient may actually die undelivered, but this event, as well as rupture of the uterus, is less apt to occur than in locked head. Besides all these hazards to the mother, the child is in danger of perishing, not from compression of the brain, but from the continued pressure of the uterus, after the evacuation of the water, interfering with the regular performance of the function of circulation. These are surely no trivial evils resulting from protracted labour; and the utmost that I feel at liberty to concede in favour of delay, is, that it may be permitted longer in cases of arrest, than of impaction. Many eminent men have placed an undue confidence in the power of nature, and have been hostile to the use of instruments. For a long time I was influenced by the high authority and plausible arguments, as well as bold assertions of these practitioners, but experience has compelled me to adopt the opinion, I am now, with a firm and solemn belief of its correctness and importance to maintain in this chapter. From the strength of the recommendations of the partizans of nature, we should suppose, that whenever the child could actually be born without aid, no hazard occurred, and, on the other hand, that instruments must of necessity prove not only very painful in their application, but dangerous in their effects. Now, the first supposition is notoriously wrong, for innumerable instances are met with, where the mother does bear her child, without artificial aid, and much, doubtless, to the temporary exultation of the practitioner, but, nevertheless, death takes place, or, at the best, a tedious and bad recovery is the consequence. The second supposition is just as positively untrue; for in the majority of cases, if the practitioner

be humane and gentle, the introduction of the instrument gives little or no pain; in so much so, that in many books we meet with strong and just reprehension of the clandestine, and unnecessary use of instruments, which could never possibly take place, if their application were attended in such cases with much pain. Then, as to the pain occasioned by extraction, that may be greater than the patient was just before suffering; and yet not be greater than is often experienced in a natural labour; or even granting it to be uniformly greater, a concession I make for the sake of argument, it is but for a short time, and, on the whole, the suffering of the patient is less than if nature had been allowed at length to expel the child. These positions are perfectly correct in all cases of arrest, when the practitioner is well instructed and cautious. Next, as to the danger to be apprehended, I cannot in cases of arrest see any source whence it can arise. The mere introduction of the forceps, if gently accomplished, can scarcely be more hazardous than the introduction of the finger, for no force is, or ought to be exerted. If there be hazard, it must be in the process of extraction, and this, it is evident, can arise only, either from the pressure of the instrument on the soft parts, or from the head and instrument lacerating the perinæum. The last event must, in general, be the consequence of want of caution, and the first can never be carried to any dangerous degree in a case of arrest, if the operator know how to direct his efforts.

"In such cases, then, we may experience much evil, from trusting too long to nature, but add little to the sufferings of the patient, and nothing to her hazard by instrumental aid. When, however, we turn our attention to the cases of impaction, the matter is different. There is greater difficulty in introducing and fixing accurately the instrument, and doubtless more pain even in this stage is given than in cases of arrest. When again we come to act with it, the suffering or pain must be increased, even in the hands of a gentle operator, in proportion to the resistance to be overcome. The soft parts have already been pressed on, during labour by the head, they must still be pressed to a greater degree; and even if the maxim, that time is equivalent to force, were acted on to a certain extent, it would be in vain to deny that there must be both greater suffering and greater danger than in natural labour, or than in cases of arrest. These sufferings, and this danger, must be in a certain degree proportioned to the tenderness which has already taken place in the soft parts, and therefore may be greatly lessened, but cannot be increased, by an early application. Their production depends on the obstacle afforded. When the head has arrived at a station rendering the application of the short forceps practicable, no good can arise from delay; we only add unprofitably to the suffering in the meantime, or lay the founda-

tion of a state, which is to render the later application of the instrument more painful and more hazardous. When mischief arises from the application of the forceps, it always is owing either to harsh and unskilful conduct, or to the state induced by delaying their use too long. If it require strong efforts to extract the child, could that child ever have been born by the power of nature, or could the uterus and abdominal muscles, after long action, retain vigour sufficient to exert a force equal to that which is often required to extract an impacted head? Indeed, our best writers, however fond they may have been of delay in cases of arrest, are disposed to deliver whenever the head has been locked. Nothing can be expected from delay except sloughing, and the alternative of speedy death, or a miserable existence; and in all cases of decided impaction, the question, I apprehend, is not whether we shall immediately deliver, but whether we may succeed with the forceps, or shall be obliged to use the crotchet.

"Holding the opinion I have been laying down, it is not without astonishment and regret, that I find Dr. Osborn stating, that in a case requiring the use of the forceps, 'all the powers of life are exhausted, all capacity for farther exertion is at an end, and the mind as much depressed as the body, they would at length sink together, under the influence of such continued but unavailing struggles, unless rescued from it by means of art.' If such a state be allowed to take place, even in a case of arrest, but more especially of impaction, it is much to be dreaded that the interference of art shall prove as unavailing as the struggles of nature. Were this the opinion only of Dr. Osborn, I should pass it in silence; but unfortunately it is the prevailing doctrine of the day; and the modern disciples of the school of patience, men of talent and observation, carry their fears of the mischief resulting from the use of the forceps, to an extravagant length, and place a mistaken confidence in the efficacy and safety of a continued action of the expulsive powers. I have much pleasure, however, in strengthening my opinion with the authority of Dr. Hamilton, the present excellent Professor of Midwifery in Edinburgh, who has long seen the hurtful effect of the temporizing system, and of Dr. Oslander, the active and experienced Professor in Gottingen.

"To place the argument in a yet stronger light, I shall examine the result of delay, as deduced from the tables, published by Dr. Breen, of the cases occurring in the Dublin Hospital, because these are the latest I have beside me, and were published without reference to any particular opinion.

"In the course of 57 years, 78,001 women were delivered, of whom one out of every 92 died, and one child out of every 18 was stillborn. If, however, we were to exclude cases of tedious labour, and attend to the rest of cases of natural labour, or the con-

sequences of a correct and healthy process of parturition, we would find the proportion of deaths to be altogether trifling; I am willing, however, to adopt this average. Let us now see the result of tedious labour.

"In women, who were in labour of their first child from between 30 to 40 hours, one in 34 died, and one child in five was still-born. Here then is a prodigious difference between even the average result of all labour, good and bad, and a protracted labour. During the same period of labour, amongst women who had previously borne children, and therefore, if requiring instruments, might be supposed to have a more permanent obstacle, or contracted pelvis, though this is not stated, about one in every eleven died, and one child in every six was stillborn.

"When labour was protracted between 40 and 50 hours in women who had not previously borne children, one in 13 died, and the proportion of stillborn children was as one in 34.

"If labour were protracted other ten hours, that is between 50 and 60, one-eleventh of the women died, and when we proceed to the period of between 60 and 70 hours, one-eighth died, and nearly one-half of the children. It is observable, however, that only one-twelfth died in the next ten hours, but this variation must arise from accidental circumstances.

"It is impossible to give any comparison of these results, with those afforded in the same hospital by the use of instruments; for artificial aid, it is evident, was always long delayed, unless in cases where dangerous symptoms not essential to labour occurred. Instruments were used, on account of tedious labour, in 11 cases, and of these 18 died.

"Now, taking the proportion of deaths in the parturient state to be, including all disasters whatever, as 1 in 92, it is most important to observe the progressive fatality arising from delay. Suffering above 30 hours destroys 1 in 34; in other 10 hours the danger more than doubles, for 1 in 13 die; then 1 in 11, and next 1 in 8, to say nothing of the children."

It appears by Dr. Collins, that mortality is very much diminished of late in the Dublin Hospital, and it affords us much satisfaction to place his statements before our readers.

"Thus, of the 15,850 cases noted, 15,084 were delivered within *twelve hours* from the commencement of labour; 15,586 within *twenty-four*; 15,671 within *thirty*; and 15,720 within *thirty-six* hours; leaving 130 above that period.

"Of the 16,414 women delivered, 4969 were *first* pregnancies; of which 72 were twin births. These 16,414 women gave birth to 16,654 children, including twins.

"In *seventy-nine* of the 16,654, delivery was effected by lessening the head, (on account of extreme difficulty in the labour, or where the child was dead and interference desirable, owing to the state of the mother), when,

after the most patient trial, the impracticability of the labour being terminated in safety by any other means, was clearly proved to us. In *six* of the 79, delivery with the forceps was attempted; but no force consistent with safety could, in this way, accomplish it. *Fifteen* of the 79 women delivered by the crotchet in difficult labour, died. See article on still-born children, where the particulars of twelve are recorded, viz.:—Nos. 173, 210, 257, 303, 504, 665, 686, 745, 817, 873, 1038, 1095. *Seven* of the twelve died from the following causes:—No. 173 from stricture of the intestine, with effusion into the thorax. No. 210 from the effects of abdominal inflammation *previous* to labour. Nos. 257, 303, 504, from the effects of labour *previous* to admission. No. 665 from puerperal fever, which at the time was prevalent in the hospital. No. 745 was admitted labouring under typhus fever. The *five* remaining cases died from the effects of inflammation and hæmorrhage, or injury produced by pressure. *Two* of the five suffered from hæmorrhage: one *previous* to the delivery of the placenta, and the other subsequent to its expulsion. In both, it was necessary to *pass the hand into the uterus*. One of the two had been force-delivered with a former child, and all her children were still-born. These circumstances added considerably to the bad effects arising from the difficulty experienced in the present labour, and must have contributed much to the fatal termination,

"The number of infants born was 16,654, of whom 284 died *previous* to the mother leaving the hospital, being a proportion of 1 in 58½, which is a very small mortality.—Of 16,414 women, 164 died, or about 1 in 100. and death was caused in some by accidental diseases."

We have now given a specimen of the merits and demerits of the production before us, and must leave our readers to consult the original work on other points in it. It is, in our opinion a good statistical account of the Dublin Lying-in Hospital for ten years, and one that will be referred to by subsequent writers on obstetrics. Although we do not agree with the author on many points, we consider him a safe, experienced, and judicious obstetrician.

—

The British Medical Almanack for 1836.

THIS is really a most useful and meritorious little work, and has undergone great improvements since its first edition. It concentrates much important information from sources which are not easily accessible. The Chronological History of Medicine, which is very judiciously condensed from Hecker. is too good; we mean to say, it is a shame that a set of lazy sinners, who never read a

dozen books in their lives, should have the result of so much laborious reading compressed into a few pages for them.

The Supplement to the Medical Almanack contains Dr. Grant's Classification of the Animal Kingdom; the Characteristics of the different Races of Mankind; several ingeniously constructed tables relating to medical statistics; French and English Weights; a Formulary of New Medicines; an Epitome of Auscultation and the Physical Signs of Thoracic Diseases; Antidotes of Poisons, &c.

In short, this well conceived, and neatly executed work, offers in a small compass and at the moderate price of two shillings, every thing that can assist the memory of the practitioner on subjects where it is most likely to be occasionally at fault.

We recommend every medical man in England to possess himself of the book, and we heartily wish the author all the success he deserves.

THE METROPOLITAN UNIVERSITY.

WE have received a very argumentative and judicious letter, addressed by Dr. Epps to the Right Hon. T. Spring Rice, on the subject of the intended Metropolitan University; in which he very clearly exposes the injurious effects of conferring a monopoly on two of the many medical schools in this metropolis, namely, the London University and King's College. It could scarcely be supposed that a government which has done so much in destroying corporate monopolies of all kinds, would propose a new one; but nevertheless—we grieve to indite it—we need scarcely observe that the fact is so. On a former occasion, the Privy Council refused to grant the power of conferring medical degrees to the London University, as it would be to the manifest injury of all the other medical schools in this metropolis; but now the same government which com-

posed a great portion of that council, allows itself to be influenced by the proprietary of the above-mentioned institutions, in establishing a London University on the basis of the grossest monopoly, for the benefit of the same joint-stock companies. It is quite certain, however, in our opinion, that neither branch of the legislature will ever sanction or support a new university on such narrow and unjust principles. It is astonishing that a government which has done so much for the diffusion of education, could for a moment entertain the idea of closing all the medical schools in the United Kingdom, except the chartered ones; as if instruction were not as good in all the unchartered as in the favoured pair. But neither the public nor the legislature will ever tolerate such injustice; and more especially as the would-be excluded schools, have also their friends in the Houses of Lords and Commons.

This left-handed policy must have been suggested principally by the opposed shareholders of the London University and King's College—the political Peachums and Lockets, who to serve each other, have no objection to plunder their formidable rivals in the other medical schools, and to fill their coffers by emptying those of opponents, who have by fair competition in the republic of science, justly obtained an adequate reward for the exertion of their talents, and seriously injured, if not almost ruined one of these institutions. We are very much disposed to believe that the old medical corporations have tampered with the government on the subject under consideration. They have discovered rather late, that the medical schools of Great Britain and Ireland are by far too numerous, and ought to be reduced, if practicable or possible. It was a matter of course, that the opinions of the Colleges of Physicians and Surgeons, and of the Society of Apothecaries were obtained,

though each of these bodies had its own interests to advance; and these being opposed to those of the Professors and Lecturers, it is not difficult to divine the kind of opinion which the framers of the New University would receive from such quarters. There is no doubt, however, but the different medical schools in this country will petition Parliament against the intended monopoly, which will, shall, and must be blown into thin air; and that the new Metropolitan University will be founded on an equitable basis, and worthy of the age in which we live.

We also feel assured that Mr. Warburton, who has evinced so much interest, zeal, and philanthropy in medical matters, and who is so well qualified to advise the Government on the subject, will never consent to the establishment of a new monopoly in medicine, as no one is so well able to judge of the imperfections of the present system, which were so clearly and forcibly expounded before him.

It is likewise to be borne in mind, that as Chairman of the late Parliamentary Committee to inquire into the present state of Medical Education and Practice in this country, he has a duty to perform to one branch, and by far the most powerful one, of our legislature, as well as to the public; and that whoever may be ministers, or form the Government, the present House of Commons will and must obey public opinion. That House is in favour of wise and liberal measures, and no ministry, whether Whig, Tory, or Radical, can henceforth carry measures in opposition to reason and justice. It appears to us, therefore, from the preceding statements, that the old adage is incontrovertible—*vox populi, vox Dei*; and that the attempted bubble of a new monopoly will explode and end in smoke—so far as it favours two medical schools founded by a tribe of traders under the disguise of joint-stock proprietors. No, no. Science belongs not

to joint-stock companies, or to certain countries, it is open to all men:—*patens omnibus scientia*.

—o—

INSURANCE OFFICES IN RELATION TO MEDICAL PRACTITIONERS.

We feel pleased to observe that a leading morning journal has admitted some sensible letters from a correspondent, who styles himself Philo-Physicus, on the presentsystem pursued by Insurance Companies, of requiring certificates gratuitously from all grades of medical practitioners; as we were the first to direct attention to the subject.

Were the public press to admit articles of this kind more frequently, it would confer most signal benefits on the public, as well as on the medical profession. It has, however, of late lent its powerful aid to the profession, and will continue to do so, because the more it reports those cases of civil and legal proceedings, in which medical evidence is given, the more it will advance the interests of society.

It is to be recollected that medical evidence is conclusive in a vast number of civil, criminal, and other proceedings, in the different courts of justice, from the highest to the lowest. It affects life, liberty, property, and reputation in every class of society; and the more it is brought before the world, the more cautious and correct will it be.

The custom adopted by Insurance Companies, of requesting medical certificates gratuitously, concerning individuals who may be about to assure their lives, is most unreasonable and unjust. It is difficult to perceive on what grounds any class of society can expect to occupy the time of a medical practitioner, for an hour or two, without adequate remuneration. In the present case, the whole history of a man's life, his former diseases, hereditary predisposition, his temperament, habit, all functions, must be most carefully examined, as well as his present state of health, before a proper certificate can be given:

in fact, much more time is expended, than in a consultation, for which a double *honorarium* is always presented. It is obvious to all, that the Insurance Company is the most interested party in the affair, infinitely more than the person about to assure his life, or than his medical attendant; and the Company ought therefore, in justice, pay for the advantage it solicits gratuitously. If the patient feed his medical adviser, he might sometimes expect, for value received, a favourable certificate, when an unfavourable one would be given. But legally qualified physicians and surgeons are sworn to act honourably and justly in the discharge of their professional duties, and will not violate their oath, to please either patient, or an Insurance Company. Paid or unpaid, as witnesses, they must testify the truth; but they are not bound by any law or custom, to give their evidence, and lose their time, to the injury of their families, to affluent persons, without proper remuneration.

We think the profession deeply indebted to the *Times*, for inserting the letters of Philo-Physicus, and we hope that the subject to which we have alluded, as well as many other medical ones, will be frequently submitted to the public through the medium of the newspapers. It is but justice, however, to the public press in general to state, that it is equally favourable to the interests of medical practitioners, the protection of which must, in all cases, be beneficial to the public.

A few years ago, medical matters were wholly excluded from the newspapers; until questions on contagion, quarantine, &c., were at length deemed worthy of notice. In a well conducted metropolitan newspaper there is a corner for all classes of society, except the medical; though the latter is a numerous, respectable, and most influential one, and may benefit a daily publication, as much, if not more so, than many others.

WESTMINSTER MEDICAL SOCIETY.

Saturday, Dec. 19, 1835.

DR. ADDISON, PRESIDENT.

Interesting Case in which Fibrinous Concretions were found in the Heart—Use of Iodine and its Compounds in Secondary Syphilis, Gôitre, Ovarian Dropsy, and Hydrocele.

MR. WADE related an interesting case, in which fibrinous concretions were found in the heart: it was the case of a young woman, whose body he had just examined, at the request of her medical attendant. Mr. W. did not see the patient during life, but heard the following particulars from the gentleman who attended her, and her friends. She was twenty-four years of age, and had been ill for nine months previous to her death; the origin of her disease appeared to have been an inflammation in the chest, which was removed by the usual remedies; but dyspnoea remained, more or less, until the period of her decease, attended with cough and expectoration of a muco-purulent character. She suffered latterly under distressing palpitations, and any exertion was attended with great difficulty of breathing. On the morning of the day on which she died, she ate her breakfast as usual: she was suddenly taken giddy and faint, with great fluttering at the region of the heart. She appeared to refer all her sufferings to the cardiac region, where her hand was constantly placed; and the lips were blue. From this last symptom, and the embarrassment of the respiratory organs, her medical attendant considered she was labouring under congestion of the lungs, and immediately bled her to about twelve ounces. She, however, became gradually fainter and fainter, and died at 7 P. M.

The *post-mortem examination* was made twenty-four hours after death. On the *left side* there was complete adhesion of the pleura costalis to the pleura pulmonalis, the lung on that side was much consolidated, presenting appearances of hepatization: in the lower part of the organ there was a small cavity about the size of a nut, filled with muco-purulent matter, slightly tinged with blood.

There was no adhesion of the pleura on the *right side*, and the lung was tolerably healthy, being crepitant throughout. The heart was small and flabby; an ounce of pale-coloured serum was found in the pericardium; the left ventricle was not more than half its natural size, its cavity being greatly diminished: the right ventricle was very small, both in its cavity and parietes; the latter being not more than an eighth of an inch in thickness in any part; both the auricles were slightly contracted. The right auricle was completely filled by a firm fibrinous concretion, which extended through the auriculo-ventricular opening, into the cavity of the ventricle, completely obstructing the passage of the blood. The concretions adhered very firmly to the tricuspid

valve. No other diseased appearances were observable. Mr. Wade observed that some pathologists consider polypi, or fibrinous concretions, to be *post-mortem* effects, whilst others believed they were formed during life; he, himself, considered there could be no question of the last opinion being the correct one in all cases; for he believed that some degree of motion, with a languid circulation, was necessary to their formation, as they are found in the cavities of the heart, the pulmonary arteries, and the aorta, especially the former; also in the superior longitudinal sinus, where are situated the chordæ Willisei which, no doubt, act mechanically, as do the chordæ tendinosæ, and valves about the heart. These concretions are also observed occasionally in arteries, which have been much obstructed by ossification: it is not uncommon to find these formations adherent to the spicula of bone, and forming a serious obstruction.

Many authors believe these polypi susceptible of organization. Bouillaud, in his "Essay on Obliteration of Veins," mentions two instances of organized polypi: in one example, the right auricle was filled with a fibrinous concretion, traversed in every direction by minute vessels. In the other case, both the auricle and ventricle on the right side contained organized fibro-albuminous matter. The individual subject to the last case died with all the symptoms of ossification of the heart. There are several other cases on record. With regard to himself (Mr. W.), he had in numerous instances examined these concretions most attentively, and had never been able to detect the slightest signs of organization. He asked the experience of the Society with regard to this circumstance.

Use of Iodine.

After a short time, as no member rose, the president said he would take the present opportunity of alluding to a report in which a member of that Society* had fallen into the error of supposing that he (Dr. A.) considered iodine not only useless, but perfectly inert. Now, as he had seen two cases in which death resulted from the use of that medicine, he could not have considered it inert. He had said of iodine, that he was disappointed in the use of it, having found it only partially successful in gôitre, less so in scrofulous affections, and quite useless in tumours occurring in the abdomen. The preparations he spoke of were uncombined iodine and the hydriodate of potass. With regard to the hydriodate of iron, he had found it of great use in open scrofula; but he could hardly name that among the other preparations of iodine, as

iron by itself was so powerful a remedy. He asked Dr. Thomson to favour the Society with the result of his experience in the use of iodine, and its compounds.

Dr. Thomson thought iodine, when uncombined, often gave disappointment, from the fact of its inducing great febrile excitement, and setting up an action different from that which should be produced to remove the disease of obstructed glands; he rarely employed it uncombined. The hydriodate of potass he had employed in various ways, and had very seldom been disappointed in its effects: indeed, he entirely relied on it in secondary syphilis, so invariably successful had been his employment of it in that affection in all its different stages and characters. So much did he depend on it, that if a patient came to him who had had a primary syphilitic affection which had been healed without the use of mercury, and secondary symptoms now presented themselves, he should try it alone, and he believed with success. In treating disease, the use of mercury often required to be some time suspended, in order that an effect might be produced. Iodine possessed this advantage, that when one preparation of it ceased to be effective, another might be substituted with complete advantage, and a saving of time was thus effected.

Mr. Wade inquired whether in those cases of secondary syphilis which Dr. Thomson had treated with iodine, any scrofulous symptoms were present, as he (Mr. W.) generally found such cases the most obstinate. With regard to his own experience in cases of secondary syphilis, he had found the oxymuriate of mercury and the compound decoction of sarsaparilla the most useful remedies. Had those patients Dr. T. treated been previously under a course of mercury?

Dr. Thomson replied, some of them had been under the influence of mercury, which did not succeed in curing them. Out of 12 or 15 cases of secondary syphilis, of all kinds and in all stages, that he had treated in the North London Hospital with the hydriodate of potass, all, with the exception of one person, completely recovered; that solitary failure he attributed to the unsettled character of the patient, rather than to the want of virtue in the medicine, as the man left the hospital before he had fairly tried the effects of the treatment.

Drs. Jewel and Chowne, each mentioned a case in which the use of iodine appeared to be attended with good effect in ovarian dropsy, and which cases led each of these gentlemen to think favourably of the medicine in that disease; but subsequent experience had convinced them of its utter uselessness in such affection.

Mr. Ure had seen cases of hydrocele completely and speedily cured by the following lotion, as recommended by M. Ricord, of Paris:

* We believe the worthy president alluded to a paper, published in a late number of the "Medical Gazette," by Mr. Forbes Winslow, on the use of iodine.—*Reporter to Med. and Surg. Jour.*

R. Tincturæ iodinæ, unam partem;

Aquæ destillatæ, partes sex.

Ft. lotio ter in die usurpandæ.

Absorption rapidly followed this application. With regard to the use of iodine in bronchocele, he believed it only useful in that one of the four species termed "glandular," or simple enlargement of the thyroid gland. In that species he had undoubtedly seen the iodine of great use.

Some further conversation took place between Dr. Thomson and Mr. Bird, as to the most proper and successful way of detecting the presence of iodine in various fluids; after which the Society adjourned to Saturday the 9th of January, 1836.

Hospital Reports.

NORTH LONDON HOSPITAL.

Clinical Remarks on a Case of Anemia. By Dr. Elliotson.

THIS is a case of anemia, gentlemen, depending on internal circumstances altogether—simply from some internal deficiency. It frequently happens that there is a deficiency of blood found, accompanying deficient menstruation, and the patient becomes pale; the causes of which, I believe, we do not know. The case we have to consider is that of C. H., aged 24, who was admitted on the 24th of November. The report states that her complexion is rather blanched, her lips pale, and she has been subject to head-ach. About four or five weeks ago she felt a severe pain in the chest and head, accompanied with loss of appetite and debility. She has had occasional fainting fits since that time, and has been getting gradually weaker. She took some medicine the first fortnight, but she does not know what it was. Her symptoms on admission were constant pain in the head, referred chiefly to the forehead, which also was tender on pressure, and tinnitus aurium. There was pain in the chest and sternum, which appeared as though something was scraping her, and there was tenderness on that part. She had no cough, but was subject to fainting fits—she fainted yesterday morning. There was no hysterical fits. She had loss of appetite and nausea after taking food, and there was considerable debility; her menstruation was regular but scanty, and attended with pain in the region of the uterus: her bowels were confined; her tongue clean, moist, and pale; pulse 100, small and weak.

Now, these are the ordinary symptoms of anemia. The paleness approaching to a pallid waxiness of the complexion; a pale tongue, and great whiteness in the sclerotic coat of the eye: fainting is generally present; if the patient does not actually faint away, she still feels a degree of faintness. You observe, too, the catamenia, though regular, were scanty. Now, the catamenia

are often quite deficient, or if not they are almost always of a pale colour, last only a short time, and recur at longer intervals than natural—here there was only deficiency in quantity. You observe, too, that this patient had head-ach, a very common symptom where there is a deficient supply of blood, and which is often attended with great throbbing of the temporal arteries and tinnitus aurium: these symptoms occur both when there is a deficiency, and when there has been loss of blood. Hysterical symptoms were also present, as the tenderness on pressure on the forehead and epigastrium, but there was no decided hysteria. Now, hysterical symptoms are common in anemia; there is generally more or less of them present. The pulse, too, is generally quick in this disease, but there is no substance in it, it is thin and weak. In this case I believe there was a bellows sound at the heart, but which fact appears to be omitted in the book. Now, a preternatural sound of the action of the heart is not uncommon in these cases: I observed this first many years since. I was directed to it from generally finding palpitation in chlorosis—and this is, in fact, a case of chlorosis—and it was supposed some disease of the heart was present. You find, in cases of this kind, there is a bellows sound in the region of the left ventricle when the heart strikes against the ribs. Laennec mentions that he has often observed preternatural sounds of the heart after hæmorrhage, when no disease of the organ was present. I have frequently, too, noticed these sounds in anemia—this woman had a preternatural sound at the heart. I do not attempt to explain the cause of that symptom. Now, it is generally said that anemia or chlorosis occurs just at the commencement of menstruation, so that the menses do not appear, or if they do, they are scanty; but that the disease will often occur after menstruation has been established for years: this is a case in point, and is interesting on that account.

Now, fortunately, we have a pretty certain remedy in this complaint—iron, in any of its forms, does a great deal of good. After blood has been lost in any quantity, or where there is a deficient supply of it, and no organic disease is present, iron is certainly the very best remedy. Now, we commenced by giving this patient two drachms of carbon ferri three times a-day, with the house diet; this was on the 24th. On the 27th her appetite was improved, and she was better. On the 28th we increased the dose to three drachms. On the 1st of December she was much better; the colour was returning in her lips and cheeks, and she got up for several hours during the day, though she was so weak on her admission that she was obliged to keep her bed. On the 5th we increased the dose to half an ounce. On the 8th she had pain of the chest only of an evening—the head-ach and

tinnitus aurium were gone. On the 12th she went out quite well, not altogether rosy, but with a good complexion, and she was quite strong.

—
Clinical Remarks on a Case of Medullary Sarcoma. By Mr. Cooper.

GENTLEMEN—I invite your attention this morning to the case of Daniel Sullivan, aged 33, admitted Sept. 30, who has a very large tumour on the neck, extending from the left angle of the jaw nearly to the right, and downwards almost to the sternum. The disease commenced nine months ago, and gradually attained its present size. Some scars may be observed in the neck, left by abscesses, which he formerly had in the West Indies. He has been in the Infantry more than 22 years, has seen a great deal of service, and lived freely. On his admission into the hospital his health was good. The tumour has a peculiar elastic feel at several points, very similar to what would be produced by the presence of a fluid. About a fortnight before this man's admission into the hospital an opening was made in the tumour, but nothing was discharged but bloody serum.

Oct. 3rd. Has had very severe rigors, followed by fever. Pulse 120; tongue furred and dry; great thirst and difficulty of swallowing.

7th. Febrile symptoms have subsided; rests pretty well; pulse 88; appetite good.

12th. The swelling, which during the febrile attack presented an erysipelatous appearance, has now given way at different points, and several ulcerated openings, filled with portions of slough, have formed in the skin.

19th. Allowed milk, beef-tea, and a pint of porter.

22nd. Several large sloughs have separated, but without any material diminution in the size of the tumour: frequently there is bleeding from the ulcerated openings.

Nov. 19th. Tumour now presents much of the character of fungus hæmatoides. The exposed surfaces of the diseased mass are of a whitish colour, and disposed to bleed. In other places the skin is extremely prominent, of a dark purple colour, the swellings lobulated, and when the parts are handled hæmorrhage is sometimes brought on. The man's health has been declining during the last three or four weeks, and he is very much emaciated.

The disease, called *medullary sarcoma*, and, in its ulcerated state, *fungus hæmatoides*, receives the first of these names from its substance being frequently of the consistence similar to that of the medullary substance of the brain, and the latter from its tendency, when ulcerated, to throw out a large bleeding mass. Most commonly it consists of portions of this medullary deposit, contained in fine membranous partitions. Three forms of medullary sarcoma, or of the fu-

men encephaloide, described by Laennec—the *encysted*, another *without any cyst*, but circumscribed, and a third where the medullary deposit is diffused in the tissues affected. It may commence in almost any texture, or upon any surface. A vascular organization is conspicuous in it, and as the coats of the vessels are remarkably delicate, they are apt to give way, and then blood is mixed with the medullary matter itself. Medullary sarcoma differs from scirrhus in containing no dense fibrous septa, and in having no central hard nucleus, being a soft pulpy substance intersected by, or contained in very fine, delicate, almost imperceptible membranes. Medullary sarcoma is very common in young persons and even in children. Scirrhus and cancer, on the other hand, are diseases of more advanced periods of life. Medullary sarcoma is not, however, restricted to young persons, but takes place in others, and this sometimes in combination with scirrhus. In certain instances on record, the removal of a scirrhous tumour has been followed by the growth of a medullary one; and I remember a case of this kind, which Sir Astley Cooper gave me some particulars of, a year or two ago.

Our patient Sullivan presents an example of medullary sarcoma in an external situation, and in the ulcerated state. The exposed parts of the morbid mass occasionally bleed; but the medullary matter does not protrude through the openings in the skin, in the form of a rapidly increasing growth, as is frequently exemplified, and of which you may read some particularly interesting histories in the writings of Abernethy, Hey, and Wardrop. The man, on his first admission into the hospital, was under the care of Mr. Liston, who then had charge of my patients on account of my absence from town, and who decided not to attempt the removal of the tumour, because it seemed to him that its character was malignant, and that an operation would only be accelerating the patient's death. If this opinion were right at that time, the reasons against operating now, are infinitely stronger, because the tumour has extended itself, so as to cover nearly the whole of the neck, and the health has declined in such a manner, that it is doubtful whether the man would come out of the operating room alive. The great loss of blood, the uncertainty of being able to take away the whole of the swelling, and the probability, not to say the certainty, of a relapse, if the immediate dangers of the operation were got over—are then the considerations, which lead me, very reluctantly, to concur in the judgment delivered by Mr. Liston. The greater part of the tumour is very moveable, and, I have no doubt, might be dissected off the subjacent parts without great difficulty, but there is a portion of the tumour under the left angle of the jaw, which is more attached, and the depth and extent of which is not known.

I am not aware that, in this case, any of the neighbouring absorbent glands participate in the disease, as very often happens.

—o—

NEW POOR LAW ACT.

To the Editor of the London Medical and Surgical Journal.

SIR—As the public press, both medical and non-medical, has for some time past been literally inundated with communications from various practitioners in the country, respecting the inadequate remuneration offered by those intrusted with carrying the New Poor-Law Bill into effect, to such of the medical profession as are desirous of undertaking the management of the sick poor, and also censuring the conduct of those, chiefly junior members of the profession, who have accepted the proffered guerdon previously refused by the resident practitioners, it may be as well to devote a short space to the inquiry: 1st, How far practitioners, by their conduct towards each other, are justified in expecting liberal treatment from others; and 2ndly, How far the strictures against the junior members, are in this instance justified by circumstances.

Now, in the first place, it does not appear to me that the conduct of medical men generally, is such as should be evinced by members of a liberal profession, (using the term "liberal" in its proper, and in its perverted sense). For example, have not practitioners, from time immemorial (either to gain the favour of the higher classes, or influenced by the selfish motives of keeping others out), been in the habit of proffering their services at dispensaries, workhouses, &c., for nothing at all, or for barely the cost of the medicines furnished? And if this has been voluntarily done by themselves, is it not absurd that they should now complain of others underrating their services? If one gentleman is called to a case previously attended by another, although by the express wish of those most interested, namely, the friends of the patient, is he not generally considered an interloper, and regarded with much the same feeling as would be displayed by a dog, towards another who had purloined his bone? Is it not common in country towns especially, for the different practitioners to be scarcely upon speaking terms with each other? It is well known that such is the fact, though there seems no earthly reason why it should be so, or why jealousy, selfishness, and absence of all friendly feeling, should hitherto have been so peculiarly characteristic of our profession. I say hitherto, because I fancy I have lately observed evidences of a better spirit prevailing, and such as makes me confidently look forward to the display of a better understanding, and a more kindly feeling towards each other.

We now come to the second part of my inquiry; namely, "How far the strictures against the junior members, are in this instance justified by circumstances." And here I shall endeavour, as concisely as possible, to prove that they are by no means justified; and in order to do this, I shall merely adduce the case of medical assistants. Now, it is well known that 30*l.* a year is about the average amount of salary offered to this numerous, but degraded class, by their more fortunate professional brethren; some few, it is true, offer more, say 40*l.*, but it is notorious to all, that gentlemen, making between 2000*l.* and 3000*l.* a year by their practice, think they act liberally in giving 50*l.* And for this 30*l.*, 40*l.*, or 50*l.* a year, as the case may be, a young man must give up some of the best years of his life, his liberty *always*, and *frequently* his most intimate friends and relatives. Now what, in addition to the salary, does he gain by this sacrifice? Why the acquisition of a connexion, which, unless (which is seldom the case) he enters into partnership with his employer, will be of no use whatever to him in forwarding his future interests: It will perhaps, be said, oh! but he gains that experience in his profession which will better qualify him for practice—granted: but so does his employer in every case he attends, and yet he would doubtless think it rather odd if such a plea were argued by a patient, as an excuse for deducting the greater portion of the amount of his bill—in short, who would be well paid, if only those who gained no experience in the exercise of their calling? The real question seems to me to be this: Does not an assistant generally do as much as he for whom he acts? Is he not generally quite as useful, quite as efficient as a partner would be? And if these questions are answered in the affirmative, as they must be if fairly considered, then let me ask, on what ground can remuneration so disproportionate to the services rendered be defended? And yet those who offer such terms to gentlemen, frequently in every respect their equals, never seem to entertain an idea that they are acting otherwise than honourably, aye, and liberally; and would doubtless be greatly surprised at hearing them described as "miserable pit-tances," "base allowances," &c.: but when a young man, unable from want of funds to establish himself in practice, and unwilling to degrade himself by accepting the wages of a footman, undertakes, in the hope of bettering his condition, to attend a district of paupers for something less than the resident practitioner, then these consistent gentlemen are immediately up in arms, and he is at once accused of being actuated solely by mercenary motives, and stigmatized as one "who dishonourably supplants his more respectable neighbour by under-bidding him in his contract." Might not the scriptural

injunction, "First cast out the beam," &c. be advantageously studied by these worthies?

In saying this much, however, I disclaim all intention of making any, the slightest apology, for the conduct of those of the guardians who have allowed economy to stifle the promptings of humanity, when considering the best means of providing medical attendance for the poor. My only object being to shew, that the members of the profession themselves, furnish the best excuse for their present treatment by these guardians, and for every other indignity with which they are assailed. Whether a more liberal spirit manifested throughout the profession itself, would cause the said gentlemen to treat its members with more respect, may perhaps be questioned, but at any rate let it be tried, and in the meantime, let us hear no more about "base allowances," "miserable pittances," "disgraceful conduct," but above all, no more prating about the dishonourable conduct of those, who, driven by practitioners themselves to the necessity, have in some instances, by accepting inadequate remuneration, done an injury to the interests of the profession generally. I am, &c.

MEDICAL BOTANY.

PLATE XI.—*Datura Stramonium*.

(Thorn-apple).

Off.—The plant and seeds.

The thorn-apple is an annual plant, indigenous in the north of America, but now grows wild on dry hills and uncultivated places in England. The herb grows from one to two feet high. The stem is straight, cylindrical, smooth, a little shining, simple below, dichotomous at top, with diverging branches, very slightly pubescent, leaves about the size of a hand, alternate, a little succulent, oval, pointed, unequally sinuated and toothed, of a dark green, shining, and marked with veins, having short footstalks, cylindrical, a little canaliculated at the upper part, flowers axillary at the division of the branches; fruit an ovoid capsule, covered with very sharp prickles, consisting of four incomplete cells, communicating two and two, and opening equally by four valves.

Every part of the plant, when bruised, has a disagreeable smell and nauseous taste. The thorn-apple is a strong narcotic poison, producing vertigo, torpor, death. Dr. Barton mentions the cases of two British soldiers, who ate it, by mistake, for the *Chenopodium album*: one became furious, and ran about like a madman, and the other died, with the symptoms of genuine tetanus. The best antidote to its effects is said to be vinegar. The leaves have been analyzed by Promnitz. He got gummy extractive, 58; extractive, 6;

fœcula, 64; albumen, 15; resin, 12; and salts, 23=100.

The seeds are small, kidney shaped, brownish, and rough on the surface. They contain the narcotic principle in a more uniform degree than the other parts, and hence are more to be depended upon for internal use. They are said to be added to ferment for liquors, to render them more stupifying of criminal purposes. An excellent analysis of the thorn-apple seeds has been published by M. Brandes in Buchner's *Repertorium* for 1821, and in which it is shown that its peculiar properties depend upon a peculiar alkaloid, *Datura*.

Med. use.—Dr. Stoerck first tried the herb as a remedy in mania and melancholy, with considerable success. It has also been employed, and sometimes with advantage, in convulsive and epileptic affections. Dr. Barton of Philadelphia gives it in powder, beginning with doses of a few grains, and increasing them, in some days, to 15 or 20. In a case, in which it was exhibited to the extent of 30 grains, it dilated the pupil of one eye, and produced temporary paralysis of the eyelids. Hufeland gave it in the form of a tincture, prepared with two ounces of the seeds in four ounces of wine, and one of diluted alcohol, in diseases of the mind. The inspissated juice of the leaves has been most commonly used; but its exhibition requires the greatest caution. At first, a quarter of a grain is a sufficient dose. Externally, an ointment prepared from the leaves has been said to give ease in external inflammations and hæmorrhoids. And the bruised leaves, according to Pleak, soften hard and inflamed tumours, and discuss tumours in the breasts of nurses, from indurated milk.

The smoke of the stramonium has been much extolled for the cure of asthma. Its use in this manner has been derived from the East Indies, where, however, other species of *datura*, the *fatuosa* and *ferox*, are employed. It is the root and lower part of the stem which are used. These are to be dried as quickly as possible, cut into slips, and beat so as to divide the fibres. The manner of using them is by filling the bowl of a tobacco-pipe, as with tobacco, and inhaling the smoke. Stramonium smoke excites a sense of heat in the chest, followed by copious expectoration, and sometimes attended with temporary vertigo or drowsiness, and rarely nausea. It frequently gives relief when a pipe is thus smoked upon a paroxysm being threatened, or even after its commencement; the patient falls asleep, and awakes recovered from the paroxysm. In some cases a perfect cure is effected, but more commonly the relief is only temporary. It has been found very valuable as a palliative. The direct application of the remedy to the seat of the disease is at least rational.

SELECT LECTURES,

FROM

M. BROUSSAIS'

*Course of General Pathology and Therapeutics;
translated and revised*

By JAMES MANBY GULLY, M.D.

LECTURE XXIX.*

*Characters that are common to the Abdominal
Phlegmasiæ.—Conclusions.*

At the commencement of this course, I gave you a general summary of the facts that were to serve as preliminaries, and prepare you for the language which it was my intention to employ. A division being made, I entered upon the first section of diseases; namely, inflammations: we have studied them; first, in the exterior of the body; next in the openings of the mucous membranes, where they partake partly of the external and partly of the internal character; and, thirdly, in the interior of the body, or viscera, commencing with the abdomen. For pursuing this course I have had an urgent reason, which is, that the abdomen is the recipient of the great modifiers of the system, and particularly of the medicines, by which the physician strives to act on the morbid condition, and beneficially to modify the economy. It was of the greatest importance to be in the first place, acquainted with inflammation in the digestive canal, because it is on it that we are almost invariably obliged to act, in treating a patient. In order to complete this subject, I then

considered the same phenomenon in the other organs of the abdomen.

Now, in the series of questions which we have treated of, have we seen any diseases? No: it is still the phenomenon of inflammation, developed in different organs of the exterior and interior of the body. I say that these are not diseases, because the phenomenon in question rarely passes through its periods, so as to constitute a pathological unity; and generally to present inflammation of an organ in all its shades, as such unity is to propose the adoption of a chimera. One might, by straining a point, do so, in regard to any small circumscribed inflammation, such as a boil or an erythema, the periods of which may, in fact, to a certain point, be followed from beginning to end; but so soon as this inflammation has extended, and become so intense as to cause disturbance of the economy, it is no longer possible. Medicine will never be understood until these propositions are: let us then endeavour to establish them on a solid basis.

If an inflammation is sufficiently intense to excite the heart and accelerate the course of the blood, and especially if it be mortal, it is no longer a disease similar to those that are confined to the exterior of the body.

A distinction should be made according to the organs affected, and the intensity of the inflammations. If the organ be a secondary one, and only slightly affected, the pathological unity may exist even in the interior of the body. The skin affected with a circumscribed boil or erythema, the lower portion of the colon, or a very minute spot of the stomach, attacked with a slight phlegmasia, the cure of which may be easily effected, realise these two conditions, and exhibit inflammation in a certain degree of simplicity or unity. But if one of these conditions is changed, if the organ in question is affected to a great extent, the unity ceases to exist, the simplicity disappears, the disturbance extends into the system, the viscera become so affected, the skin from being the chief point in the onset, becomes only secondary, and that of the colon or stomach becomes complicated with other viscera.

It is extremely difficult to detect the inflammatory unity of an important organ

* Between this lecture and the last that I have selected, M. Broussais treats of various phlegmasiæ, which, as they do not develop any of the peculiar features of his doctrine, I have omitted. The phlegmasiæ alluded to, are those of the liver, spleen, pancreas, kidney, uterus, and peritoneum; these, though not germane to the object I had in view, in compiling the lectures, namely, the exposition of his own opinions, are so replete with valuable observations, as to make me regret that other occupations oblige me to keep that object alone before me.—J. M. G.

slightly affected, of the stomach, for instance. A man must have a well-formed habit of observation, and be a profound physiologist, to distinguish such a slight affection, which by vulgar medical men would be taken for a neurosis, and about which even the most skilful physiologist might well be embarrassed. Are the intestines affected in slight degree, the same error on one hand, and the same difficulty on the other, are produced. The same may be said of the kidneys and uterus. When inflammations are commencing they are not recognised, reference is only made to the disorder of the functions: these are, gastric disorder, constipations, diarrhœas, &c.; vague words which show ignorance of the fundamental character of these diseases, and a stopping short at what is most prominent in them. But, you will ask, how do *you* know this? I answer, that a close and persevering attention has taught me to distinguish such shades from among all others.

When any important organ whatever is seriously disordered, the disturbances that ensue are so numerous, as to put out of sight the inflammatory unity. Those who have attempted to describe the phlegmasiæ of the digestive canal as such, fall into confusion, from which they are unable to extricate themselves. These phlegmasiæ do not proceed as does a small phlegmon of the skin. We can describe tolerably clearly an articular inflammation, a slight attack of gout, an erythema caused by fire, &c., but the inflammations of the viscera propagate, multiply, and disseminate; and the phenomena consequent on points, being simultaneously or successively affected, as well as the changes of the predominant point of irritation, render its progress variable, uneven, disordinate, apparently capricious, and the general history exceedingly difficult. To give a lucid exposition of it, you must have followed with the eye all these movements of the inflammation, and have driven from your head all the absurdities of the humoral ontology; but this it is difficult to do, science being yet, on this point, only nascent, and the requisite faculties for it being, moreover, of some rarity. In order to cultivate medicine with any degree of profundity, we must have men who go in the footsteps of the most distinguished philosophers, moralists, physical philosophers, and legislators, and who are not content with learning only one disease and one corresponding remedy. So long as the physician neglects the approximation of facts and reasoning, he will be below what he ought to be; and in calling on him for the remedy of a disease, he will be justly likened to a mechanic who is required to find some piece for a broken article.

I have said that the slight phlegmasiæ of the abdominal viscera are obscure; antiquity knew nothing about them, and the moderns have made unintelligible entities of

them. But the serious affections of the same viscera are still more confused. For the rest, the obscurity is here owing not only to the variations of situation and intensity, but also to the great quantity of nerves the abdomen is provided with. Nature's first object being to sustain the life of the animal, by obliging him to nourish himself at any price, she contrived that this abdomen should exert a powerful influence over the brain, the seat of the will; and this influence the animal exercises by means of the nerves, in the same manner as the genital organs, which have likewise a great number of nerves, make theirs felt, without which nothing would lead us to the accomplishment of an act which appears beastly to those to whom it has but feeble attractions. These visceral influences are subordinate to the action of the nerves, of which there is a considerable mass, generative of the necessity for our nourishing ourselves, and for reproduction. But, you will say, have we not equal necessity for breathing, and yet there are not so many nerves, nor so much sensibility in our lungs as in our digestive and generative organs. This is all true: but you have no occasion for the volition to breathe: non-voluntary nerves preside over respiration, and the pulmonary aliment is found in every part of the atmosphere. Aliment for the first digestion on the contrary, is not so presented, particularly when an animal is carnivorous: it must be sought out, he must look for it, fight for it, and prepare it by a series of very multiplied voluntary acts. The object, that is, to satisfy the necessity for generation, also requires numerous proceedings. It was therefore necessary that the intellect should be powerfully influenced by the organs, wherein reside the wants of nutrition and of generation: it was necessary that these organs should be provided with an immense quantity of nerves.

How then would you, that a cavity so rich in nerves as is the abdomen, should be affected as others are, and that a phlegmasia of the digestive canal should be compared, as regards the sympathies, with a phlegmasia of the skin? What hope can you entertain of describing it as pure and simple, of isolating it from the other organs, and of composing a particular history or monograph of it, that shall exhibit nothing but what is exclusively peculiar to it? Will not the economy be inevitably affected by it?

I am therefore authorised in saying, that what I have treated of are not diseases, but the phenomenon of inflammation in different organs, the manner of the disturbance of whose functions is to be carefully remarked.

Sometimes an important organ may kill, although it alone may be affected. Not to stray from the facts which I have pointed out to you, I may recall to your minds, that when a violent blow, that suddenly disor-

ganises a portion of the mucous membrane of the digestive canal, is inflicted, life cannot continue, and the individual perishes, in the same manner as when a certain extent of the mucous membrane of the internal gastric sense is destroyed by a poison, or by an inflammation. Whatever the connexions may be that preside over these phenomena, such is the fact—the gastro-intestinal mucous membrane cannot be disorganised independently of the brain. Meanwhile, until this fact is explained, I make use of it to judge, by the state of the cerebral functions, or of the innervation, of that in which the mucous membrane of the digestive organs is, and I am scarcely ever deceived. I have not obtained this mode of diagnosis by divination, but I have all along paid so much attention to the observation of these connexions, being, as they were, of the greatest interest to me, that I arrived at results on this point that might have been considered impossible.

The history, therefore, of visceral inflammations is far different from that of external inflammations, and demands far greater attention. I repeat, we have not been studying similar diseases in the external and internal parts of the body, but only the phenomenon of inflammation modified according to the vitality of the organs. If, unfortunately, I have not been happy in making this proposition understood, I am sorry for it, for it is a fundamental one.

Another important proposition which I would recall to you is, that inflamed organs are incessantly tending to inflame others, and especially the digestive canal. If they are violently and suddenly inflamed, they may kill the patient by their influence on the centres of innervation, before the inflammation has had time to develop itself in any viscus, even in the nervous centres themselves; such as extensive burns, widespread erysipelas, superinflammatory scarlatina, some very confluent variolæ, &c.; but, if the inflammation be less intense, and if it continue, it is more or less reiterated in the digestive canal. Well, even in this case it is difficult to describe, in an isolated manner, the inflammation of the digestive canal, inasmuch as secondary and nervous phenomena are joined to it, which may be numerous, and are complicated with those of the point primarily affected. Such inflammations are the most formidable difficulties of medicine; and thus it is that four thousand years have elapsed before a just idea has been formed of them. Yet so it is: primary inflammations of the digestive canal may produce rapidly mortal neuroses. So it is: when these are extensive they become complicated with secondary inflammations. So it is: inflammation of the external organs, if considerable, is reiterated in the internal, and particularly in the digestive tube; arrived at which, it is more and more dis-

seminated in the system, so much so, that if a pure and simple phlegmasia of that tube can scarcely be conceived of. Of a pure and simple metritis, a cystitis, or nephritis, we may conceive, but not of a gastritis, unless it be very, very limited: but then it is mistaken by physicians, except by the small number of those who have become habituated to the observation of it.

As regards the phlegmasiæ of the apertures of the mucous membranes, you have seen that, when they are sufficiently intense to agitate the heart and disturb the nervous system, those of the viscera are imminent, and that there also the digestive canal is the first affected.

For all these reasons, therefore, how difficult must the formation of lucid monographs appear to you, of the visceral inflammations, of the inflammations of the apertures of the mucous membrane, and even of those of the most secondary organs, such as the skin.

At the time when the physiological doctrine appeared, its propositions were exclaimed against, and it was accused of attributing every thing to the digestive canal. This accusation proceeds from impatient persons, who will not give themselves the trouble of understanding all the parts of it, and who judge of questions before they have investigated them. I have said, and I repeat, that there is no serious disorder in which the digestive canal does not take some part; only admit the fact that inflammation is disseminated by the nerves, and you may imagine this almost mechanically. The organs possessing the greatest number of nerves will receive the greatest proportion of inflammation. This is precisely the position of the digestive canal, besides which there are a great number of secretory apparatus, and it receives a vast quantity of blood; in a place where blood and nerves abound, there cannot fail to be an extreme tendency to inflammation.

Let us examine the method employed by those who write monographs on the pure and simple inflammations of the organs. This method gives an air of clearness to the exposition of the symptoms, but at the bottom, it is all confusion. When they describe an inflammation to you, ask them how they establish its characters, and whether it is by that only which appertains to the organ whose state they depict. If they do but this, they have only a very few symptoms to enumerate; in gastritis they will not mention more than sixty or eighty; but they take the irritations of the other organs as the attributes of that whose inflammation they describe.

In order to trace these kinds of inflammation, it is necessary to distinguish all the co-existing inflammations, and mention them according to their degrees of importance. But those which surround phlegmasia of the digestive canal, when long continued,

are so numerous, as to give considerable anxiety to our monograph writers; therefore, when they behold three, six, or ten diseases, superadded to a gastritis, they no longer regard it as a gastritis, but a fever—an utter mistake that might be avoided, if they adopted my method. Had the phenomenon of inflammation to follow as a thread, they would no more be lost in a vague, and they would feel how impossible it is to regard the phenomena of nervousity, or inflammation of other organs, as characters of inflammation of the digestive canal; instead of which they say that these phenomena are complications—complications of what? That is what they must tell us. An intense inflammation disturbs the economy, and gives rise to other irritations; but are these irritations similar diseases to those experienced by the same organs when primarily inflamed? Acute pains of the bladder occurring in an individual affected with gastritis, would you say that this is a complication of inflammation of the bladder? It is not a complete cystitis, it is only a repetition of the phenomenon of irritation, that exists elsewhere in the degree of inflammation, but not necessarily here. Muscular pain occurring in the same individual, the question and answer are the same. These are secondary phenomena to another of the same nature, complications of the primary inflammation, and not inflammations such as they would have been had they existed alone. This secondary irritation sometimes rises to the degree of the primary irritation, or even exceeds it; here again is another possibility. To these must be added the vices of secretion, of exhalation, of nutrition, of innervation, which arise, in different degrees, in the viscera that are secondarily affected, besides suppurations, ulcerations, &c.; all proving that the word complication indicates a crowd of widely-varying phenomena, and such as it is absolutely necessary to distinguish. This I had in view when I stated that inflammation is developed here or there, and that it disseminates irritation: had I, instead of this, said that it becomes complicated with other diseases, I should have led you into error. On opening the work of a nosologist, to read the description of a primary inflammation situated in an organ wherein you observe a secondary one, and you have seen it last a certain period of time, and proceed in a certain manner, you would be considerably astonished at seeing that your complication had not proceeded in the same manner, and that it had not lasted the same length of time as the primary inflammation of the organ. Once more I say it is the phenomenon of irritation that is developed and repeated in several organs, wherein it proceeds according to the constitution of each one, and according to the predispositions that impress immense varieties on it.

Moreover, the partisans of the method in

question behold in these phenomena general symptoms that are added to the particular ones. Do they describe a nephritis-cystitis, or gastritis, accompanied with fever, they tell you it is a general symptom: if lassitude accompanies, they tell you the same, and so on; in this manner they make a series of general symptoms. I have already inveighed against this abuse, and at present I content myself with repeating what has been proved in another place, that these supposed general symptoms are only repetitions of the phenomenon of irritation, repetitions that are more or less nervous, more or less inflammatory, according to the organs, and which are reproduced in some ratio, with the intensity of the primary inflammation. This kind of language only expresses facts, without prejudging their nature; if you adopt it, you will see how all confusion and ontology disappear. In fact, can any thing be more true or more clear than to say, when inflammation arises slowly in a point, and is simple, it does not disturb the economy; when it bursts forth with violence, it causes disorder in it, by irritating the nerves, by deranging the secretions, by altering the organic movements, and that the nerves propagate the excess of innervation that exists in the primary seat of the inflammation? Indeed, if this inflammation develops in an organ having no communication with the central nervous apparatus, it is purely local, and the economy feels it not: you have this demonstrated in the plegmasiæ of paralytic persons.

All the secretory organs are under the influence of the nervous system, and their products vary according to the state of innervation; the saliva, the bile, the semen, &c., are altered in their composition when irritation reaches, through the medium of the nerves, the organs, whose office it is to elaborate them.

Nor have the muscles the same contractile energy, nor obey so readily, nor answer the will, when the inflammation of any organ has passed certain limits; the proof of which is, that by dissipating the latter they recover their freedom, and by renewing it they again fall into the same condition.

The affective faculties are also altered; and to this sufficient attention has not been paid. When a serious inflammation exists, that disseminates irritation through the system, things formerly liked are no longer so, aliments are rejected, and matter alone desisted; instinct changes, habits, tastes, desires, appetites, are all lost; the once most agreeable stimulants, as of snuffing or smoking, for instance, become insipid; the conversation or reading that previously charmed, is now irksome. But the intellect does not so soon become disturbed as the affective faculties; the latter sometimes become depraved to such a point, as that persons formerly beloved are detested, and

those preferred who were hated; meantime there is no delirium. Yet the intellect may also be affected, even in those cases where the patient is still rational. You may ascertain this by asking him about science, or other matters, that were previously attractive to him: he will refuse to answer, and beg you to leave him alone. Thus the intellectual faculties are altered, though there is no delirium; but allow the irritation to go on increasing in the focus of phlegmasiæ that is acting on the brain, and delirium will soon appear; subdue this irritation, and it will disappear. These are facts that give proof upon proof of the dissemination of irritation.

The current of the blood is accelerated, and disorders must necessarily result from it, of which I must give an account, otherwise you will accuse me of being nothing but a solidist. When the circulation is accelerated, the blood is no longer well oxygenized; it comes in greater quantity to the organs: nutrition and the secretions, which require a certain retarded movement of the blood, are deranged; the brain is not only attacked by unusual stimulations, which disturb its functions, but is, moreover, congested with blood; it is, therefore, exposed to inflammation, and we may rationally consider the acceleration of the blood's current as the cause of it. Many other organs are in the same predicament.

It has been said that fever produces inflammation; but this is inadmissible. When I have maintained that inflammation produced fever, they replied by the inverse proposition; and they would not understand that the acceleration of the blood's current might have, in certain cases, in producing inflammation. They would not understand that, when the organs are more than ordinarily stimulated, if there be a point of irritation in one of them, the blood may accumulate there, and form an inflammatory congestion; if this point be the lungs, a bronchitis, or pulmonary engorgement, will form about it—the brain being previously superexcited, and the blood coming to it with more than ordinary violence, a congestion may obtain there, &c. A change in the state of the nerves and in the blood must necessarily produce one in the vital properties, that is to say, in the contractility of the parts.

In summary, we see, in the first place, that an uni-local phlegmasia may become pluri-local; and, next, that an inflammatory disposition, common to several organs, and resulting from precipitated innervation and acceleration of the blood's current, may concentrate its effect on a predisposed and superexcited point, and develop an inflammation there.

As regards the termination of inflammation, we have seen that when it is slight, the cure is possible by virtue of certain laws, which displace the irritation, and

transfer it to the secretory organs, where it appears as if extinguished in water. Thus it is that a slight bronchitis or gastritis, may sometimes disappear after a sweat or a bilious evacuation; but if this phlegmasia occupies the major part of the visceral apparatus, this is no longer possible—autocratism yields; if it be a complete gastroenteritis or peritonitis, we cannot expect resolute crises: there is no majority of sound organs to liberate the diseased organs. What then happens? serious disorders, that kill the patients by excess of innervation, or by extensive disorganizations.

There are still other differences in the proceedings of inflammations. An inflammation—even a considerable one—occurring in a permeable organ, and one that reacts on others, as does the digestive canal, may disappear by natural crises, and sometimes even by stimulation. There is a kind of safeguard for patients that are treated by the partisans of the *natura mediatric*. But suppose an extensive peritonitis, and the matter is changed: the tissue is not one that will receive stimulation, that can get rid of it by its excretory apparatus, or vent it upon others, and you cannot rely on beneficent nature for sweats and other secretions; extravasations will take place; the patient will be carried off by the violence of the nervous phenomena, or his disease becomes chronic—he will die in detail. When pompous eulogiums were made of the resources of nature in acute diseases, and when you have heard mentioned the powers of crises, these vast peritonites, and the terrible inflammations of the spinal cord, were put out of sight; nothing but fevers were seen, which are almost always phlegmasiæ of secretory organs, nothing but symptoms, depurative and conservative movements, &c.; there was no reasoning from facts. If you shrink from these reflections, you are no logical physicians. The word inflammation once pronounced, you must follow up all its consequences.

What have I deduced from these facts with regard to the prognosis? These two short propositions:—the more limited the inflammation is, the better is the prognosis; the more extensive it is, the worse. What with regard to the treatment? The following propositions:—

1. To circumscribe the inflammation in the smallest limits; because, once limited, it readily terminates. To be ever on guard against its propagation and dissemination: not to wait until the nosological utility is completed: always to learn where the irritation is, in order to become master of it.

2. When this cannot be done, to at least diminish the intensity of the inflammation, in imitation of nature, by exciting the eliminators; an indication that is divisible into two sections:—A. To irritate the inflamed part itself when it abounds in secretory and exhalant apparatus, because it is proved

that, after blood lettings, it may lend itself to a supersecretion that may aid in relieving the inflammation. B. To irritate another organ that may also secrete, and this is the more prudent plan. This proposition includes the cures that are supposed to oppose my principles; whereas they only confirm them.

3. To seize the moment when nutrition becomes possible, in order to return to the system the materials that it has lost.

4. To look to the abstraction of the causes that have produced the disease, and of those that are analogous to them. Thus the study of causes becomes fundamental. Those who affect to leave them in a vague state, or who deny their importance, have not sufficiently reflected.

5. To give constant provision of two principal agents—air and caloric; a pure air—no chilling nor excess of heat.

6. When we have failed in subduing the phlegmasia, and it has gone on to suppuration, to aid the work of local reparation which cicatrizes ulcers, resolves engorgements, causes the elimination of foreign matters of that process; in short, that you see in external wounds and tumefactions in surgical cases, for it is with surgery that the study of medicine should begin. In such cases sedatives and stimulants are alternately employed;—the same must be done internally.

7. To aid the return of the vital properties and fluids to the normal condition. You have seen how every phlegmasia that lasts a certain time alters the fluids and nutrition, and you may be tempted to take this fact as the basis of the principal indication; but be not deceived; and, above all, have a care not to lapse into humorism;—even when mucous shall have entered the system, they will leave it, and all will come round with good air, and proper aliment.

Such are the leading points to which I would direct your thoughts.

—

[This lecture concludes one great section of the subjects concerning which the opinions of my author are peculiarly his own—original in the manner in which the facts are connected—original in the process of reasoning, and in the practical inductions drawn from the facts. I think that in the twenty-nine lectures which have been selected, abundant refutation will be found of the absurd assertions so lavishly put forward with regard to the Broussaian doctrines of inflammation and fever, as well as abundant opportunity afforded of rectifying the partial and erroneous views that may have been embraced by those whose knowledge of them has been gleaned from the meagre and rapid disquisitions of our metropolitan lecturers on medicine. For how often is this doctrine, which has revolutionised pathology more decidedly than any

previous one, dispatched by a few words (if mentioned at all) in the “full and complete courses of forty-five lectures,” that hitherto comprised the whole pathological teaching required in a London medical education! Students are told that it is only “a theory,” at the same time that they are led to believe that a theory is an unsubstantial edifice, based on a gratuitous assertion or hypothesis: granting which to be correct, though it is opposed to the proper definition of the term, I would ask whether, in the preceding lectures, any thing resembling a theory is to be found? Theory is nothing more than the grouping of facts, and their reference to one recognised principle or principal fact; and in this view, what is advanced by Broussais on the subjects of inflammation and fever is a theory—one that differs widely, in the mode in which it is built up, from the ideas of Boerhaave, Hoffman, and Cullen, on the same subjects. Theirs were *bonâ fide* hypotheses, and answer precisely to the absurd definition of theory above mentioned—the *error loci* of the former, and the *spastic stricture* of the two latter being conditions imagined by the respective brains of those writers, and made the basis of all their subsequent reasoning. Yet Cullen's nosology, founded on this spasm, is the test of students of pathology to this day! If these lectures shall have only led any portion of the readers of the *Medical and Surgical Journal* out of such a beaten yet irrational track, into a field of more philosophical reflection on the nature, causes, and cure of the pathological states therein treated of, my object will be attained.

The other great section of the Broussaian doctrines of diseases, which comprehends the neuroses, will probably at some future time form the subject of another course.

J. M. G.]

—o—

On the Diseases of the Skin.—Anatomy, Physiology, and Pathology of the Tegumentary Apparatus, or the Skin.

THE diseases of the skin are not comprehensively described in any modern medical school in this country, and students receive the highest testimonial, a diploma, or license to practice, without any or very little knowledge of their nature or treatment. It would be impossible to defend the omission or exclusion of cutaneous diseases in a course of medical education. I shall therefore describe them minutely, and refer to the works of the best writers on the subject. It will, I think, appear, on a brief reference to the Anatomy, Physiology, and Pathology of the Skin, or to speak scientifically, of the tegumentary tissues, that they afford an immense field for investigation and study; and because the almost innumerable diseases of this system, which are of the most frequent occurrence, ought to be fully understood by

every class of medical practitioners. I am aware that a few elementary works may be procured on this subject; but these are seldom studied, because candidates for medical honours in London, Dublin, and Edinburgh, are not examined on diseases of the skin unless by the Universities or Colleges of Physicians; and never, so far as I have heard, by the Colleges of Surgeons or Societies of Apothecaries. But the public health and the personal interests of the members of the medical profession, render the study of cutaneous diseases imperative; and for this reason I shall describe them minutely.

It would be utterly impossible to form a correct opinion upon the importance of diseases of the skin, unless the anatomy and physiology of the tissues that compose it be clearly understood. But as these are generally described by anatomists, and known to well educated medical practitioners, I shall therefore notice them very succinctly on the present occasion.

Anatomy of the Skin.—The structure or organization of the skin, in infants, adults, and aged persons, should be known by all who undertake the treatment of cutaneous diseases; and according to Baron Alibert, even in quadrupeds, and in all the osteozary animals.

The latest account of the anatomy and functions of the tegumentary system, is by M.M. Breschet and Rousel de Vauzeme, which was read before the Royal Academy of Sciences, Jan. 1834, and published in the "London Medical and Surgical Journal, 1834. v. 5." This essay is much too long for citation, but it comprehends the following heads:—1. Dermis, skin; 2. Nervous papillæ, or the mucous body; 3. The apparatus for the secretion of perspiration, composed of a glandulous parenchyma, or of the sudoriferous and hydrophorous canals; 4. The apparatus for inhalation, or the absorbent ducts; 5. The apparatus for secreting horny substance, or the peratogenous apparatus; 6. The apparatus for secreting colouring matter, or the chromatogenous apparatus; 7. The epidermis or cuticle, with its appendages—the nails and hairs.

The skin or corion envelopes the body, varies in consistence and thickness in different regions, is sensitive in mammiferæ, of a whitish red colour, permeable, extremely vascular and papillary (nervous); and therefore liable to inflammation, and painful disorders. "It is by this layer," (the papillary,) says Baron Alibert, "that tegumentary apparatus sympathises with the centre of moral affections, with the intimate source of emotions and thoughts; it is the papillary tissue that is the true source of contact, and the most powerful means of relation."

The skin is supplied with a vast number of arteries, veins, lymphatics, and nerves, with simple sebaceous and mucous glands, which are also called follicles, lacunæ.

There are three sets of pores, one for transmitting the hairs, the other for the passage of the vessels, and the third the sebaceous follicles. Many able anatomists deny the existence of pores, as these were not detected by the aid of the strongest microscopes; while Chevalier is of opinion, that there is an infinite number of minute velamina on the cuticle, which form a bibulous or hygrometrical covering, in which the terminal vessels are lodged, and through which, during life, exhalation and absorption are effected. (*Lectures on the General Structure of the Human Body, and on the Anatomy and Functions of the Skin, —also Grainger's General Anatomy, &c. 1829.*)

The rete mucosum is placed between the true skin and cuticle, and will be immediately described.

The epidermis or cuticle, which was long considered inorganic, is now believed to be organic, that it admits certain fluids, allows others to escape through it, and that it possesses a vitality peculiar to it. It is very thick on the heel, ball of the great toe, and hand of certain mechanics; all of which may be thrown off in erysipelas or scarlatina, specimens of which I have in my possession. Some anatomists have seen pores in the cuticle (Lewenboek, Richat, &c.); others could not detect them (Cruikshank and Gordon). Cruikshank has well remarked, that whatever may be the process by which sweat is conveyed to the surface of the body, it is not by mere transudation by which fluids escape in dead animal and vegetable matter. It is subject to many morbid alterations. It nourishes and regenerates itself. It becomes hard and thickened, as in corns, scaly as in ichthyosis and scarlatina; and again is analogous to mucous membrane. All the periphery of the living body is covered by this diaphanous membrane, which is unalterable by air, of a compact, elastic tissue, and prolonged into the intestines under the name of epithelium. It is mucous internally, and squamous, or scaly on the surface of the body. It is formed by the white layers placed between it and the true skin (pigmentum), is a horny substance excreted by the superficial white layer, and nourished by serous vessels. (Alibert.) The cuticle is now considered an organic substance, though blood-vessels, nerves, or lymphatics have not been traced into it. If it was inorganic it could not be intimately attached to living structure, nor could it be regenerated when destroyed by blisters, scarlatina, erysipelas, or ichthyosis. It is also remarkably imputrescible; that portion on the heels has been found in tombs in which the rest of the skeleton was reduced to dust. This white substance (pigmentum) is composed of two layers in animals, and is the source of coloration in living beings. It is called the rete mucosum, rete malpighianum, because it is covered by Malpighi, and consists of fibres, arranged in the form

of a net-work. This stratum is denied by some anatomists (Bichat, Chaussier, Dr. Gordon, Lawrence, and others). Those who describe it have been unable to trace nerves or blood vessels in it. "But we generally find," says Professor Quain, "on attentive examination, a viscid semi-fluid stratum, occupying the situation of the rete, which, however, is pale and inorganic, and, most probably, a secretion produced by the vascular surface of the cutis."—(*Elements of Anatomy*, &c. 1834.) It receives the extremities of a vast number of capillaries and lymphatics. It is the seat of the colouring matter, and, according to the conclusions of many anatomists, of those horny processes which are sometimes seen on the skin. Its existence is denied by Bichat, Chaussier, and Rudolphi, and described by Quain, Grainger, and others. M. Chevalier considers it a second or internal epidermis (*Op. Cit.*). It may also be regenerated.

Alibert and others state that they have observed a transparent layer under the skin in man and animals, and beneath this is the cellular tissue, which has great influence in the development of cutaneous diseases.

This tissue covers the minutest fibres of muscles and nerves, contributes essentially to the structure of organs, forms some exclusively, fills the intermuscular spaces, gives the external surface of the body its most beautiful forms, and is considered as the primitive tissue of the whole tegumentary and other systems. It is the seat of a vast number of diseases which may penetrate into its areolæ, as furuncle, struma, carbuncle, steatomatous, and atheromatous tumours, with many other diseases. The sebaceous follicles are described as shut sacs by some anatomists; are situated on the external surface of the cutis, and lined by processes of the cuticle. Some consider them distinct glands. M. Chevalier entertains the last opinion, and divides them into two kinds, one set being imbedded in the skin, and the other being placed between the rete mucosum and cuticle. The mouths or ducts of these glands or follicles open obliquely on the cuticle, and are often apparent on the nose, cheeks, edge of the eyelids, axillæ, &c. They secrete an unctuous fluid, which repels watery fluids, as we see exemplified when the hand is immersed in water. This sebaceous matter may be squeezed out in the shape of small worms, popularly termed "flesh-worms." This secretion is totally distinct from perspiration.

The appendages of the tegumentary membranes are the hairs and nails, and in animals, horns, feathers, scales, &c. The hairs (*crines*, *pili*) are horny filaments, which appear on the human body, except on the palm of the hand, but very much on the scalp, pubes, axillæ, face, eyelids, eyelashes, nose, ears, &c. The root of each hair is attached to a nervous papilla of the skin, and the cuticle is prolonged and iden-

tified with its substance, &c. The whole body is covered with hair, unless the palms of the hands and soles of the feet. The root of each hair is situated in the skin, or cellular substance beneath it. Blood-vessels, and, according to some anatomists, nerves, pass into the root or bulb. The connexion between the hair and cuticle is not satisfactorily explained. Some suppose the cuticle ascends on the hair, others that the hair perforates it. The hair is considered insensible, as destitute of nerves; but Professor Elliotson and Baron Larrey have recorded cases in which the hairs were exceedingly sensitive, and many others have attested the same fact in the disease termed *plica polonica*. The nails (*ungues*) are horny productions, composed of lamellæ, or scales. The root of each nail is received into a sulcus or groove in the skin. The under surface of the nail is attached to the papillæ of the skin; and its upper surface is covered by a cuticle which dips into the groove, and is then reflected over the lanula or white of the nail, and passes under its free extremity at the end of the finger, and is identified with it.

Mucous Membrane.—The tegumentary apparatus is prolonged into the passages of the body, the eyes, nose, ears, mouth, lungs, œsophagus, stomach, intestines, urethra, bladder, ureters, kidneys, vasa deferentia, and tubular structure in the testes of males. In females it lines the vagina, uterus, uterine or Fallopian tubes, and lactiferous tubes in the mamæ or breasts. This membrane is attached to subjacent organs by cellular tissue. That portion of it which lines the digestive and respiratory organs was termed gastro-pulmonary by Bichat, and that which lines the genital and urinary organs, genito-urinary mucous membrane. The tegumentary and lining membrane of all the passages of the body are continuous; and, therefore, the diseases of the one will affect the other.

The skin is an absorbent, exhalent, and contractile organ. In inferior animals it serves as a protection to external violence, and in the human species protects the surface of the body from the injurious effects of chemical agents. This object is effected by the secretion of the small arteries, and of the sebaceous glands or follicles.

The capillary vessels of the skin secrete a peculiar fluid, which is constantly passing off, unless interrupted, from the external surface, in the form of vapour, termed insensible perspiration, or condensed into liquid or sweat. The atmosphere and health of the individual modify this secretion; but the quantity passed, according to the experiments of Lavoisier and Seguin, is about thirty ounces, nearly two pints, and fifteen ounces from the lungs in twenty-four hours. Haller estimated the insensible perspiration at twenty-eight ounces, and Abernethy at two pints and a half, in a person of ordinary stature in the same period.

The perspiration has great influence in reducing the temperature of the body.

The sebaceous follicles secrete an oily matter, which is often observed in the form of drops on the surface, more especially on the forehead. In fine, the skin secretes a gaseous substance. It strongly sympathises with all other parts of the body, and each part with it. Thus most cutaneous diseases are sympathetic; for the skin sympathises with disorganization of all other organs. But its strongest sympathy is with the mucous membrane of the digestive and respiratory systems, and is continuous with it. (Chaussier, Ribes, Hebreard, Wibrand, Rayer, and others.) This fact explains why, in acute exanthemata, there is nausea, vomiting, or diarrhœa, pulmonic congestion, scaly herpes, in asthma, or the suppression of chronic eruptions followed by this disease, as I have repeatedly known. A strong sympathy also exists between the brain and skin; first, by nerves; and, secondly, by continuity; for, according to Dr. Fletcher and others, mucous and cellular membranes, or membrane, for they are identical. Thus we frequently observed cerebral congestion, coma, or delirium, in small-pox, scarlatina, or measles, or on the sudden repression of these and other eruptions. Again, the ingestion of cold fluid into the stomach may either suppress perspiration or cutaneous exhalation suddenly, or excite various eruptions on the skin. Warm drink, on the contrary, promotes perspiration. The skin also sympathises with the generative organs. The application of ice to the skin, or standing on a cold floor, the feet being uncovered, induces an immediate evacuation of the bladder. In fine, the skin is intimately connected with all organs, and all diseases may affect it. "It was on this account," says Alibert, "that this extensive envelope was a great subject of consideration with Hippocrates, Aretæus, Cœlius Aurelianus, and the other ancient observers. The skin is also influenced by an immense number of external objects, cold, heat, fire, light, injuries, &c., and is, therefore, liable to be diseased by such causes. The influence of the sun in certain climates is proverbially known to bronze the skin, while the diminution of the influence in crowded cities is a constant cause of paleness or etiolation."

Pathology of the Skin.—When we consider the diversified structure of the integuments which are popularly termed the skin, their sympathies with all parts of the body, the innumerable varieties of external influences to which they are subject, and the many functions they perform, we must expect that their diseases must be numerous. Thus each of the tissues which contributes to form the common integuments of the body, or tegumentary apparatus, is subject to peculiar diseases. We shall be convinced of this fact if we study elephantiasis in the derm, chorion, or skin, ichthyosis in the epi-

derm, or cuticle, cancer in the neurilema, various (warty) eruptions in the sebiparous canals, and exanthemata in the reticulated body. "The skin," observes Baron Alibert, presents constant diseases in its texture, in its consistence, in its colour, in its nutrition, and in the circulation of its fluids. It sometimes changes into an inert tissue, and deprived of vitality, mortification arrives under all its forms; it is subject to ramollissement (softening), to induration. We find in it hypertrophies, anormal mutations, or all the laws of nature, if I may use the phrase, invested. The skin, then, is of great interest to us, if we consider it as the seat of a multitude of diseases, whose external character vary according to the causes that produce them, and the greater part of which result from the continual errors and immoral habitudes of the human species." — *Monographie des Dermatoses, &c.*, 1832.

The importance of cutaneous diseases is not properly estimated by medical students or practitioners in general. Few consider this class of diseases minutely, or understand their pathology and treatment. The multitude of these maladies have been classified; but unfortunately the classifications are almost as numerous as the individuals who have proposed them. I shall next describe the etiology, diagnosis, and treatment of cutaneous diseases in general, and then give the history and treatment of each class of diseases. In the execution of this task I must observe that I have laid the best works extant, both national and foreign, under contribution, and extracted and arranged the most valuable parts in each, with a view of placing them in regular order—added the result of my own experience in public charities for nearly twenty years.

The *etiology* of cutaneous diseases has led to a great diversity of opinion. Some have exclusively ascribed them to constitutional derangement, others to infection, more to want of cleanliness. We certainly observed cutaneous disease most common in delicate infants, and we find that, by improving the general health and appetite, we generally effect a cure without any local application. This is the usual result when children are our patients. The students who attend the institutions to which I am physician, are often surprised at the favourable termination of eruptive diseases in children without any local treatment except ablation; and frequently after external means have been repeatedly tried by others in vain. Some cutaneous diseases are said to be infectious; such as variola, rubeola, and scarlatina, which generally occur to the same individual once only, though any one of them may affect him twice. It is worthy of mention, that the febrile or exanthematous diseases may occur twice in the same individual, though very rarely; while itch and syphilis, which are unaccompanied by fever, may occur several times.

Want of cleanliness is a source of cutaneous diseases, according to the most eminent writers, (Willan, Alibert, Plumbe, Rayer, &c.) and hence the frequency of such maladies among the poor. Every one acquainted with the anatomy and physiology of the skin, will readily understand that irritating substances applied to it cannot fail to induce inflammation; or, in other words, excite some cutaneous eruption or disease. Thus the natural secretion of the skin, or dirt of any kind allowed to lodge upon this tissue, must be a cause of disease.* If any part of the dress makes undue pressure, or causes irritation, the skin becomes red, inflamed, or blistered.

It is also a received opinion, that irritation of the mucous membrane of all the passages of the body, but especially of the digestive and respiratory organs, may cause cutaneous eruptions. The modern opinion of anatomists as to the identity of the skin and mucous membranes, affords a satisfactory explanation. They allege that the external covering of the body or cuticle, and the internal lining of the canals and organs mentioned, are continuous; and, moreover, that there is a strong sympathy between them. It is an axiom which cannot be denied, that irritation on the skin may derange the whole economy, and so may that of any other part of the body. In proof of this position, we need only refer to the exanthemata or eruptive fevers, to syphilis and other diseases. A blow on any part of the body, causing a contusion or a wound which might be covered with a pin's head, may excite tetanus, derangement of all the functions, which is followed by death.

Again, certain diseases or remedies may cause an unnatural appearance of the skin. Jaundice causes universal yellowness of the external as well as internal parts of the body; and a long-continued use of the nitrate of silver induces a permanent livid or dark appearance of the skin, which no plan of treatment hitherto employed has succeeded in removing. It is a very general opinion that impurity of the blood is the cause of cutaneous diseases; and we are often solicited to purify this fluid. The modern medical doctrines are opposed to this conclusion; but evidence is still wanted to set the question at rest. Every practitioner of moderate experience must acknowledge, that he employs sulphur, mercurials, antimonials, alteratives, sarsaparilla, &c., in cutaneous diseases; if not to purify the blood in such cases, at least to

effect a cure; on what principles, except the tonic or alterative, it remains for him to determine. He also exhibits acids or saline remedies in purpura scurvy, the last stages of typhus and yellow fevers, in malignant or blue cholera upon the former principle, and often with success. Some cutaneous diseases are peculiar to infants, others to children, more to adults, and some to old age. Many are peculiar to seasons, climates, trades, and modes of life. Thus grocers and bakers are liable to peculiar diseases.

The diagnosis of cutaneous diseases is still extremely imperfect. Some of the best writers have subdivided the different stages of the same disease into different species, both on the same and different parts of the body. Plumbe and Rayer adduce many proofs of this position. A vast diversity of opinions exists as to the treatment of those complaints. I have long divided cutaneous diseases into the acute or febrile, and chronic or non-febrile; and based the treatment upon these principles. In the latter, which are the more numerous, the improvement of the general health by aperients, tonics, and alteratives, with occasional use of external remedies, has been the most successful plan in my practice. In a vast majority of eruptive diseases on children, internal remedies, nourishing diet, cleanliness, ablution, and bathing, are sufficient, without any external remedy. The ampest attestation of this fact is daily afforded at the Hospital and Dispensary to which I am physician.

In exanthematous or other cutaneous diseases, accompanied by fever, the usual remedies for fever are indispensable. It matters little whether the disease be sanguinous, vesicular, pustular, &c., purgation, depletion, diaphoretics, and local bleeding, are generally required. In erysipelas, variola, scarlatina, rubeola, &c., general or local depletion, purgation, &c., are our chief remedies.

These diseases are often accompanied or succeeded by delirium, cerebral and pulmonary congestion, inflammation or congestion of the brain or lungs, which imperiously require antiphlogistic remedies, warm bathing, &c., as will appear in the separate history of each of these diseases.

In chronic cutaneous diseases, the chief indication of treatment is, to improve the general health, advise a nutritious diet, as white meats, milk, eggs, fresh vegetables, ripe fruits, and cleanliness, which very often effect a cure, after all medicinal agents have failed. These complaints very often arise from derangement of the general health, disordered digestion, filth on the skin, which induces inflammation. According to this etiology, improvement of the general health, and removal of inflammation of the skin, are the objects to be effected; we therefore order baths, fomentations, cata-

* So important did Sir Astley Cooper consider the function of the skin to health, that he stated in his last course of lectures, published in the *Lancet*, 1824, that one means he employed for preserving his own health was, sponging the surface of his body every morning with cold water.

plasms, simple or medicated, sea-bathing, vapour, sulphurous, ioduretted, and other medicinal baths, and in many cases with success. Fumigations are also valuable remedies. (Sir Arthur Clarke, and Dr. Wallace, of Dublin, and Decarro in Germany, Dr. Green, and others, in London.) These may be generally or partially applied.

Sulphurous preparations have long maintained a high reputation in certain cutaneous diseases, and are very much employed both internally and externally. Sulphurous fumigations and mineral waters are very generally recommended. Preparations of mercury, arsenic, antimony, lead, zinc, copper, &c., are much used. The preparations of iodine are now favourite remedies. Mercury is considered a specific in syphilitic and other chronic eruptions; arsenic is given in solution and pill (Asiatic pills); and lead, zinc, and copper, are used in lotions and ointments.

I may here observe, that the greatest caution is necessary in using arsenical preparations, as the digestive organs are often insidiously inflamed by them, the health injured, and life sooner or later destroyed. A vast number of internal remedies have gained popularity, as lime-water, sarsaparilla, burdock, scurvy-grass, hyssop, clivers, tar-water, &c. &c.; but of these the first and second are the best. They were formerly supposed to purify and sweeten the blood, or to act by improving the digestive and cutaneous functions. Blisters and irritants are sometimes employed in obstinate chronic cases, with a view of exciting a new action in the affected part; but they are rarely resorted to in this country. Ointments and lotions are used on the same principle; but these are generally ineffectual, as they are seldom properly applied. They are daubed over scabs, scurfs, &c. and seldom come in immediate contact with the diseased part of the skin. But if the skin be denuded by ablution, and the seat of the eruption placed in contact with these remedies, then benefit very speedily ensues, provided the general health is undergoing improvement at the same time.

—o—

INTRODUCTORY LECTURE TO THE

COURSE OF CLINICAL SURGERY,
NOW BEING DELIVERED AT THE HOSPITAL
LA CHARITE.

BY PROFESSOR VELPEAU.

Exposition of the present state of practical medicine—Difficulty of estimating facts—Immensity of false facts—Difference of conclusions drawn from them—Their application to the Medical Sciences.

THE commencement of each medical session, and the return of the season of study, naturally leads us to cast another glance on the course we mean to follow. For my own part,

having to teach surgery at the bedside of the patient, it is to clinical surgery that I should direct your attention.

And first, gentlemen, let me ask you what is clinical surgery? You would fall into a strange mistake, if you were to imagine that it is a separate science, or, properly speaking, a distinct branch of surgery; but you would be no less mistaken, were you to confound it with purely theoretical surgery, such as that which is taught without the hospitals. There, the diseases are classed, and systematically arranged, so as to be studied one after the other in all their details, without having the patient under your observation. Here, on the contrary, there is no previous arrangement; nothing factitious. Examining the patients before describing their diseases, the professor is obliged to take the facts such as they present themselves, and according as they present themselves. It is a symptom that occupies him one day; and a therapeutic effect the next. In some cases a single disease will suffice for a lecture; at another time, several will be required. The subjects under consideration sometimes lead to the discussion of general questions, more frequently to special ones, sometimes to pathological anatomy, sometimes to etiology, and to the nature of diseases, either in the same lecture, or in separate discourses, without regard to nosological arrangements, and of such a kind, that the details given always return to that fact with which they commenced.

Thus one subject as well as the other constitutes surgery: but that in the lecture-rooms, the rules laid down cannot be elucidated to you, except in the form of preparations or plates, the original of which must be sought for elsewhere. In clinical lectures, on the contrary, surgery is seen in a state of nature, deprived of a veil and isolated, such, in a word, as each of you will recognise it in his own practice. In the schools it is like a woman when dressed, who seeks to gain your good opinion; in the hospitals, she has no dress; her ornaments are left at the door; her natural beauties as well as her imperfections are perceptible. In fine, in the first case the picture is drawn beforehand, and often embellished by the painter; in the second, the picture is drawn from the original, and in a state of nature. Those who find fault with clinical surgery as being necessarily superficial, as not thoroughly examining any question, as recurring one hundred times to the same subject, and leaving a number of others in oblivion, have taken up a wrong idea. The object of clinical instruction is not, nor cannot be, to take in all subjects. In fact, it is from systematic lectures, from theoretical courses, that you should derive your scientific knowledge. Instead of superseding or rendering them useless, clinical studies refer continually to elementary studies. These two branches of science, instead of repelling, mutually strengthen each other; for clinical studies are, after all, only a check on specu-

lative notions by bedside observation, as a perpetual metamorphoses of theoretical principles to practical application. But, in truth, clinical surgery elucidates particular subjects. It is it that decides in the end all the most important questions of pathology. If many subjects are passed over, it is because they do not properly belong to this study, or that there are not means of treating them better or differently than they are taught in a regular course of pathology: or rather, clinical surgery becomes pathology, when it treats of subjects of which the examples are not under observation. As for repetitions, the professor of clinical instruction is really obliged to resort to them; but this is precisely one of the advantages of the study. Dwelling incessantly upon new facts, he may frequently revert to the value of such or such a precept. No surgical operation can be otherwise estimated. Besides, when rules are to be established, it is clinical study that must demonstrate them: or when a truth is to be demonstrated, so as to carry conviction to every mind, it is by the repetition of facts that we support it.

Clinical instruction, then, is a mode of teaching which does not supersede any other, and that no other can really supersede. Besides, each person is at liberty to think for himself, to apply his own method, or follow his particular predilection. It is bedside pathology; no other definition can be given of it. The picture is sketched in the presence of the original; but the colours are prepared beforehand by the organization, and the artist is to choose his brushes, his canvas, and his frame. Thus, gentlemen, you may expect to find in clinical lectures the same difference of opinions as in philosophical matters, or as in the other courses of study belonging to the medical sciences. The professors are in this, as well as in every science, humorists, solidists, vitalists, eclectics, empirics, with their systems, and favourite methods; some judging *à priori*, others *à posteriori*, each telling, according to his notions, what he is pleased to call his facts.

FACTS! Let us pause for a moment on this word; never has it been so much used as in these days. Facts are said to be the basis of every thing; without them no science is tenable. Yes and No, gentlemen: we may say of facts what *Æsop* said of the tongues that he had served up at the table of *Xanthus*. They are at once the best and the worst of all things! A fact is like a cipher, it carries with it its peculiar signification. Unchangeable in its nature, it seems at once past doubt; nothing can lessen its value. All our reasonings rest on facts. It is by referring to them that we explain the nature, the causes, the progress, the dangers, and the therapeutics of diseases. No person advances a step in the healing art without calling them to his assistance. There is not a physician who, even unknown to himself, does not make them the law of his actions. The mind cannot work

without them. The natural basis of all our determinations, they are indispensable to the solution of all problems; but thus, gentlemen, facts are the source of all our errors. Nothing can lie like a fact. Who has not understood them, a thousand times, different from what they really are? It is, if I may use the expression, because they are the greatest hypocrites in the world. They present themselves every day to our eyes, under the most deceitful appearances. They seem to court all those that approach them, and hasten to adopt the language most pleasing to each: from the time of *Hippocrates* to the present, they seem to wish to deceive all mankind. *Pinel* referred to facts to prove that all diseases commenced in the solids: they demonstrate, according to my opinion, that many affections commence from the liquids. In a certain hospital they would lead us to believe that antiphlogistics may prevent, or even cure, certain cancers of the uterus; while they intimate to me on another side that this is not true. They permit on one side the assertion of the cure of white swellings, the advantage of the amputation of the neck of the womb; on the other side they contradict it. Listen to their treatment of erysipelas: according to some, the best mode of treatment is mercurial ointments; another recommends sanguine emissions; a third, nitrate of silver; a fourth, blisters.—Facts would prove to me that all these practitioners are mistaken.

The public were led to believe, by the intervention of some surgeons, that lithotripsy was attended with scarcely any danger; having taken off the mask, they have avowed to me, in private, that this was a false fact; that, upon the whole, lithotripsy was little less dangerous than lithotomy. Facts have taught the English physician that purgatives are powerful antiphlogistics; whilst in France they consider this sort of medicament as the most frequent causes of inflammation. While they deny the specificity of syphilis among a certain set of physicians, they peremptorily demonstrate to me this specificity. After having convinced several physicians and surgeons that depletion was the only efficacious treatment in inflammations, it has pleased them to prove, to my satisfaction, that the best remedy for certain phlegmasiæ, even the most severe, will be found in the class of caustics, styptics, and irritants in general.

Judge, gentlemen, by what I have just related, how much reason we have to deprecate facts! To give you a just idea of their value, it has been said that facts are, in medicine, what money is in the commerce of civilised society. Of themselves they are every thing, and they are nothing. They are the materials, the instruments, that every one moulds and works according to his own views. As they lend themselves to every one, we may refer to them all the good and all the bad that science contains, though the fault ought definitely to fall on the person who employs them.

Nothing, in short, is more complex than

the question of facts. After they are established, we must interpret them. You can scarcely conceive, gentlemen, the numerous difficulties that these two points alone present. You will perhaps shrug your shoulders, when I tell you that a number of men even among those most honoured by society, are the least apt to propound facts in medicine. Nevertheless, nothing is more true. You are told that bleeding and leeches will cure angina: *it is a fact*. Well! it is not a fact, though it has been repeated for ages. A true inflammatory angina may last from six to twelve days; left to nature, it would not last much longer. It is by other means that we must stop its progress. What I say of angina is applicable to almost all pathological facts. A patient cannot pass urine, the sound is used; but the instrument is very soon stopped. The surgeon then concludes that there is stricture of the urethra; this is *a fact*. Nevertheless, this fact may be denied. The obstruction may be quite independent of a stricture of the urethra. A luxation, a fracture, or a necrosis, are very material and very palpable facts. But, gentlemen, do you think that it is always easy to establish their existence, that nothing could be mistaken for these facts?

If you seek in the autopsy the traces of the disease observed by you during life, do you think you will meet with less difficulty? According to one, you have in a vein, an artery, or the digestive tube, the effect of intense inflammation; it is *a fact*. Another will prove to you that *it is not a fact*. It will be the same with tubercles, or erosion of the cartilage, &c. The reason is, that in medicine and in surgery each fact is composed of several elements, and that the greater part of these elements are in their turn fugitive and complex, as is the fact taken altogether; and if the smallest part of this fact escapes you, it will no longer be the same; and you will be deceived in the conclusion you draw. Before we can positively assert *a fact*, we should have studied it very closely; and should possess a degree of intellect, which is not met with in every physician, nor in every age.

When we attempt to interpret facts, how many new difficulties do we not meet with! A pain is felt; one attributes it to inflammation in the eyes, another to neuralgia of the eyes, a third to an obstacle to the course of certain matters. Are the terms of heat, redness, and swelling more explicit? No, gentlemen, they are not. After death the mucous membrane of the intestines is found gorged with red livid fluids, the *fact is undoubtedly* there; but whence does it arise? Is it from inflammation, hypostasis, or imbibition? In a patient who has fallen on the shoulder, you prove, past doubt, there is crepitation; the fact cannot be denied, but does it arise from a fracture, from some inequality of the cartilages, from a deformity of the articulation, or from the friction of some of

the tendons? Who can flatter himself that he properly interprets facts with regard to therapeutics? They have been examined, listened to, and interpreted for three thousand years. So many of them have been collected, that science and its avenues are, as it were, encumbered with them. Nevertheless, which are the points of practice put beyond any sort of dispute by their testimony? Have they decided without any doubt a question relative to trepanation, to the best method of treating cataracts, fistulæ lachrymales, diseases of the ear, the utility of tracheotomy, the operation for empyema, of paracentesis, or the rules to be followed in the treatment of fractures, in the reduction of luxations, or in the performance of amputation? See into what dreadful confusion surgeons have been led by their interpretation, with regard to diseases of the eye, erysipelatous inflammation, the employment of taxis, and the operation for strangulated hernia? Yes, gentlemen, you must be aware, that the interpretation of facts has been at all times, and ever will be, the quicksand of therapeutics.

Whilst you are using some particular remedy, the disease progresses, and tends to produce a thousand unforeseen phenomena; a host of unknown actions at the same time operate on the organization; external agents incessantly re-acting on the whole, endeavour, on their side, to give a change to the results and the observable facts. A medicine being administered, if the state of the patient rapidly changes, we are sure to be gratified by it. Is the old proverbial expression, *post hoc, ergo propter hoc*, against which so much has been said, to be always the datum of our decisions. It appears to our understanding, under the form of a law which we repudiate, against which we incessantly defend ourselves; but on purpose, or without our doubting it, or in spite of ourselves, we always follow it. It is, in reality, that there is no other means of reasoning, the effect being necessarily preceded by the cause. The most common error is, that the effect is not referred to the proper cause. You have to treat a diffused inflammation, a rheumatism, or an orchitis; you treat these affections by the application of leeches, and the patients are cured in fifteen, thirty, or forty days. Yes, but how are you to be certain but that the patients would have recovered as quickly, simply by rest and regimen. If the progress and duration of each disease were as fixed and determined as the revolution of a planet, nothing would be more easy than to arrive at positive conclusions with regard to it; but as nothing can be more variable than the succession of morbid periods, as diseases which at first appear the mildest, may afterwards assume the most malignant forms; whilst those that at the commencement appear the most fearful, sometimes terminate the most favourably, it is almost impossible for a practitioner to avoid being deceived by a thousand different illusions, and led into continual mistakes. A

woman is seized the evening of her delivery with all the symptoms of intense metro-peritonitis. I prescribe bleeding and the application of forty leeches. The next day I find her out of danger. The interpretation of the fact is simple and easy; it was the result of the sanguineous depletion. Yes, but we learned that there had not been any leeches applied nor had the patient been bled! There is nothing in which this sort of confusion more frequently occurs than in therapeutics of ophthalmia. I shall give you one example out of a thousand. A man employed in grinding ceruse, came into the hospital with pretty severe conjunctivitis of ten days' duration. I employed the usual emollient lotions for three days, hoping that rest and the change of habits would be sufficient to cure his ophthalmia. His state being absolutely the same, I ordered on the fourth day a solution of the nitrate of silver to be dropped into his eyes. The next day we found considerable improvement. I thought myself obliged to attribute the change to the nitrate of silver. Well! the pupil in charge of the prescription had not applied it! The patient was not the less cured in three days after.

If all the honour, and all the sincerity possible; if the most ardent wish to discover the truth; if a calm and reflective mind does not prevent us from the false interpretation of facts; what can you expect, gentlemen, from men who judge before they have seen; who only look at facts through the medium of their prejudices or of their systems; who have their heads too hot, or their ideas too subtle to acknowledge that any thing could escape them, or to be convinced that the corner of the figure which they perceived was not the whole of the picture?

The natural philosopher, the chemist, the geologist, turn, return, divide, decompose, recombine, multiply, and reproduce the facts that they are investigating, until the interpretation is clear and invariable. The medical practitioner is obliged to wait for his facts, to seize them as they pass, and to be contented with the side that offers to him. He cannot, in general, either decompose them, nor reproduce them in order to appreciate them; he must reach them through so many different objects, that the cleverest in the end lose them. I do not exaggerate when I say that the field mingled with all possible coincidence, is the most obscure intricacy, the most inextricable labyrinth that can be imagined.

The object of these details, gentlemen, is to show you, that facts will often lead you into error; that you must receive them with caution; that it is easy for a teacher, if he wishes to deceive you, or if he be deceived himself, to make you admit them as he understands them; that in examining them you should be cautious, and be persuaded that some of their appearances may easily escape your observation; lastly, I wish you to understand that those who tell you that

facts are every thing, who talk of them incessantly, do not attend to what they say, and may lead you with themselves into false views, and into the highway of wanderings and deceptions.

To resume, facts are not science; they serve for the outline, and that is all. After having established and interpreted them, we must weigh them, compare them, and draw the inductions that reason may decide on.

Morgagni committed a serious error by saying, that *observations ought to be weighed but not counted*. It is probable that those who repeat this sentence every day, do not comprehend it. Whatever the facts may be, they should be carefully counted: that cannot be disputed. All circumstances being the same, a hundred facts are better than two. A single fact may be more conclusive than a hundred others, I know that; so is a piece of gold of more value than a hundred pieces of copper; but that is not the question. We want to know if a hundred similar facts, a hundred facts of equal weight, are not worth more than two, or than ten out of the number. It is only after they have been well established, well interpreted, each one separately well weighed, that it is useful to count them. When money is offered to you, first you make certain that it is the proper coin; you then ask if it is copper, paper, silver, or gold; then you try the weight, and the value of the gold; and afterwards you count the pieces. It ought to be precisely the same with regard to facts. When they have been proved, interpreted, weighed, counted with the precaution of separating them from any alloy, we should consider them *de novo*, to see what they furnish science, what we may expect from them, and how they should be employed, in drawing inductions.

Consider for a moment, gentlemen, how many things the mind has to review in this preparatory work, and you will find, I trust, that among the facts that are daily talked of in medicine, there are many that are useless; notwithstanding our superabundance of facts, it is not to be wondered at that we are still so poor in this respect, nor that science presents so many lacunæ for want of well attested, well interpreted, well weighed, well counted facts: it is to this point that our successors will probably spend their lives in verifying, establishing anew, by other facts, those very facts that we are now collecting, as we ourselves do at present with regard to those bequeathed to us by past generations; when once you understand these ideas, you can apply them to all the branches of medicine. Surgery cannot deny their truth, or rather they apply equally to it as to internal pathology.

(To be continued.)

Foreign Medicine.

Memoir of Dupuytren.*

WILLIAM DUPUYTREN, Baron, Chevalier of the Orders of the Legion of Honour and of St. Michel, was born at Pierre, Buffiere, October 5, 1778. His primary studies were pursued at the colleges of Ranal, Magnal, and La Marche; and he commenced when very young, the study of anatomy and surgery. At the age of seventeen he was appointed prosecutor at the *Ecole de Santé*, at Paris. From that period he devoted himself with ardour to the teaching of anatomy and physiology. Having attained the degree of doctor in surgery, he contended with M. Dumeril for the situation of *Chef des Travaux Anatomiques*; and though defeated at that time by one vote, he obtained the situation in the month of Ventose, in the year 9; when his competitor was transferred to the chair of anatomy. It was at this time that M. Dupuytren, having Bayle for his assistant, gave himself up to the prosecution of pathological anatomy, of his researches in which he has given an account in the "Journal of Medicine, Surgery and Pharmacy," edited by Corvisart, Leroux, and Boyer. On the 13th of September, 1802, M. Dupuytren obtained by concours the office of second surgeon to the Hotel Dieu at Paris. On the 5th of September, 1803, he was named assistant chief surgeon in that establishment; and at length surgeon in chief on the 9th of September, 1815. A very brilliant concours, and one of the last which were held respecting the chairs of Professors in the Faculty of Medicine, placed him in the chair of Sebatier, February 15, 1812. M. Dupuytren is first surgeon to the king, member of the Academy of Sciences, of the Royal Academy of Medicine, &c.

Could I have dispensed with the following notice of M. Dupuytren, it would have been to me a great relief; for it occasions me considerable embarrassment. I am sure of exciting dissatisfaction. That M. Dupuytren has many failings, I will not dispute; for like other men, he was endowed with passions at his birth; but that is of little consequence to his patients. I know that complaint is made (and with some reason) of his not being a sociable colleague; that he aims at surgical omnipotence; and that there is a certain despotic inflexibility in his manners. It would be painful, however, for me to speak of this. I can still more readily believe, that he has shrewdness enough to see that talent alone is not a sufficient recommendation with the dispensers of patronage; and that he is a sufficiently skilful diplomatist to cause his merit to be properly rewarded. But where

* is the evil in all this. It is a reproach, which is only offered to those who succeed; for they only are exposed to our view. But, those who are distanced in the race, are often nothing more than vanquished blunders, struggling to escape the shame of defeat. When persons well or ill intentioned and informed, come to whisper accusations of all kinds, I listen to them; for that can do no harm; but I hardly like to let the public into the secret of things spoken into the ear. I shall endeavour, by and bye, however, to say what I think of M. Dupuytren, considered in this point of view; and hope to reconcile things which are sometimes much at variance—justice, propriety, and truth.

Should I, as is very probable, be accused of partiality, I avow unreservedly my opinion that M. Dupuytren is a surgeon of the highest order; I know not that in France we could, with any prospect of success, look for his rival. The public voice accords to him this position. It is not I who place him there; for it is there I find him. I would not frame a panegyric; but I state a fact; and I say that the reputation of the Professor at the Hotel Dieu, is the highest in our country. Is it deservedly so? I think it is; and I shall proceed to substantiate my opinion.

M. Dupuytren is a surgeon and chemical professor; and I have to speak of him under this double aspect. The art of surgery, in the opinion of most people, is only the art of performing operations. With them a great surgeon is a man whose talent is at the end of his fingers, like that of a pilferer; from which it follows that they do not understand the art, but debase it. Physicians long thought the same; and this foolish opinion was the cause of the long inferiority of surgery, with respect to the other branches of medical science. To-day it is otherwise; surgery occupies the rank it ought to maintain. A surgeon is a medical man, who occupies himself particularly with what are called *external* maladies; or, in other words, those which the hand can touch, or the eyes perceive directly; and who, in order to cure them, employs all the methods he may think requisite, but especially those which are called operations.

M. Dupuytren appears to me equally superior in all the parts of this difficult art. He has an admirably precise *coup d'ail*; a steady hand; a *sang-froid* equal to every emergency; and that innate tact which is required in every art. A physician and a surgeon are born, as well as a poet or a painter. At seventeen years he was honourably named to the situation of prosecutor at the *École*; whence it is evident, that almost from his birth, he had a decided predilection for a surgical career; a career which he ran with success, because he entered on it with ardour; for we only do well that which we like to do. From his

* Translated from the *Médecins Français Contemporains*, 1827.

rst essays in practice, till his arrival at the eminence where we now behold him, and during the fifteen years passed at the Hotel Dieu, he has seen an immense number of facts of every kind; and has been able, better than one less favourably circumstanced, to study and improve his profession. Favoured by a fortunate position, and practising in so large a theatre, the habit of seeing and doing, has given him (among other qualities we shall have to mention) the talent of discovering the disease in its proper situation and extent. In fact, that which particularly distinguishes this practitioner, in my opinion, is his diagnostic skill; and diagnosis is sometimes as obscure in surgery as in medicine. The maladies are not, and can not be *external*, speaking rigorously. There is nothing really external in the human body, but the cutaneous surface. All the affections which come under the surgeon's care, are more or less difficult to make out well; because they are often concealed in the depth of some cavity; such as the uterus, the bladder, the nasal fossæ, the pharynx, &c.; because, though partly visible, their origin is farther off. In an articulation, for instance, the origin may be in the interior of the bones. The consequences of an error are serious, and sometimes irreparable.

It may thus be judged how ridiculous and exaggerated is the idea of the certainty of surgery, if we apply it to diagnosis. We see, it is said, and we touch; but what do we see and touch most commonly? Symptoms, and not the disease itself; symptoms upon which the mind deliberates, and at last decides. Now M. Dupuytren is particularly remarkable for the certainty of his diagnosis. It would be difficult, I believe, to carry it farther. He observes with attention, but quickly; rarely undecided, he judges with promptitude. Arrived at the bed of the patient, his five senses are on the alert; and after some minutes of questions and investigations, his examination is finished. It might be often thought that he had cast only a hasty glance at the patient; but his lecture proves that he has seen all, and seen well. In a case in which the student or young practitioner would see nothing remarkable, he points out a number of interesting circumstances, and deduces from them numerous consequences, for all of which he gives a reason. I have heard very few medical men interrogate a patient with so much intelligence and point. His questions have always an end in view; and the answers generally serve to strengthen his diagnosis. I have rarely seen him mistaken, either with respect to the nature and seat of the affection, or as to the probable issue, and the effects of the therapeutic agents employed. Nor let it be supposed that these decisions are not precisely formed, or are vaguely expressed, so that they may, like the ancient oracles, be applied any

way. It is thus many practitioners act; but, on the contrary, I have been astonished at the care, and especially the assurance, with which M. Dupuytren enters into the most minute details as to facts which exist only in futurity. He describes a pathological alteration, concealed as yet in the recesses of organs, as if he already saw it; and when the scalpel has dissected and laid it bare, the truth of his description is made apparent to every one. Whence comes this art of diagnosis, so useful and so brilliant? It is owing to the habit of seeing diseases, and especially to that mental faculty which Spurzheim calls *comparative sagacity*, and Gall the *power of induction*. People sometimes speak, and I have spoken myself, of medical instinct. It is probable this instinct is only rapid calculation.

Is M. Dupuytren never in error? There are some who have made that absurd declaration without believing it themselves; but my own observation has satisfied me that he is sometimes mistaken, which does not surprise me, nor ought it to surprise any one else. It is said he once performed the operation of lithotomy on a patient who had no stone in the bladder. He had sounded several times; he had ascertained the presence of a calculus; he had heard, and made the spectators hear, the shock produced by the sound striking on the foreign body. Well, this body so well ascertained, did not exist after all. I have often heard this fact mentioned; and it is very freely repeated, because it is a great satisfaction to find a colleague in fault; but it only proves that any error is possible in diagnosis, even in the case of the most experienced practitioners. The same thing happened to Cheselden, to Desault, and twice to M. Roux, who avowed it with a candour which did him honour. M. Dupuytren is not equally frank. If we consulted only the declarations he thinks it convenient to make to the public and his students, we should believe him infallible. So overweening is his ambition of superiority, that he exercises extreme care in concealing not only his serious errors, but the slightest inexactitude. A reproach, however insignificant, and whether merited or not, appears to him to overthrow his reputation for ever. I shall return to that particular of his tactics.

On a good diagnosis depends the indication, and the method of fulfilling it; and M. Dupuytren is not less talented in curing surgical diseases than in discovering them. There is no part of his profession which he has not thoroughly explored, and into which he has not introduced some alteration, more or less beneficial. Without aiming at a complete enumeration, which would occupy too much space, I do not fear the charge of exaggeration in saying, that very few surgeons have evinced so much surgical talent in the invention of modes of operating, and

so much ability in their execution. The *Dictionnaire des Sciences Medicales* contains a list sufficiently long, but still incomplete, of the inventions or improvements due to the genius of M. Dupuytren. It mentions in particular the application of blisters in phlegmonous erysipelas, the most rational theory of certain inflammations, such as *faruncle* and *anthrax*, together with the mode of treating them by long and deep incisions; the determination of the different degrees presented by burns, a division which is a little arbitrary, but which is not without advantage as regards treatment; the modification introduced into the Foubert's operation for *fistula lachrymalis*; the invention of a new proceeding for the cure of *grenouillette*; of researches into the different kinds of cataract, and the invention of a needle for performing the operation of depression; the amputation of the body of the inferior maxilla, and a new mode of amputating limbs at the different joints; some excellent observations on the ligature of arteries, and the danger of ligatures *in reserve* in the operation for aneurism; the invention of a new proceeding, and of a new instrument, for the cure of artificial anus, by taking away the partition which separates the two folds of intestine; an invention which M. Richerand attributes, but without sufficient proof, to Dr. Physick, of America; and some very ingenious observations on callus, and the luminous consequences he has thence deduced in the treatment of fractures. We may add to this, that no practitioner has better understood the theory of fractures, or has employed more sagacity in the contrivance of apparatus for favouring the re-union and consolidation of the bones. He endeavours to attain that object by the most simple means, and he has often succeeded by placing the limb in a convenient semi-flexed position. He has contrived for fractures of the fibula and radius, apparatus, on the subject of which a writer has been very inappropriately facetious, because it is very ingenious and very useful. Among these works, and among those which it would be too long to enumerate here, there are several of which the first idea did not originate with M. Dupuytren; although, in his lectures, he gives as his own the slightest peculiarities in his practice. The bilateral operation for the stone, for instance, of which the advantages are very much exaggerated at the Hotel Dieu, was described and practised some years before M. Dupuytren, by Chaussier, Ribes, and Beclard. This is a fact known to every one. M. Dupuytren has the merit of having raised the operation to honour, by his example and operative dexterity. The double lithotome of which he makes use, resembles so strongly the instrument of Flurant, that I am induced to believe it is the same. But in spite of all his borrowings, partial or complete, I do

not believe there can be found in France a practitioner so rich in practical contrivances, and to whom surgery is indebted for so many useful and novel methods of procedure. Pathological anatomy owes him, perhaps, not less than surgery. M. Dupuytren was one of those who established that science in France. The subsequent labours of Bayle, of Laennec, of Broussais, and of Andral, have added much to our stores of knowledge; but the first impulse was given by M. Dupuytren. He has, in a very eminent degree, a creative and inventive faculty, and knows, with admirable foresight, how to modify general methods of practice, according to the particular cases of individuals.

As an operator he possesses a combination of those valuable qualities, which are all more or less necessary, but which are only met with in the great masters of the art. From having been long accustomed to see the blood flow and the patient suffer, he has acquired an imperturbable *sang froid*, and an unshaken self-possession. The most unexpected accidents never disconcert him; and it is especially in these unlooked-for occurrences that he exhibits all the resources of his talent. He is then seen to struggle with obstacles; to seize with alacrity the new indications which are presented, and to contrive, on the instant, means for fulfilling them. Is there nothing here but good fortune, or instinct as we call it? It might be thought so; but when the operation is terminated, we are astonished at hearing him dilate at length upon what has just taken place, with a method and order of detail which are remarkable. He explains the motives of what he has done, with as much precision as if he had weighed and elaborated the subject in the silence of his study. He indicates the various methods which might have been employed; together with their respective inconveniences and advantages; and justifies his conduct by practical examples and solid reasonings. We are then convinced that he has done nothing at hazard; but that, on the contrary, he has reflected, deliberated, and calculated much; and that he has not come to a decision at last, but on substantial grounds; although for all this only a few minutes have been necessary. I have been witness to facts of this kind; and I confess the art of healing has never appeared to me more grand, and more worthy of admiration, than on these occasions.

M. Dupuytren performs all the ordinary operations of surgery with ability; but in this I see nothing that ought to surprise us; for, in the hospitals of all the great cities there are operators who can amputate a leg or an arm well, extract a calculus, or extirpate a tumour in a satisfactory manner. Much less ability is required for all this than is generally imagined. So far as regards manual dexterity and agility of motion, the

professor at the Hotel Dieu is not without rivals; and there are some who are even his superiors in that respect. M. Roux, for example, is more adroit, taking this word in its purely mechanical acceptation. He has also incontestibly more grace and vivacity. We are not to conclude from this that he operates better, but simply that he has more freedom and ease in his movements, though they may not be more sure. If it were allowable to regard a surgical operation only as a spectacle, and the surgeon as an artist performing his part, I should give the preference to M. Roux over M. Dupuytren, and all the surgeons of Paris. But in my opinion, the art of surgery is far from consisting entirely in the application, more or less adroit, of cutting instruments. It consists especially in the diagnosis of diseases; in the appreciation of indications; in practical experience; and in all these respects I place M. Dupuytren in the first rank.

Frere Jacques used to say to the patients whom he had just cut for the stone—"I have operated, but God must cure you." Surgeons no longer speak in this manner; but they act in accordance with it. The success of an operation is in a great measure dependent on the care and the subsequent treatment to which the patient is submitted. In this respect also M. Dupuytren evinces the same superiority in his practical views. He never operated without having submitted his patient to an appropriate regimen, and without having satisfied himself that his general health will not materially suffer from the operation. He also appears to me to be a sufficiently good physician in treating the affections which ordinarily complicate traumatic injuries. I say a *sufficiently good*, not a *perfect* physician; for in this respect I do not consider him completely beyond the reach of censure. The greater number of surgeons, indeed, are to blame in this particular; allowing themselves to be governed by rules which are too mechanical. M. Dupuytren is one of those with whom this defect is least apparent.

—o—

CHARTER TO THE LONDON UNIVERSITY.

The noble opportunity for the Government to exalt itself in establishing Freedom in regard to Educational Honours, considered in a Letter to the Right Hon. T. S. Rice, Chancellor of the Exchequer, &c. &c.

[The following letter is in accordance with the independent and philanthropic views which its author delivered before the Westminster Medical Society, against granting a power to confer Degrees on the London

University, or any other London School of Medicine. It will be perused by every liberal member of the profession.—ED.]

Honourable Sir,—When Vice clothes itself in the garb of Virtue, she is the more dangerous, because more difficult of detection; and hence, sometimes even the good embrace her, without being aware—until the consequences of the embrace become apparent—of the hideous being they have acknowledged. MONOPOLY often attires itself thus; to the hatefulness and the injuriousness of which, the Government, of which you were and are a member, have testified by the measures they have, in the various sessions, brought forward, to destroy, or at least to mitigate, the evils of some of the most extensive monopolies. Every unbiassed mind, looking upon these proceedings of the Government, has come to the conclusion, that the necessity is seen, on the part of the MINISTRY, to abolish all monopolies, so far as such abolition can be effected with safety.

One monopoly, that stands most in need of abolition, is exhibited by the Universities of Cambridge and Oxford. These Universities exclude all save those of a *particular creed*; and thus make the honours of literature and of science to depend, not upon a man's *talent*, but upon his *religious opinions*. The atrocity of the monopoly thus created, is now generally felt; and a universal cry for an abolition of the unsalutary power perpetuating this monopoly, has been raised throughout the kingdom. To that cry it has not been possible, on account of the peculiar constitution of Oxford and Cambridge Universities, to pay any effectual regard.

What has happened? The evil is felt. Individuals, not content to wait till the removal of the evil shall be effected through the influence of public opinion acting upon the House of Commons, and, through that house, on the House of Lords, determined to realize the privilege of obtaining the power of conferring *Honorary Degrees*, without the degrading condition of submission to a *particular creed*. These individuals, instead of going to the LEGISLATURE and demanding that an UNIVERSITY should be established within the METROPOLIS, combined together, and, by subscribing for certain shares, constituted a *large proprietary* of shareholders, who determined to raise an edifice, which, with its adjuncts of teachers, should be called, *The University of London*.

The building was raised; the teachers were appointed; and the system of instruction commenced. Forthwith an attempt was made to obtain a Charter, not merely of *Incorporation*, but for *giving Degrees*.

It seems, moreover, from the nature of the motion of Mr. Tooke, in the House of Commons, on March 26, 1835, that a Royal Charter of Incorporation had been drawn up, and approved of, by the Law Officers of the Crown, in 1831.

Now, Sir, What would have been the consequence of giving such a Charter* to the London University? What but the establishing another monopoly—a monopoly of teachers!

The proof is easy. The object of a College, and of all schools, is to *teach*. The skill of the teachers, and the means possessed for the manifestation of that skill, ought to be the only grounds upon which any pre-eminence can be claimed. Each teacher becomes interested in communicating scientific truth in the most clear and comprehensive manner. There is a beneficial, a scientific rivalry, pregnant with advantage. But, if there be any exclusive advantages possessed by particular teachers, what is the consequence? To render this apparent, take two lecturers, A. and B., both of whom are equally talented. They make known that they lecture. They are equal in talent to instruct, and in the possession of means for instruction. Those anxious to be instructed, hear of their intentions, and determine to place themselves under their instructions; some under A. and some under B.; but, by some contrivance, B. has managed to obtain a peculiar, an exclusive advantage, namely, that *his* pupils will be enabled, by attending his lectures, or teachings, to obtain a *degree*—which A.'s pupils *will not*. Does it not follow, that *plus advantage*, added to *equal talent*, must give B. an injurious superiority? And, in addition, does it not follow, that this superiority must be injurious to A.? And, is not the possession of such a superiority, a manifestation of the exclusive principle—a monopoly of the worst character?

Such a monopoly would have been established, had the London University obtained the Charter, which they sought. But they would have obtained a monopoly of a more glaring character, had the Charter sought for been granted.

The ACADEMICAL SENATE OF Professors would have been the *examining body*. The Professors, or the Teachers, would have examined *their own pupils*.

It is true, Sir, that the plan proposed by the Government, obviates the *latter* evil. And, in this view of this important matter, every enlightened mind must agree with Mr. Hume, that the "Government is in the novel position of taking the lead of them"—the proprietors—"in the general liberality of the plan."

What, then, is proposed by the Government? It may be stated thus:—

I. *That a Board of Examiners, to be termed THE UNIVERSITY OF LONDON, shall be authorized by Charter to confer degrees.*

II. *That pupils from the London University and King's College, shall be admitted to Examination; and,*

III. *That any other Bodies for Education, whether corporated or uncorporated, may, from time to time, be named by the Crown, and their pupils be admitted to Examination for Degrees.*

Such are the intentions of Government; intentions indicative, evidently, of the fact, that *Degrees* are to be conferred upon the prosecutors of every department of learning and of knowledge, divinity excepted.

To this, no liberally-minded individual can object. But, in developing this intention, one circumstance occurs, which mars the beauty of the plan. It is this: that while "The University" can confer all Degrees, save those on Divinity (an excellent exception), the individuals, on whom these Degrees are to be conferred, are not *all who may be qualified by their learning and knowledge*; not all who have laboured hard to acquire every necessary information; but those only who have been educated at "any chartered College within the metropolis."

Now, Sir, is not this giving a positive monopoly to the teachers in chartered Colleges? Is not this as much as asserting that the education of students is better within the walls of a chartered College than within the walls of any other building?

Is not this a species of *intellectual consecration* of bricks and mortar? Is not this a sacrifice to the god of wealth, because the largeness of the building seems to have some weight in the matter? Finally, Sir, is it not saying to those beginning their studies in London, Gentlemen, go to the King's College, and to the London University—become pupils there; for there you will have talented lecturers, and there, in addition, you will be able to gain honorary Degrees?

But, Sir, it may be said, that the Government plan is not so exclusive as this; for it is expressly stated in the communication from Downing Street, August 19, 1835—"Any other bodies for education, whether corporated or uncorporated, may, from time to time, be named by the Crown, and their pupils be admitted to examination for Degrees."

But, Sir, it is stated in the preceding clause, that a particular class of pupils is at once admissible to examination for degrees—"Pupils from the University and King's College to be admitted to be examined."

Here, sir, at once a priority is given to these educational bodies over other schools. And why? Are they better teachers at these thus styled colleges, than at other schools? Personal comparisons would be invidious; and, therefore, should be avoided. But it may be asked without fear, is the education at either of these institutions superior, in reference to the production of *real qualification for medical practice*, to that given at the private schools, as they are called?

Let, sir, an application be made to the examining boards of the Apothecaries' Company, and of the College of Surgeons, and

* This Charter included the power of giving medical degrees.

let a report be presented from each body of the pupils, *passed or rejected*, as belonging to the individual schools, and I, myself, as a private individual lecturer, am quite willing to abide by the result, as a testification of the nature and of the sufficiency of medical education as given at the private schools.

Is it then just, sir, that the pupils of any one institution, or of any institutions, should have the priority given to them of starting in this *intellectual race* for intellectual honours in advance of the pupils of other institutions?

I sincerely believe, from various sources, that it is the wish of the government to act in this matter with the greatest fairness; but is it not apparent that selecting the pupils of the London University College, and of King's College, is giving an undue priority?

It may be asked, *What, then, do you propose?*

I propose, sir, that the government of this country, recognizing the grand truths, that *science has no country; that scientific men have generally been those who have received no aid from collegiate education*, should declare, that

LITERARY AND SCIENTIFIC HONOURS SHALL BE OPEN TO EVERY INDIVIDUAL WHO CAN PROVE HIMSELF QUALIFIED TO POSSESS THESE HONOURS.

And, that, in addition,

THESE HONOURS BEING GAINED, THE INDIVIDUALS GAINING THEM, SHALL HAVE EVERY LEGAL PRIVILEGE CONNECTED WITH THE QUALIFICATION.

For, sir, in regard to the latter point, it would evidently be absurd to give an honorary degree, as *indicative of qualification*; and, then, afterwards to require the qualified to pass another ordeal, previous to the realization of the benefits of such qualifications.

It is true, sir, such a plan would require the sweeping away—many, in the *present state of society*, scientific, or rather *pseudo-scientific* NUISANCES; but the gain would be immense—the loss would be nothing.

And, sir, what a noble memento such a majestic proceeding on the part of the government would be of that government—what a pleasurable satisfaction would arise in the mind of yourself—a member of such a government, in contemplating the fruits of such a purpose! And, finally, what a thought to console on leaving this world—"I have been an instrument in removing a mighty barrier to the diffusion of education and enlightenment among the people."

Trusting, sir, you are capable of appreciating the high behests connected with the government on this important question,—I have the honour to remain, Right Hon. Sir,

Your obedient servant,

JOHN EPPS, M.D.

Lecturer on Materia Medica and Chemistry, and Director of the Royal Jennerian and London Vaccine Institutions.

London, Dec. 17, 1835.

DUPUYTREN'S CLINIC.

Hæmorrhoids.

Two kinds of hæmorrhoids have for a long been recognised; the one *internal*, the other *external*. So long as the hæmorrhoids have not degenerated in their structure, so long as they do not give rise to hæmorrhage, or to abundant discharges of sero-purulent fluid, throwing the patients into a state of profound and characteristic anemia, the excision of these bodies is not advisable to remedy the accidents, or rather the inconveniences to which they give rise. Antiphlogistics effectually dissipate them. But when the life of the patient comes to be either nearly or remotely threatened, when the inconveniences are sufficiently great to require prompt attention, or when the hæmorrhoids have undergone a process of degeneration, antiphlogistics are not sufficient, and no other means but excision, according to M. Dupuytren, can be employed with success. It is to these degenerated hæmorrhoids, which require prompt and bold treatment, that the present article relates.

We have already observed that there are two kinds of hæmorrhoids, internal and external, which may or may not exist together. They form a chain of tubercles disposed in a circle, either without or within the anus, and this arrangement has acquired for them, from M. Dupuytren, the name of *hæmorrhoidal pads*. The external hæmorrhoidal pad is formed of a circular range of soft and roundish tubercles, of a brown colour externally, where they are covered by the skin, and of a bright red colour internally, where they are enveloped by the mucous membrane. Rarely ulcerated on their external surface, they are frequently so on their internal, and give rise to hæmorrhages more or less abundant, and to purulent discharges, which tend to weaken the patient.

The *internal* hæmorrhoidal pad, situated within the anus, is often strangulated by the sphincter, in consequence of its becoming swollen, or by the protrusion of the lining membrane of the rectum. It gives rise to the same unpleasant consequences as the former, and is known by the bright red colour of the tubercles. The two varieties, as we said before, sometimes present themselves at the same time in the same patient.

Individuals afflicted with the latter species (the *internal*), walk the streets with difficulty. Arrested every now and then by the severity of their pains, they may be seen either to carry their hands to the part affected, or sitting down on a post or projecting stone, in order to make the hæmorrhoids re-enter the anus. But these expedients afford only a temporary relief, and a return of the pain quickly follows a new escape of the tumours.

More or less reduced by the abundance and frequency of the hæmorrhage, or the

flow of sero-purulent matters, the patients become thin, their skin is pale, and they have the appearance of persons worn down by other hæmorrhages, or abundant suppurations. They often fall into a state of sadness, and even of profound melancholy. Their intellectual faculties are weakened, and they are often known to attempt their lives. All this while the local degeneration is making progress; a cancerous affection of the anus, and of the inferior part of the rectum, declares itself, and the death of the patients will be the end of this progress, or of the abundant flux, if these unfortunate tendencies be not efficaciously opposed. Excision is here the only means of effecting this. Let us first speak of the mode in which it ought to be performed, and then of its inconveniences, its dangers, and the means of avoiding them.

When the diagnosis has been established, and the excision decided on, we lay the patient on his side at the border of the bed, the legs extended, or, better still, the one bent forcibly on the thigh, the other stretched out. If the tumours be *external*, we desire the patient to make strong expulsive efforts, and by this means the piles are forced out. They are seized by pincers with broad points, while an assistant separates the buttocks, and are excised by means of curved scissors. This mode of proceeding offers very little difficulty.

The excision of *internal* hæmorrhoids is more difficult. In order to bring them to the exterior, so that they may be removed entire, the patient ought to have the buttocks immersed in a warm bath, and should be directed to make violent efforts at expulsion. As soon as the tumours appeared externally, the patient should be quickly laid on the bed, in the position recommended above; and the operator, promptly seizing the excrescences, should excise them altogether, without giving them time to re-enter.

Before the operation, M. Dupuytren is accustomed to prescribe a gentle laxative and an enema. We shall see by and by what are the reasons for this precaution.

The excision of hæmorrhoids is not exempt from inconveniences, neither is it without danger; but these inconveniences are little to be dreaded, and the dangers may be happily prevented. Nevertheless, two patients died from hæmorrhage following the operation; one in the hospital, the other in the city. The danger consists entirely in this hæmorrhage which may follow the excision. In the case of *external* tumours the blood is effused outwardly; the hæmorrhage is immediately perceived, and may be easily arrested by cauterization. It is also to cauterization with a heated iron that we ought to have recourse in the case of *internal* hæmorrhoids; but here the application of the cautery is more difficult, and the hæmorrhage may be more easily overlooked. That which reveals it to an attentive and enlightened surgeon, is a feeling

of heat which the patient experiences in the abdomen, and which appears gradually to increase in proportion as the blood accumulates in the intestines. To this may be added the greater weakness of the patients, his more pallid countenance, the smallness of the pulse, a cold sweat over the body; in fine, all the symptoms of internal hæmorrhage.

When once this accident is discovered, we must hasten to get rid of the blood contained in the intestines, either by desiring the patient to make expulsive efforts, or by a cold injection. By these efforts at expulsion the wound is always brought into view, and then M. Dupuytren employs what he calls a *haricot cautery*. It has, in fact, the shape of a bean, having a little stalk fixed at one end into its umbilicus, and at the other united at right angles with the handle. By means of this instrument he cauterizes the place where the jet of blood issues. This is always effectual in arresting the hæmorrhage; and M. Dupuytren has never seen any dangerous effect follow. Whenever he operates in private practice he takes the precaution of leaving with the patient an intelligent assistant, who, at the first symptom of hæmorrhage, external or internal, applies the cautery, and precludes all danger.

Another, but a less effectual way of arresting the hæmorrhage, is to introduce into the rectum a pig's bladder, which is afterwards filled with charpie. Although this method succeeded in the first case in which he tried it, M. Dupuytren found it objectionable, from the great inconvenience which patients experienced from it, and the apparatus was almost always expelled by the efforts provoked by its presence.

The other accidents which sometimes attend the excision of the hæmorrhoids are much less serious and alarming. A considerable swelling of the cellular and adipose tissue of the anus constantly takes place, the principal inconvenience of which is the impossibility experienced by the patients, for four or five days, of going to stool; but the laxative and the injection by which the bowels were cleared out before the operation, and the abstemious diet to which they are restricted, render the necessity less pressing, and retard an evacuation a few days without inconvenience. The tumefaction may also give rise to a retention of urine, but for that we possess very efficient remedies. The tumefaction itself may be combated by the application of leeches. The operation of the caustic is always limited to the place to which it is applied, and M. Dupuytren has never seen the inflammation spread to any distance over the coats of the intestine.

The pain produced by the operation is sharp, but almost momentary; and this inconvenience, inseparable from the slightest operation, cannot be put into the balance with the pain and danger of the affection.

The superintending care of the surgeon

ought not to be confined to the time of the operation, and of the cauterization of the wound. The patients are exposed to other dangers, from which it is in his power to shield them. We have already said that patients affected with degenerated hæmorrhoids are reduced to a state of profound anemia, a state of asthenia produced by the abundance and frequency of the hæmorrhage, or of sero-purulent discharges. These evacuations, to which the patients have for a long time been habituated, cannot be suddenly arrested without their cessation reacting on the whole economy. A state of general plethora is produced, congestions of blood take place in the lungs, the liver, the brain, &c., and organic affections of these organs may supervene. The patients frequently fall into a state of alarming insensibility. The arteries beat with such violence, that we should be led to suspect the existence of aneurism, if these anomalous pulsations did not change every instant their situation and strength.

If the patient be young, vigorous, and plethoric, and if the discharges *per anum* be of a sanguineous character, bleeding at short intervals should be practised for some time. If the discharges be of a purulent nature, an issue may be established, or the cautery applied to a neighbouring part; or, if the case be urgent, both these means may be employed at the same time. Such are the most likely remedies, and such is the most rational prophylactic treatment of a plethora, the existence of which exposes to very great danger.

With respect to *external* hæmorrhoids, when once their excision has been performed, the cicatrix which is produced, either by the constriction of the sphincter itself, or the tension of the integuments and the radiating folds of the anus, is in general sufficiently effectual to prevent the protrusion of the *internal* hæmorrhoids, and we may then dispense with the excision of the latter. This excision, however, like that of *external* hæmorrhoids, is in general not followed by a return of the disease, and the patients are for ever freed from their malady.

The first of the following cases is that which has furnished the text for the preceding observations. It is followed by several others cited by M. Dupuytren, and by one which we observed, a short time ago, at the Hotel Dieu.

CASE I.—The patient was a man, from 36 to 40 years of age, thin, and of a bilious temperament; weakened by frequent and abundant hæmorrhage from the anus. The hæmorrhoids were external, and were removed without difficulty, by a few cuts of the scissors. No hæmorrhage followed the operation, but considerable swelling took place around the anus. The only inconvenience of this, was a suspension of the fecal evacuations; but the patient had taken a laxative the day before the operation, and on the morning of the day itself, an injection

had been administered and returned. Abstinence, with the application of leeches and emollient, sufficed to moderate the irritation. The tumefaction has diminished considerably; and the patient may be considered as cured.

CASE II.—About twelve years ago, a very rich banker, at Paris, of a bilious temperament, about 45 years of age, and for a long time subject to hæmorrhoids, had copious discharges from the anus; in consequence of which, he had been gradually reduced to a state of very great weakness and anemia. Pale and dropsical, he became daily more emaciated, and incapable of mental exertion. To write a letter, was a fatiguing, and almost impossible undertaking. M. Dupuytren having been called in, examined him, and detected the existence of internal hæmorrhoids. He proposed their excision, which was promptly acceded to. It was the first operation of the kind that the surgeon had undertaken. An injection having been given and returned, the patient first took a hip-bath, and then lay on the edge of the bed, with the thighs held assunder. Violent efforts at expulsion caused the protrusion of the hæmorrhoids; which was seized with broad-pointed forceps, and entirely removed (not without difficulty) by means of curved scissors. There was no *external* hæmorrhage; but M. Dupuytren did not quit his patient, who, in about a quarter of an hour, grew pale, and became weaker and weaker. The pulse was small and hard; a cold sweat covered his body; and he felt in the abdomen a sensation of heat, continually mounting higher and higher. From these symptoms, M. Dupuytren could not mistake an *internal* hæmorrhage. He immediately desired the patient to make efforts at expulsion, and a great quantity of blood, scarcely congealed into clots, was discharged. Cold injections were tried without success; the flow of blood was not arrested. A pig's bladder was then introduced into the rectum, and stuffed with charpie. This contrivance succeeded perfectly; and it was not without great difficulty that the bladder could be maintained in its situation, in consequence of the involuntary efforts which constantly tended to displace it, and which did displace it several times.

The hæmorrhage which occurred here, very much weakened the patient, retarding very much the convalescence; and might have proved fatal, had it not been promptly arrested. He has since had no return of the affection, nor any interruption to perfect health.

CASE III.—The brother of the banker to whom the last case relates, was affected with the same disease. He lived at Berlin; but having heard of his brother's recovery, and a similar state of weakness having come on, M. Dupuytren was consulted by letter. From the report of the celebrated surgeon who attended the patient, he could not

doubt the existence of hæmorrhoids and recommended their excision. But the accident which had happened to his former patient, had led him to contrive a method of arresting the hæmorrhage at once, and thus obviating the only danger which can accompany that operation. He therefore wrote the rules to be followed; and recommended, if hæmorrhage should follow, cauterization with the bean-shaped iron.

The surgeon at Berlin paid no attention to this advice: immediately after the operation he left his patient. Shortly after he was gone, symptoms of internal hæmorrhage supervened. Paleness, and a cold sweat came over him. One of his younger brothers, who had witnessed the first operation, recognized the mischief and its cause. They ran for the surgeon, but were not able to find him. Time now was pressing, and the danger imminent; when the young man had the presence of mind to introduce a pig's bladder into the rectum, as he had seen done in the former case. He filled it with charpie, and thus, happily succeeded in arresting the hæmorrhage. The loss of blood, however, had been so great, that the patient was a long while in recovering.

CASE IV.—In the month of last December we saw, in the Hotel Dieu, a similar case, which we think may be usefully detailed in connexion with the preceding. The patient was a young woman, who had for some time been a prey to sharp pains in the region of the anus. She was pale, weak, infiltrated; and had, in fact, all the appearance of a person reduced by frequent and abundant hæmorrhage. There was a considerable eversion of internal membrane of the rectum, and a very large hæmorrhoidal tumour strangulated by the anus. After several days of repose and low diet, baths and emollient applications having been at the same time employed, the tumefaction was lessened, the hæmorrhoid was reduced, and it was determined to free the patient from it by excision.

The patient, lying on the edge of the bed, with the limbs well separated by assistants, she made (as directed) considerable expulsive efforts; in spite of which, however, whether from rest having diminished the swelling, or from the weakness of the patient, the size of the protruded parts was not very considerable. M. Dupuytren then caused three assistants, each armed with forceps, to seize three different points of the tumour, which, together with the everted portion of the mucous membrane of the rectum; he was thus enabled to excise. But little blood was lost during the operation. It was of an amaranth colour, and resembled that which is found in persons weakened by hæmorrhage. No jet appeared; and it seemed possible, therefore, to spare the patient the pain of cauterization; taking the precaution, however, of committing her to the care of a dresser, with instructions to watch

over her with care, and in case of hæmorrhage, to give a large injection, so as to distend the rectum and expel the blood it contained, and then to have recourse, without hesitation, to the cautery.

These precautions were not unnecessary. The patient lost but little blood; the hæmorrhage being arrested by cauterization. Whether from fear, however, or from the pain of the excision and the cauterization together, the patient had a violent nervous fit, which alarmed the dresser, and unfortunately determined him to open a vein in the arm. In consequence of this she was attacked with violent pains in the head and palpitations of the heart, both which M. Dupuytren did not hesitate to ascribe to the imprudent venesection. He was the more easily led to this conclusion from a case which he had at the same time under his care in private practice. It was that of a young man who, having lost a considerable quantity of blood from hæmatemesis, had in consequence very severe pains in the parotid glands, which part they quitted only to appear, with equal violence, in the calves of the legs.

The swelling induced by the cauterization was inconsiderable. The patient laboured under a diarrhoea for some days, but this complication was successfully treated; and after some months' residence in the hospital she went out, still weak and pale it is true, but cured of her malady, and of the cause which produced her weakness. At home, it is probable, she was not long in obtaining a perfect restoration to health.—*La Clinique des Hopitaux.*

—o—

NEW INVENTION—OPERATING TABLE AND INSTRUMENT CASE.

WE have examined an apparatus, the invention of Dr. Veitch, of Chelsea, by which, and within the space of three feet four inches in length, two feet in breadth, and three in height, there is not only an admirable operating table, but every instrument and bandage necessary for operations may be so classed and arranged as to give the wounded man requiring surgical aid all the advantages that the best operating theatre can confer. It will be equally applicable to the navy, the army, and private practice, because portable, where the surgeon is frequently compelled to operate. It now stands in the Model Room of the Admiralty, where it has been examined by some of the most accomplished and distinguished officers of the army and navy with approbation, because likely to diminish the loss of life, as well as to abridge the complicated pain and misery, the result of the day of battle, by the certainty and celerity with which its powers can be, under all circumstances, applied. These are our deliberate opinions, from having minutely inspected it.

INJUSTICE, JOBBING, AND IMPOLITIC
LEGISLATION OF THE DUBLIN COL-
LEGE OF SURGEONS.

OUR readers will be astonished at the facts we are about to submit to their notice, which show the partiality of all our medical corporations. The intriguers of the Dublin College of Surgeons are now placed in a very awkward predicament by the resignation of Mr. Kirby, their Professor of the Practice of Medicine. The College have passed a by-law that no one should be eligible to the vacant chair, unless a member of their own body; and discovering that even this monopoly might introduce a gentleman eminently qualified for the office, a second by-law is suddenly passed, to the effect that such member must be a *practising* surgeon. The object of the second piece of legislation was to exclude Dr. Green, one of the lecturers at the Richmond Hospital School, a physician in the highest estimation, one of the few good pathologists in Dublin; a popular lecturer who has a large class, and one who is universally respected by his professional brethren; and would be supported by every liberal man amongst them as a candidate for the vacant office. But Dr. O'Beirne, Mr. Carmichael, and the other lecturers of the Richmond Hospital School, among whom is Dr. Green, have given the most triumphant opposition to the College School. They cannot be forgiven, nor any one of their associates. But mark the mean and despicable conduct of the professor-

makers in Stephen's-green. They pass a second by-law, excluding all members of their body from the chair of physic, unless a *practising* surgeon; and this vile and iniquitous law was made for the express purpose of excluding Dr. Green, who, a year or two ago, unfortunately lost his hand in consequence of the bursting of a gun, and was necessarily compelled to abandon surgery, and to practise as a physician. He cannot practise surgery, in the above sense of the word, and being a formidable rival in a flourishing school, a new by-law was concocted for destroying the voice of nine-tenths of the College, who are his supporters, but all of whom must obey the monopolising junta who framed it. Thus it appears that, were it possible for Sir Astley Cooper or any other equally eminent honorary member of the College to be a candidate, and meet with such a serious injury as Dr. Green has unfortunately met with, instead of generosity, as well as justice, influencing his brethren in electing him, for teaching modern pathology depends more on brain than hand, whatever the manualists of the Dublin College may think to the contrary—he should be excluded.

What shameless absurdity! What consummate folly! but what atrocious inhumanity towards Dr. Green. Such injustice was sure to meet its reward. The Solons of Stephen's-green have now discovered, that not one of their manualists is fit or competent to take their chair of Practice of Medicine, which remains vacant at present, and must until they repeal their infamous by-laws. All physicians are excluded. Dr. Corrigan, who is one of the very best pathologists and best attended lecturers on medicine within 300 yards of

the College, is ineligible, Dr. M'Adam, even *honourable* Park-street professor, and others, are also physicians, and "not members of our body, as practising surgeons." The jobbers, have, we understand, reasoned as follows:—

"Dr. O'Beirne, Mr. Carmichael, Mr. Ellis, Dr. Brennan, &c. are Radicals, —have nearly ruined us, and erected much better attended schools in our very faces, and so exposed us before the Parliamentary Committee, that a crowded auditory looked on us with marked contempt and indignation for our delinquencies in monopolising every thing for ourselves. None of these will do, though every one of them is qualified even by our recent by-laws; but they have larger classes than ours, and will not desert them. Mr. Carmichael abolished apprenticeships, put many thousands out of our pockets, by his absurd scheme of introducing the policy of the London and Edinburgh Colleges, of allowing students from all parts of the kingdom to present themselves for examination. Besides, he founded the Richmond School. He ought not to get the chair; and, moreover, if offered it, he would refuse it.

Dr. O'Beirne has seen more surgical and medical practice during the late war, than half the College; is a *practising* surgeon and physician; but he horribly exposed us in London, enough to damn our reputation; is a papist, and a man of such a nice sense of honour, that, on the proposal of the first job, he might take it into his head some day to challenge the whole of us, and fire at us one after the other, in regular military order, leaving the dead and wounded on the classic plains of the Phoenix-park. He is too honourable, talented, and dangerous a character to have any thing

to do with—ergo, we shall not elect him. Mr. Ellis would be a most efficient lecturer, but he is the successor to Mr. Kirby, is too clear-sighted to be duped, is a rancorous opponent, a successful rival, and as bad an exposé of our intrigues as O'Beirne. *Omnes*, he must be kept out."

Who, then, is to be the surgical operator that is to contend with Corrigan, Green, &c. on the practice of medicine? There is not a single member of the Dublin College of Surgeons, besides those mentioned, above who is equal to the task. It is very probable, however, that some accommodating monopolist, but no pathologist, will be appointed; if there be any one even of that order such a simpleton as to fancy lecturing to empty benches. The professor makers at the College School ought to know that the present race of medical students are too enlightened for the antiquated cabinet-makers at the Dublin College; and will not attend impotent lecturers. There is another remarkable fact in relation to the policy of the Irish College School, which is this, that all the Universities, Colleges of Physicians and Surgeons, and Societies of Apothecaries in the United Kingdom require the lecturer on Practice of Medicine to be an M.D., and a member of the Physicians' College, if a teacher in London, Edinburgh, or Dublin, before his lectures will be recognized. But mark the exception in favour of the Dublin College School. In all the other schools in the Irish metropolis, the lecturer on physic must be a Doctor in Medicine, and a member of the College of Physicians; but, in the favoured school, he may be a D.D., an LL.D. or A.S.S. Now, how the examining bodies can act so glaringly partial, is

to us astonishing. No individual is allowed to lecture on medicine in London unless he is a member of the College of Physicians, nor in any provincial school, unless he is an M.D. of some University. The effect of this law is, that the lecturer must pay a large sum to the College, run the risk of being rejected, revive his classical and medical studies, before he can obtain a recognition. Why then, we inquire, should there be partiality shown to the Dublin College Professor? We call on the College at at Lincoln's Inn, and the wisacres at Blackfriars to act impartially, and place the favoured school on the same ground as all others. These, and all other examining medical bodies, should teach their Dublin brethren that an *operating or practising* surgeon is not qualified to teach the practice of medicine; nor is there a single hospital surgeon in this metropolis, who would have the presumption to attempt it, though, by the way, they almost all have to practise medicine. It would be an insult to the commonest understanding to inquire, are not the London Hospital surgeons as competent as the Dublin, and as well qualified to lecture on Practice, Medicine, &c.? Nevertheless, the Medical Corporations will not recognise them as teachers of that branch of the healing art, though they tolerate one individual of that class, because another Corporation desires it. Yet, to hear the evidence of these bodies about their *strict impartiality* before the Parliamentary Committee, and, to read it in the published report, one would really imagine them just, pure, and beyond suspicion, in management of Medical Education and Practice. But the example before us disproves their evidence, and is a disgrace to them. Let

them at once enforce their regulations impartially, and no longer outrage the many able lecturers on medicine in Dublin and elsewhere, by tolerating the glaring anomaly to which has given rise to these strictures. Let them show the Dublin College School that the course of education must be the same as in every rival Medical School, and in every one in the kingdom.

If the Dublin College of Physicians were not powerless, or if they acted as they ought to have done, they never would be subjected to such an insult as exclusion from a lecturership, which custom and law have assigned them. But they are actuated towards the surgeons by the same illiberality; and would not on a late occasion, join them in a medical society, since denominated the Surgical Society of Ireland. The old leaven of the London Colleges exists in the Dublin, and nothing good in policy can emanate from either, as regards each other or the branches of the profession which they have so long injured. It is, however, most consoling to know, that these conflicting bodies will, ere long, be reformed, liberalised, and united in one faculty; or perchance entirely abolished, and their places supplied by better. Thus the old proverb that a house divided against itself cannot stand.

—o—

THE METROPOLITAN UNIVERSITY.

We are happy to state that the views we offered on the intended monopoly in the London University are in accordance with those of the profession in the different medical schools, as well as of Mr. Warburton, and of the friends of rational reform in the education and practice of medicine in this kingdom

Several deputations have waited upon the Chancellor of the Exchequer, since our last publication, for the purpose of remonstrating with him against the proposed monopoly, and we are pleased to state that the Right Honourable Gentleman heard all with the greatest attention. We have also reason to know that the remonstrances of all the schools, will produce the desired effect.

—o—

NEW INVENTION.—PORTABLE OPERATING TABLE AND SURGICAL INSTRUMENT CASE, FOR NAVAL, MILITARY, AND GENERAL PRACTICE.

It affords us great satisfaction to direct the attention of the profession and the Governors of Hospitals to the description of a new invention and a most valuable one, made by Dr. Veitch of Chelsea, an experienced Naval Surgeon, which will be found in another of our pages. We have designated it as above, and earnestly recommend every Surgeon to inspect it and possess it. It, in our opinion, will be invaluable to the Naval and Military Surgeon, and also to every practical Surgeon. It is now at the Admiralty, and has been inspected by several of our bravest and most experienced naval commanders, every one of whom has highly approved it. Among those we may mention the name of one of the bravest and most experienced of them, the Earl Dondonald, late Lord Cochrane, who, after the closest inspection, declared it to be admirably adapted for the purpose for which it is intended, and that it ought to be in every ship of war. It opens at the top and forms a table, while its compartments are sufficient to contain every instrument and means necessary to the practical surgeon, and these are so numbered, that

any person who is able to read may, in cases of necessity, act as assistant to the operating surgeon, which is often a great advantage during the heat of battle. It is scarcely necessary to mention, that the instruments are concealed from the view of the patient, and not displayed on tables, as in our largest metropolitan hospitals. The whole apparatus occupies a very small space, may be purchased for three pounds sterling, and would be a useful ornament in every private surgery. It reflects great credit on its inventor, and will be the means of transmitting his name to posterity, as one who most materially contributed to relieve the sufferings of all engaged in the defence of their country. Veitch's portable operating-table and surgical instrument case will have a niche in the annals of surgery.

Hospital Reports.

NORTH LONDON HOSPITAL.

On the Treatment of Stricture—from a Clinical Lecture on Stricture, by Mr. Liston.

MR. LISTON objects to elastic bougies, as they may turn upon themselves and the point may be carried into a direction precisely opposed to the one required—he considers the metallic curved bougie the most useful instrument. If obstruction to the bougie arise from contraction of the muscles about the urethra, by diverting the patient's mind you will succeed in subduing the spasm. The instrument acts by reducing the irritability of the passage; all effect of the introduction should be allowed to cease before the employment of another.

He could not see the necessity of using caustic—neither as recommended by Duran, who mixed Armenian bole and escharotics in his bougies, for the purpose of removing warts or carbuncles that were supposed to exist;—or the nitrate of silver, as used by John Hunter, and afterwards by Sir E. Home, and as now revived. He had no objection to the employment of nitrate of silver for the purpose of reducing irritability, but this could be effected otherwise; he did not consider it safe

or proper to use it as a caustic to the strictured part.

Sir E. Home relates a case in which his caustic bougie had been introduced 489 times, which did not effect a cure after all, the patient after that having occasion to use a bougie daily. The same objection he should raise to cutting instruments in all their various forms as recommended by various surgeons. He was certain that in slight cases this sort of apparatus was not required, and in bad cases that it could not be attended with any benefit; even if the stricture were perforated by a sharp instrument, or the *lapis infernalis*, a contraction would inevitably take place afterwards, of a more tight, unyielding, and rigid kind.

The plan Mr. Liston invariably pursued was to get an instrument, however small, to pass the strictured part: the case then was completely in his power; great care and caution of course were necessary in these operations, but a surgeon must not be disappointed if he failed at his first attempt of getting a passage through the contraction; for if any water came away at all, he ought to succeed in passing the catheter in one of his attempts, and even sometimes where there was not even water passing. In very bad cases, such as lately had been in the Hospital, when the instrument had fairly passed the stricture, and got into the bladder, it should be retained in that position for 48 hours, by means of a tape attached to each of the rings of the catheter, brought under the thigh and attached to a bandage passed round the waist. A profuse discharge coming on is proof of an effort of nature to remove the foreign body; the passage becomes larger, and the instrument may be passed larger and at longer intervals. The fear of retaining a catheter more than two or three days arises from the possibility of the end of the catheter forming a nucleus for the calculus. It has been recommended in impassable strictures to pass the catheter down to the contracted part, and allowing it to remain there; and that it would then slip into the bladder—that plan he had never found successful. Mr. Guthrie mentions a case in which it had been kept in eighteen days—he succeeded in getting a passage, and then passed the instrument daily; a practice which Mr. Liston certainly did not approve of.

Anomalous Affection of the Head.

PHILLIS H. T. aged 40, servant, was admitted November 24, under the care Dr. A. T. Thompson. The history, as follows, was obtained from her sister. Latterly the patient has suffered considerable anxiety of mind from some domestic affair, and has complained of pain at the back part and left side of the head, which she has described as sometimes dull and heavy, whilst at others it was sharp and laminating, seeming to shoot

through the head. This pain has been much increased on her suddenly rising up—and she has absolutely screamed out with it when first awaking in the morning, and raising her head from the pillow. The recumbent position does not appear to have any effect on the pain. About a month ago she was overturned in a coach as she was coming to town, on which occasion her suffering was much increased; but her sister does not suppose her present affliction originated at that time. During the last fortnight her memory has been much impaired, there having been occasional wandering. She also suffered from drowsiness, and slept very soundly at night, until last night, when she was exceedingly restless and walked about. She has just menstruated. Previous to her last menstruation she complained of a violent pain in the back; she passed two weeks over the usual period. She has occasionally had slight chills coming over her—at other times she has been hot, but there has been no perspiration. Her taste has of late been vitiated, most things appearing disagreeable to her—appetite impaired—thirst great—her bowels have not been open latterly—she suffered formerly very much from hysteria, she has been cupped at the back of the neck. Her present symptoms are great drowsiness, with evident display of loss of memory—as she is frequently putting the same question after it had been answered—there is a dull expression of the eyes—the pupils are contracted—she frequently starts with pain in the head, which she refers to the left side and back part of it. The scalp is preternaturally hot, and pressure on it, a little way behind the left ear, is attended with much pain. The pulse is 70, and rather labouring—her skin is warm and dry—her tongue moist and slightly furred—her appetite impaired—thirst great—bowels confined—urine natural.

On the 25th November, she was cupped on the back of the neck to eight ounces, and a blister was applied behind the left ear, and a pill composed of one grain of ipecacuanha and one of calomel given every hour.

27th. She has less pain than when she was admitted, and when asleep is roused with considerable difficulty; the cupping and blistering afforded her no relief, her pulse continues as at last report, and she is much the same generally, except that the bowels have been moved, the faces were dark and offensive.

R. Antim. tart., gr. vi;

Aq. distil., ℥vi.

M. capiat coch. amp. duo 3ta hora.

30th. The medicine made her sick—she has been getting more and more drowsy, seemingly unconscious of any thing around her. There does not appear to be much pain in the head, but there is a great degree of stupor—the bowels were moved yesterday—she shews her tongue readily—it is rather swollen, and there is a slight mercurial taint

of the breath. Pulse 84; less labouring, but it is fuller—the pupils are contracted—the head is not preternaturally hot. A blister was applied behind the left ear, and the following mixture substituted for the pills.

℞. Ammon. carbon., ʒj;

Mist. camphora ʒvi.

Capiat coch. mag. iij. ʒt. r. 4ta quaque hora.

Dec. 1. The urine and fæces were yesterday passed involuntarily, but since then the bowels have not been opened—at present there is a great degree of stupor which is increased towards evening. Her breathing is stertorous, the scalp is not preternaturally hot, the pupils are contracted, the eyes are more sunken within the orbits, the integuments of the forehead are occasionally corrugated, some difficulty was experienced in getting her to put out her tongue, which was retracted slowly afterwards; it was covered with a slight fur, was much swollen and indented by the teeth. The cheeks are slightly swollen, the mercurial factor in the breath has much increased, and the gums are tender, her pulse is 104, fuller and stronger. Her skin is warm and moist, and she has perspired a good deal. She is quite motionless and passes her urine involuntarily. She has some degree of consciousness, knowing that her sister was present, and answering some questions that were put to her.

2nd. To-day lies quite senseless and motionless, her countenance has a very bloated appearance, the lips and cheeks are moved by expiration, the eyes are much sunken within the orbits, the pupils are contracted, the integuments of the forehead corrugated, scalp of natural temperature. Pulse 106, strong, full, but rather irregular and intermittent, she is not capable of protruding her tongue, breath still has a mercurial factor, her respiration is rather hurried and stertorous, attended occasionally with a peculiar kind of noise expressive of pain. Her skin is warm and moist, her bowels have not been opened to-day, urine passed involuntarily, thirst moderate, has taken a little beef-tea, the eyelids do not close when separated.

C. C. ad ʒviij temporibus.

The stertorous breathing was somewhat diminished after the cupping, but increased towards the evening.

3rd. The stupor is less than it was yesterday; she protruded her tongue when asked to do so, it was swollen and covered with a whitish brown fur; she complained of pain in the lower part of the back, her countenance has not the bloated appearance it presented yesterday, but is more cadaverous, her eyes are very much sunken and are surrounded with a dark areola, the temples appear sunk, the cheeks emaciated, and the nose sharp; there is no colour in the countenance, the pupils are alternately contracted and dilated, sometimes as small as a pin's head, whilst at others they form one-third of the transparent cornea, the cheeks and lips are not puffed out during expiration as

they were yesterday, the forehead is still corrugated, the eyelids are not quite closed, the breathing not quite so quick, and stertorous as yesterday, but the quick and noisy respiration seems to come on in paroxysms of about ten minutes' duration, and there is an intermission of comparatively free and easy respiration for about the same period. Her pulse is 140, strong and rather full, not perceived to be intermittent or irregular to-day. The bowels have not been opened, the urine has been passed involuntarily. Mr. Taylor ordered a blister to the occiput; six drachms of castor oil were given her. The bowels were opened very freely soon after the administration of the oil, the fæces were not particularly offensive, or of unnatural colour, she did not pass them involuntarily. The nurse observed some convulsive movements this evening, in the upper and lower extremities; they were, however, slight, and of short duration.

A friend who called to see her to-day, stated that previous to the impairment of her memory the patient took a pint of strong gin, neat—the causes of this excess were attributed to great mental anxiety, and the pain in the head.

4th. She is very much improved—the countenance much altered for the better—and she is quitesensible. Pulse 105, smaller and weaker than yesterday—respiration easy and natural—skin cool and dry, tongue coated with a whitish-brown fur; bowels open; fæces and urine passed voluntarily. The pupils are less contracted, and the alternations of contraction and dilatation have ceased. She complains of pain in the lower part of the back, and has been asking for gin. There is great tenderness of surface over the chest and down the back in the region of the spinal column. Ordered to take a small quantity of white wine whey occasionally, and a grain of calomel at bed-time.

7th. Continues about the same as at last report. Pulse 102, small and weak—respiration natural; skin cool and dry, no perspiration; tongue slightly covered with a whitish fur—pupils not much contracted—bowels open—the fæces and urine passed voluntarily. During the last two days she has been very cold in the day-time, becoming very warm towards evening—and, after continuing warm a short time, perspires freely.

℞ Infusion Cinchonæ ʒiiss. 2nd a quaque dozel paroxysm calid. invent.

8th. This afternoon she was attacked with a sharp pain in the left side of the chest, soon afterwards her head became very hot; and the action of the carotid and temporal arteries became very strong; pulse weak, 130—respiration quicker again and laborious—skin warmer and dry—she is more drowsy to-day—pupils rather more contracted—bowels open, fæces and urine passed voluntarily.

C. C. ad ʒviij.

—The pulse was fuller after the cupping. The action of the carotids and temporals

much diminished in strength, and the heat of the scalp much less. About two hours after the cupping she was covered with a profuse perspiration—she has eaten nothing lately, there is some difficulty of swallowing. She drinks a small quantity of white wine whey occasionally—she was sensible of the cupping.

9th. The heat of the head is somewhat greater to-day than it was last night—she is very drowsy, sleeps very soundly and for a long time—she opens her eyelids slowly when roused, and soon relapses into her former condition; she occasionally opens her eyelids and stares about her, the pupils are rather contracted, the difficult deglutition is not constant and is sometimes greater than at others. Her friends stated to-day that all kinds of tonics had always operated as stimulants with her, causing great excitement.

R. Potassæ sulphatis, gr. xv—Pulv. Rhei. gr. x. M. ft. pulv. hora. somni sumendum, hac nocte.

Omitt. inf. Cinchonæ.

11th. The head has not been quite so hot since the last report; in other respects she is the same.

R. Ammon. carbon. gr. vi;

Infusi lini 3 iss. 4ta. quaq. hora.

Allowed to have some chicken broth.

12th. Countenance very much improved; at times she sits up and talks quite rationally, at times she is wandering slightly, she is very drowsy, sleeps a great deal and very soundly—respiration pretty tranquil—pulse 104, rather weak and irregular. Skin cool and dry, she does not perspire. The head is rather warmer than the other parts; tongue pretty clean, bowels open—the fæces are sometimes passed involuntarily, at other times not. She occasionally looks about her with a vacant stare, her pupils contracted; sighs frequently.

14th. Little difference since last report; pulse 106, rather stronger. A purgative was given her to-day, omit whey.

Since this report she has been gradually getting better, and is now nearly recovered, having a good appetite and being very cheerful.

Transposition of the Thoracic and Abdominal Organs. By M. Bally.

A MAN, twenty-five years of age, went into the hospital of La Pitie, with an inflammation of the ileum and ileo-cæcal valve. The progress of the disease was at first slow, and even admitted some hope of recovery; but the local affection becoming complicated with symptoms depending on disturbance of the innervation, or in other words, the disease having assumed a typhoid character, it rapidly advanced to a fatal issue.

At my first visit I discovered the transposition of the heart, and predicted that of the other viscera of the thorax, as well as those of the abdomen. I claim no great merit for

this prediction; for if an organ like the heart be transposed in the formation of the child, the other organs must necessarily undergo a similar displacement. The following were the phenomena observable.

In the left side of the chest, there was no impulse in the precordial region, nor were the ordinary sounds of the heart heard there. The sound on percussion was not dull as it should have been, but was the same as in regions where the lung, well filled with air, gives the sound proper to it. On the right side of the chest, on the contrary, there was dulness to a certain extent; and in this space the sound of the contraction and dilatation of the heart (the point of which beat against the space between the fifth and sixth ribs) was heard distinctly. Many physicians and a great number of students, came to see the patient during his life. He sunk on the twenty-fifth day, with symptoms exactly resembling those of ordinary adynamic or typhoid fevers. The transposition of the viscera did not appear to make any alteration in the course of the disease.

In the post-mortem examination, which was made next day, I carefully removed the sides of the chest, in order that the organs might be completely exposed to view, in their relative situations.

The right lung had only *two* lobes; the left had *three*. The anterior border of the *right* lung was notched at its inferior part to receive the point of the heart. The anterior mediastinum, instead of tending to the *left*, was directed towards the *right*. The pericardium, free from the *left* side, was fixed to the *right* side of the diaphragm. The *anterior* part of the chest was now removed, and the pericardium opened. It was then perceived that not only had the heart changed its *direction*, but that it was entirely turned round, in such a manner that the *posterior* face had become *anterior*; the left ventricle was to the *right* and *anterior*; and the right ventricle to the *left* and *posterior*. This change of situation occasioned, of course, a similar alteration in that of the auricles, and of the veins and arteries connected with the heart. Thus the aorta, instead of being directed *from right to left*, proceeded *from left to right*. Its arch was a little to the *left*, and much more backward than in the natural state. Its descending thoracic portion occupied exactly the median line of the vertebral column, and the same in the abdomen. The vena cava was invariably found at its *left* side. Of the arteries springing immediately from the arch of the aorta, the brachio cephalic trunk issued on the *left* side; and the carotid and subclavian arteries from the opposite side. The pulmonary artery passed obliquely upwards and to the right. Of its two branches the *left* was the longest, and divided into *three* parts; the *right* was shorter, more horizontal, and had only *two* divisions. The *right* subclavian vein, longer than the other, passed in front of the tracheæ

and arch of the aorta, to empty itself into the vena cava superior, was situated on the *left* side of the tracheæ; and, in their turn, the two vena cava emptied themselves into the left auricle.

Of the two recurrent nerves, the *right* was reflected round the arch of the aorta; and the *left* round the brachio-cephalic trunk. The opening in the diaphragm for the passage of the vena cava inferior was on the *left* side.

Passing now to the examination of the abdomen, the spleen (large and well-formed) occupied the *right* hypochondrium; and the liver the *left*. The position of the latter also differed in other respects from that which it is usually found to occupy. Thus the smaller lobe was prolonged *from left to right*, over the anterior surface of the stomach. The gall-bladder, taking the same direction, and inclining obliquely from before backwards, communicated with the duodenum, which was likewise transposed. The greater extremity of the stomach was to the *right*, and this, together with the transposition of the liver, the direction of the gall-bladder, and the altered situation of the duodenum, had induced the inversion of the whole intestinal tube; so that the cæcum was lodged in the *left* iliac fossa, the sigmoid flexure of the colon was on the *right* side, and the rectum was directed superiorly from *right to left*. The pancreas was equally out of place.

It will be readily understood that the origin and direction of the arteries springing from the aorta, were reversed throughout; but I need not enter into particular details; since the position of the principal trunk being changed, the relative length and direction of its branches must be altered likewise.

SIR,—If you think the following paper worthy of a page in your valuable journal, by inserting it you will oblige,

SIR,
Your obedient servant,
J. W. MOSES.

An Explanation of the Action of Tartarized Antimony, on Physiological Principles. By J. W. Moses, M.R.C.S.

THE chemical composition of this medicine, according to some of the best authorities of the present day, appears to be involved in much doubt and obscurity; it is generally allowed to be a triple salt. However, as it is not its chemical composition, but its action, which I shall endeavour to explain, it is not necessary to dwell longer on this head.

In large doses tartarized antimony acts as a corrosive poison; from one to two grains will generally procure vomiting, sometimes purge, and lastly cause perspiration. Orfila

states, “Experience, however, proves that a few grains of Tartar Emetic may be the occasion of death, if not vomited; an extreme depression and feebleness have been known to arise from a single grain, which had occasioned *no evacuation*.” One-fourth of a grain will produce diaphoresis, one-half of one will procure some loose stools first, and perspiration afterwards. Nature, throughout all her laws, observes the most rigid economy, and this fact appears to be well illustrated in the action of tartarized antimony on the living animal. We perceive that this salt, when given in large doses, produces death; in small, vomitings and purging; and in a still smaller quantity, sweating.

These are all strong proofs of its being a most hurtful substance to the animal economy, and as such, nature exerts her strength to get rid of it, as quickly as she can, from the system, which is done with as little sacrifice of power as possible.

In small doses the salt is thrown off by the skin; the perspiration, we know, may be augmented with the least expenditure of vitality; so here nature, observing the most rigid economy, throws the hurtful substance off by this mild emunctory; which small quantity, if we could imagine it to be retained, no doubt would prove hurtful to the functions and organization of the animal. This I hold to be the simplest mode of parting with the salt, and the one attended with the least depressing effects.

Now I shall take a larger quantity, which must be ejected sooner than the former, for obvious reasons; here we observe nature directs her powers to the intestinal canal, and causes an increased secretion from it, and an increased peristaltic action, by which the substance is principally thrown off, the skin assisting in a minor degree. This mode of getting quit of the salt is attended with a greater loss of vital power than the former, as we may observe from the weakness it produces; but the quantity of the medicine being greater than in the last case, must be brought away sooner, otherwise the injurious effects it would induce, by leaving it to be thrown off by diaphoresis, would be more prejudicial to the system than the purging.

I shall now take a still larger dose; and here we may perceive that vomiting is the principal mode by which the system frees itself from the salt.

And why vomiting? Surely it is the readiest way of parting with the hurtful substance, which has been taken into the stomach in a quantity too large for nature to wait for the much slower operation of purging or perspiration, so that she directs her powers principally to the stomach, and in this way there is a greater loss of vitality than in the two former. We are well aware this cannot be avoided; did she not summon up all her remaining strength to assist her already exhausted state, death must ensue, as we see it does when a larger quantity is taken than

she is able to get rid of, even by calling into action (as her *dernier ressort*) not only the stomach, but the intestines, and likewise the skin; but all avail not, she is overpowered, and so gives up the field.

It has been stated that when tartar. antim. is injected into the veins, it will produce vomiting; and why should it not, just as well in this case as in the former? It is advanced by some of the best physiologists of the present day, that the veins have no power of throwing off any thing in the form of secretion, their structure, &c. not being adapted for it (I am aware this is a disputed point); so the substance must pass through the pulmonary circulation, and so on to the left side of the heart, and then it will not be long in arriving at the stomach and intestines, where it produces its effects, for reasons I have already given.

Why should not nature exert her powers, to free herself from a hurtful substance introduced into the stomach, in the most economical way, as well as she does to get rid of a splinter of wood, or any foreign substance, which may have been wilfully or accidentally introduced into any part of the body? I maintain that tart. antim. is just as hurtful to the healthy process of digestion, while it is in the stomach, as a splinter of wood is to the action of a muscle in which it may be lodged. When a large quantity has been taken, vomiting is produced first, by which the main bulk is thrown off; after that has taken place, there is no necessity for the system to keep up a continued action so depressing; no! then the remaining portion is parted with by the intestines and skin, there being a much less sacrifice of power in the performance of these functions, than in that of vomiting.

Douglas, Isle of Man,
Dec. 22d., 1835.

Apparent Death, which continued for Twenty Days.—A young man died in the hospital at Paderborn, who could not be buried until three weeks after he had breathed, at least to all appearance, his last breath. It was not till the twentieth day that the characteristic phenomena of death became manifest. The circumstances of the case were these:—This young man had been a little time before cured of a tertian ague, when he re-entered the hospital, presenting some signs which caused an apprehension of phthisis, without, however, presenting any well-marked symptoms of this disease. In other respects, no disturbance in his health. On the day he died, his eyes were suddenly opened, and for some minutes he found an irregular beating of the pulse. Several small wounds resulting from cauterizations, to which we then had recourse to rouse him, suppurated the second, third, and fourth days. On the fifth, the hands of the body were turned back; from

the fifth to the ninth day there exhaled from half the body an abundant sweat, free from odour. Towards the end of the ninth day, there appeared over a considerable part of the dorsal region serous bullæ, similar to those of pemphigus. The limbs still preserve their natural suppleness; and on the eighteenth day the lips still retained their red vermilion colour. For nine days the forehead continued furrowed with vertical wrinkles, and all this time the countenance preserved an expression never presented by the face of a dead body. The body was kept for nineteen days in a warm room: it exhaled not the least fetid odour, and there was observed on no part of its surface any cadaveric lividity. The emaciation was very considerable; a circumstance which, if it had existed, might have served to explain these different phenomena.

—o—

Abdominal Uneasiness.—This unhealthy sensation is too indiscriminately referred to a disordered state of the liver. It is probably more justly attributable to the large intestines, incumbered and distended by an undue retention of fæculencies, requiring a free and complete removal. The scybalous accumulations, which are apt to occur in the cæcum, colon, and rectum, cause a sense of oppression, distension, and occasionally, indeed, acute pain. This state of repletion may produce hurtful pressure on the adjacent viscera, and excite sympathetic disturbance throughout the whole digestive organs. It is often found, that the persevering use of daily enemata in those cases will finally unload the distended and torpid intestines of their impacted contents, and consequently, at once remove the constipation and abdominal distension that constitute the anomalous and ambiguous character of this intestinal, but frequently mistaken ailment. The habitual use of lavements by the French, prevents the distended state of the abdomen, that in England is often too cursorily referred to hepatic disease. Were the use of enemata to be as familiarly and constantly adopted by the people of the one country as by those of the other, an equal exemption from the imputed affection would most likely be the result.—*Kinglake.*

ESSAY

UPON SOME POINTS OF THE
HISTORY OF CATARACT;*Thesis presented to, and sustained before, the
Academy of Medicine of Paris.*BY THEODORE MAUNOIR,
OF GENEVA,*Doctor of Surgery; Member of the Medical
Observation Society.*

TRANSLATED

BY ALEXANDER THOMSON, M.B.

Of St. John's College, Cambridge.

"Observer la nature, rassembler beaucoup de faits pendre leur ensemble pour principes Qui sommes nous pour nous détourner de cette voie."—BICHAT, *Œuvres Chirurg. de Desault.*

IF, in the study of cataract, we are willing to confine ourselves to the seat, to the nature, to the principal symptoms, to the principal varieties of the disease, and to the surgical means employed for curing it, nothing is better known than this disease; it may be said that there is perhaps not one of which the history is more simple, more clear, more uniform, and the treatment more uncontestedly efficacious. But if we come to details, if we demand what is the precise value of each of the assertions of the authors, where are the proofs that have served them as a basis? if we seek for the answer to several questions of which the dogmatical works do not even speak—above all, if we would know on what side the truth lies, when there is opposition between men of the highest merit, in reference, for instance, to the comparative value of the two great operative methods, upon which, however, such long and barren discussions have been written—we are not long without convincing ourselves that the authors have consigned on this disease, as upon so many others, rather the vague reminiscences of their experience than the results of the rigorous analysis of facts accurately observed.

It is to this imperfect method, which alone is applicable the aphorism, *experientia*

VOL. VIII.

fallax, that the so discordant opinions met with at each step in medicine, and the complete omissions upon so many points that would be interesting, and frequently useful to know, must doubtless be attributed. Were it otherwise, were the constant variability of the facts the cause of the different opinions upon the same subjects, met with among the most eminent men, not only in the history of diseases properly so called, but particularly when there is question of curing them, this would imply nothing less than the definitive annihilation of all medical science. Indeed, for the existence of a science (and I speak of a science of observation), it does not suffice to assemble together, even to infinity, the most circumstantial, and the most accurate facts—the relations uniting them must be found, the limits of their variations discovered; or how find these relations, if none exist—the limits of their variations, if these variations be infinite?

Happily it is by no means so; and, as I have already said, the rather common habit of authors of referring only to their reminiscences, to the authority of others, to some selected exceptional, frequently even but slightly accurate facts, perfectly accounts both for the differences in opinion, and for the complete omissions, and even for the evident errors. Does there indeed exist a memory sufficiently perfect to retain all their details, all the facts that offer themselves to the observation, to recall subsequently their elements, by giving to each but its real value—in a word, to make complete enumerations?

Whatever simplicity the history of cataract, as I have already indicated it, presents under several points of view, it suffices to compare the results of observation, as well with what the authors who have treated of this subject have written as with what they have omitted to write, for recognizing that there still remain many voids to be filled up, some errors even to be rectified, and almost in all cases positive values to be substituted for *almosts*; in other words, all has not yet been said upon this disease, and is probable not likely soon to be so. Such was the opinion of Dr. Tartra, when he terminated his thesis for the concours by these words:—

B B B

"Nothing would be more important, in order to perfect the pathological and therapeutical doctrine of cataract, than the assembling together of a great number of well authenticated facts, the comparing them with one another under their different etiological relations, the consideration of them subsequently with reference to their ascertained incurability, to the different operative methods or processes applied to cataracts deemed incurable; finally, to the more or less perfect cures, and to the other more or less varied results that may have been obtained."

I have not assuredly the pretension of remedying the least of the imperfections I point out. Having only had the opportunity of collecting a rather large number of histories of cataracts, I shall state what I have seen, without the intention of drawing any other conclusions than those which are strictly contained within the limits of the facts.

During the whole of the year 1830, the autumn of 1832, and the spring of 1833, I have assiduously attended upon the surgical service of La Charité, and, except the first six or seven operations that were performed in the spring of 1830, and upon which I possess no information, I have taken notes of all the cases, without exception, which during these four sessions have presented themselves to be operated on for cataract. My observations are not, unhappily, complete on all the points, that is to say, they do not answer all the questions I have necessarily put to myself; but if they are incomplete they are not inexact; if several are wanting in details that it would have been very useful for me to know, at least they contain none that are not the faithful expression of what I have observed with all the care in my power.

These explanations were necessary to lead to the comprehension of how, in reference to each particular question, the results are found based upon different numbers, since I have necessarily been obliged to employ only the histories which were complete upon the point of view with which I was occupied.

Besides, strongly desiring to know positively the influence of certain accidents, which sometimes occur to complicate the operation itself, and which the by no means ordinary skill of Professor Roux cannot always enable him to avoid, I have never failed placing myself sufficiently near to the patients for seeing, as exactly as possible, the delicate manœuvres, that in this more than in any other operation are of such great importance.

The observations I have drawn up are 121 in number*, which makes a mean of about

30 patients a season, for M. Roux is in the habit of operating for cataract, at La Charité at least, only in the spring and autumn.

I shall explain, in the following order, the different points of the history of the disease which constitutes the subject of my work:—

1. Causes.
2. Commencement and progress of the disease.
3. Symptoms and diagnosis.
4. Duration of the formation of cataract.
5. Description of the operation, its difficulties and accidents.
6. Consequences of the operation.
7. Definitive results.
8. Prognosis.

1. *Causes*.—Sex, age, constitution, profession, state of health, suppression of the menstrual or hæmorrhoidal discharge, external violence or accidents, and heridity, must be passed in review.

SECT. I.—*Sex*.—In 121 subjects affected with cataract, who have been admitted into La Charité, there have been 61 men and 60 women†. This number is doubtless sufficiently high to allow its being concluded, that if cataract attack one more frequently than the other of the two sexes, at least the difference cannot be very great. I am ignorant, however, whether one has been pointed out; it has been said that men are more subject to it than women. Thus, in the *Journal Complementary des Sciences Médicales*, tom. xli, we read a note of Professor Fabini, according to which, in 500 cataracts that occurred to him, there were 268 of the male sex, and 232 of the female sex, which makes almost 53 men and 47 women in 100; a difference very inconsiderable, as may be seen. There is, moreover, found in tom. iii, *Du Répertoire général d'Anat. et de Physiologie Pathologique*, a table of the operations for cataract performed at the Hôtel Dieu, by Professor Dupuytren, from 1815 to 1821. This table is formed from the results on 207 patients, of whom 135 were male, and 72 only of the female sex. This result, apparently very different from those I have just given, however agrees with them, since the number of beds destined for men in the surgical service of the Hôtel Dieu is almost double the number of beds destined for women.

SECT. II.—*Age*.—It is a thing well known, that cataract is a disease of old age; there

special men who for a long time back had engrossed that branch of the healing art. Those diseases may, in the present day, be studied in all the hospitals of Paris, and it is not to the detriment of any other part of the science that the surgeons of our days operate for cataract.

† It must not be forgotten that the number of beds destined to the surgical science of La Charité is very nearly equally divided between the men and the women.

* It is fortunate for observation that the treatment of the diseases of the eyes, and particularly of cataract, has ceased to be the lot, in some measure exclusive, of the spe-

is perhaps no affection more specially reserved to that period of existence; but, as if to confirm that so general rule, that nothing is absolute there, where there is question of the phenomena of life, examples of this disease are found at every age. It is not even extremely rare to see cataract congenital, since a single surgeon, Saunders, was able in the last three years of his too short career, to operate upon as many as sixty of that kind. It must be said, however, that the number of congenital cataracts, or such as supervene during early infancy, is very small compared with that of cataracts that are formed in an advanced age.

In the 121 patients of La Charité* none was less than 20 years; and I have convinced myself that at the Hôpital des Enfants Malades, it is as rare to meet with blindness produced by opacity of the crystalline, or of its capsule, as it is frequent to see them therein caused by perforation of the eye, or opacity of the cornea, the consequences of ophthalmia.

The following, however, is the manner in which 112 subjects are distributed as regards the age:

From 20 to 29 years	5 patients
30 to 39 .	3
40 to 49 .	11
50 to 59 .	25
60 to 69 .	41
70 to 82 .	27

On the other hand, in the note already quoted, of Professor Fabini, the 500 subjects attacked with cataract are thus classed:

From 1 to 10 years	14 patients
11 to 20 .	16
21 to 30 .	18
31 to 40 .	18
41 to 50 .	51
51 to 60 .	102
61 to 70 .	172
above 70 .	109

* For a long time the administration of the hospitals was opposed, it is not too well known why, to young infants being received into La Charité, while they were more readily admitted into the other hospitals. It may be believed that that is one of the reasons why none of the patients whose history I have drawn up was aged less than 20 years; but the thing is not very probable. Indeed, Professor Roux has told me that he has rarely had, in his private practice, occasion to operate for cataract upon very young subjects. I frequented assiduously during several months the Hôpital des Enfants Malades, without seeing a single case of that affection; and M. Ruy, who has there performed during two years the interné service, has not, during all that time, met with but a single infant affected with cataract.

Thus cataract, then, at that age must be rare, absolutely speaking; which besides is well known.

These two tables demonstrate the immense influence of age in the production of cataract, since the frequency of this malady increases in a very considerable ratio, in proportion as individuals are more advanced in age, that is, of whom there exists evidently a much smaller number, are examined. Thus it is clear that the 27 subjects of from 70 to 82 years represent a far greater proportion than the 25 between 50 and 59 years.

I must here point out that it is not only in a general manner, and within very broad limits, that nature confines herself to the laws she seems to have imposed on herself, but she follows them, in some measure, even into the details. Thus in these two tables, of which the one is made at Paris, the other in Hungary, it appears that it is between 50 and 60 years, that is found the fourth or the fifth of the total number of subjects affected with cataract; the third nearly between 60 and 70; a little less than the fourth above 70.

It may be to a certain degree objected, that the age of patients, at the moment in which they come to have themselves operated on, is by no means the age they have at the commencement of their cataracts, and which alone is interesting to be known, since a thousand circumstances may cause these individuals to submit to their blindness during several years. The following are the results obtained relatively to the epoch of the commencement in 64 subjects:—

Cataract had commenced—

From 20 to 29 years in	4
30 to 39 .	5
40 to 49 .	11
50 to 59 .	19
60 to 69 .	21
70 to 79 .	4

The difference, as may be seen, is not very great between these proportions and those of the other two tables; the number of patients increases and decreases in the same periods of life. I must add that the men and the women are almost in equal number in each period of ten years.

SECT. III.—*Professions.*—Certain professions have been considered as predisposing to cataract; they are all those that expose themselves to the action of a very violent fire, those of blacksmith, locksmith, glass-maker, cook, &c. &c.; those in which the sight is employed upon very small and brilliant objects, those obliging the eyes to be frequently in contact with certain irritating vapours, those finally in which the greater part of the time is obliged to be passed in the full sun-light; thus it is that Petit, of Lyons, had calculated that three-fourths of the individuals affected with cataract are persons employed in agriculture.

I have noted the profession of 108 persons affected with cataract (54 men, 54 women); or, of 54 men, 30 had been very much exposed by their occupation to the inclemency

of the air, and to the ardor of the sun; 12 of them had been old military men, of whom some had made the greater part of the campaigns of the empire; the other 18 were farmers, country workmen, guards of public coaches; there were two blacksmiths, a single glass maker, who had worked for ten years at the furnaces (his cataracts had only commenced ten years after he had quitted that profession; and a working jeweller who had been employed for four years in melting metals. The last 24 followed more sedentary professions, or such as did not expose them to the same influences; they were gate-keepers (*portiers*), domestics, shop-keepers, &c. &c.

No one patient has presented himself whose trade had obliged him to look steadily at very fine and brilliant objects, or had exposed him to irritating vapours. As to the women:—12 had been employed in field labour; 6 occupied in needlework; 5 washerwomen.

The others were domestics, gate-keepers, domestics by the day, &c.; finally, had not professions which exposed them to the action of the causes assigned to cataract*.

SECT. IV.—*Constitution*.—The external conformation, the assemblage of the features constituting the temperament, have been noted in 64 subjects (35 men and 29 women).

Among the men, 30 were of a robust constitution; their hue was swarthy; they were in general very muscular subjects, though already advanced in age—some even had almost athletic forms; in the greater part the plumpness was moderate, in a small number it was considerable; some were, on the contrary, rather thin; in 5 subjects the constitution was rather slender than robust.

The colour of the hair has only been indicated in 25 men. They were, or rather had been black or chesnut in 18; white or red in 7. I also remember that almost all the men were bald, even those who were not very old; but as I have not written it in my notes, and as I depend little upon vague reminiscences, I do not give the fact as certain.

Among the 29 women, 17 had, or had had the hair black or chesnut; their hue was more or less swarthy; in 6 the hair was white; 7 presented a very marked plumpness; 5, on the contrary, were thin; the others presented nothing remarkable in this respect.

One of the features of the constitution, interesting to be known, was the colour of the eyes; it has been indicated in 64 subjects. The iris was more or less dark brown

in 24; blue, but more frequently blueish-grey in 21; ash-grey in 2. In 17 others the iris had a greenish tint; it was of a glaucous green, very much marked in some, more frequently a greyish, or even blueish ground, but with a very marked green tint (*reflet*). These different kinds of colouring were distributed nearly equally in the men and in the women; the latter have, however, offered proportionally a few more brown eyes than the men.

It has been said that the near sighted are rarely affected with cataract. In 49 individuals, questioned relatively to the condition of their sights before the commencement of the disease, 40 have assured me that it had been very good and very long; in 9 only it had been short or bad.

SECT. V.—*State of Health*.—In 93 individuals, in whom the habitual state of health has been sought after with care, 87 had in general always been in good health; a great number even did not remember to have ever had the slightest indisposition; of the last 6, some were old men, probably affected with dilatation of the bronchial cells (*emphysème*); they had short respiration, and had been coughing for several years; two complained of having sometimes difficult digestion; another had had for several weeks back paroxysms of cough, and at the moment of his entrance into the hospital: moreover it must be said that none of them considered themselves ill.

An oculist, M. Lusardi, appears to have made the same remark: "I have verified," says he, in a Memoir on the Cataract, "that, both as regards men and women affected with this malady, the greater part had enjoyed perfect health;" whence it must be concluded that cataract is generally independent of every other species of morbid state of the organism, which is far from being frequent in other diseases.

SECT. VI.—*Cephalalgia*.—Great importance has been attributed to cephalalgia in the history of the cataract; let us see if the coincidence be frequent.

Sixty-three patients have been examined on this point of view: eight men in thirty-six, had been more or less subject to pains in the head; but in two only did these pains seem to have any relation with the origin of cataracts; one was an old man of 82 years of age; he had experienced some very slight headach for several nights at the commencement of his cataracts. The second, aged 55 years, had been from his infancy, subject to violent sick-headachs (*migraines*), which had returned for as many as three or four times a month, occupying sometimes the right side, sometimes the left side of the head, and forcing the patient often to go to bed during the access; these sick-headachs had finally diminished spontaneously, then ceased all at once, and without return. It was from this period (about four years back), that he had perceived that one of his eyes

* I abstain from concluding anything here relatively to the influence of professions on the production of cataract; it will be the same in reference to the constitution, and to the different features characterizing it in reference to certain diseases, &c. I shall develop hereafter the reasons that lead me to act thus.

commenced to decline: his health had been in other respects excellent.

The six other patients said only that they had been more or less subject to pains in the head; but those pains had either ceased several years before the commencement of the cataracts, or had in no way changed at that time, or finally, had only appeared after the sight had already been weakened.

In the twenty-seven women, the pains of the head had been more frequent; sixteen indeed, without regarding themselves as ill, have said that they had been frequently enough affected with them. In eight only, they have appeared to have some relation with the cataracts. Thus, five of them were not subject to them before their sight had commenced to be weakened; but at that period, or a little before, more or less violent pains of the head had commenced to be felt, and had lasted for a variable time.

In one of these women, a frontal pain commenced at the same time with the cataracts, lasted almost without relaxation for a year, was at times very violent, then ceased spontaneously.

In another, the pains appeared at the same time with the weakening of the sight, but came on only at rather distant intervals, lasting for two or three days each time.

In a third, they were very painful lancinations, that commenced in the posterior part of the head, arrived at the forehead, persisted some minutes, then ceased but to reappear two or three times during the day, and remained scarcely more than two days without being felt.

The other three women had for a long time been subject to pains of the head, when their sight commenced to be weakened; but at that period there was a manifest increase of them.

Finally, in the last eight there was no more relation between the cephalalgia and the cataracts, than in the six men, of whom I have last spoken.

SECT. VII.—*Ophthalmia*.—Some authors, considering the capsular cataract as rather frequent, and the inflammations of the exterior of the eye as capable of having some influence upon that of the deeper seated parts, it was interesting to examine whether habitual, or very frequently repeated, ophthalmia coincided in many cases with cataracts.

Fifty-eight patients have been questioned on this subject; seven only had had rather severe chronic ophthalmia, most frequently immediately after small-pox. In three of these seven subjects, there remained very slight clouds upon the cornea, but no trace of inflammation. In three others, the eyelids had continued to be the seat of a chronic phlegmasia; the conjunctivæ were red, the eyelashes in part destroyed. There had been, moreover, at the very period of the commencement of their cataracts, a little redness and pain of the eyes, during three or four weeks in one, during two and five

months in the other two. Finally, in two patients, who anteriorly had never had ophthalmia, the eyes had been a little red for some weeks, at the period at which they were operated on.

SECT. VIII.—*Suppression of Hæmorrhoids, or of the Menstrual Discharge*.—There are few diseases, in the production of which a great part is not made to be played by the suppression of some habitual, either normal or abnormal, discharge, and especially by that of hæmorrhoids or of the menses. It is true that little faith is placed in it for the production of cataract in particular; nevertheless, Ténon says that he has remarked that the progress of the disease is generally very rapid in women arrived at the critical age; and Tartra assures us that that is the period at which they are the most subject to it. However it may be with these assertions, the following is what I have observed: in twenty-three women, who have been questioned relatively to the period of the cessation of their menstrual discharge, there have been found seventeen, in whom the cataracts had commenced five, ten, even thirty years after that period, which scarcely agrees with the opinion of Tartra; five were still regular at the moment at which the sight commenced to decline; in one only, the disappearance of the menstrual discharge had coincided with the commencement of a cataract; but the progress of the disease was not very rapid, as Ténon would have it, for, at the end of a year, the affected eye still saw well enough for the patient to have been able to guide herself had the other been lost. At that period she was seized with an erysipelas, her face swelled enormously; that affection lasted eighteen days, during which the cataract made so much progress, that after that time the eye could no longer distinguish the light from the darkness. As to hæmorrhoids, of thirty-three subjects questioned on this point (twenty-eight men, five women), twenty-eight had never had them, the other five, all men, had had them, or still had them. In one only they appear to have some relation to the cataracts; this was a vine dresser, of 25 years of age, who had had, during twenty years of his life, very painful, and frequently bleeding hæmorrhoids; then they had gradually diminished, and finally completely disappeared. It was from that period that he had perceived the weakening of his sight.

SECT. IX.—*Heredity*.—For a long time back, cataract has been regarded as capable of being hereditary, and therefore, examples of families, of which several members have been attacked by this affection for two or three generations.

If the question of heredity be one of the most difficult to resolve *rigorously*, when there is question of extremely frequent diseases, and such as without admitting any hereditary predisposition, but from the fact

alone of their habitually attacking a great proportion of a given population, must frequently be met with in several members of the same family, it is not, I believe, the same for the cataract, which, without being rare, cannot, however, it is manifest, be compared in frequency with phthisis, for instance; or it is impossible, at least in my opinion, not to believe that there is, in many cases, a disposition common to several members of the same family, a disposition which causes them to be affected with cataract, from the fact alone that they belong to that family.

The following, moreover, are my reasons:—Of 39 subjects (22 men, 17 women), who have been capable of giving certain information upon the point in question, 22 have affirmed that none of their parents had ever had the least affection which could lead to a suspicion of cataract; 10, on the contrary (4 men, 6 women), have assured us that one or several members of their family had been affected with this disease; almost all of them had undergone the operation, so that there could be no doubt upon the diagnosis.

I have been enabled with regard to heredity to determine the rather curious case of a woman whose grandfather, uncle, two aunts, two cousins (all on the father's side), had had the cataract, and had been operated on. She herself, at thirty years of age, had been affected with the same disease; finally, of the four children she had had, one had come into the world with a cataract, recognized by M. Wenzel; and what is remarkable, neither her father, nor her mother, nor her sisters, had ever presented anything similar*.

Besides these ten well-marked cases, seven other patients still have said that one or several of their parents had lost the sight, and most frequently at an advanced age; it is probable that in some of them at least, this may have been in consequence of an opacity of the crystalline, but I have been unable to acquire any certitude thereon.

Thus, in the fourth part, at least, of the cases I have studied under this point of view, the cataract had affected several members of the same family. It is impossible, it seems to me, to see therein an effect of chance.

SECT. X.—*Blows, Insolation, &c. &c.*—

It is known that some external accidents have in certain cases, with predisposed individuals, occasioned an exciting cause of cataract. When the effect follows very closely, the circumstance regarded as the cause, and when the disease has, moreover, a much more rapid course than usually,

* M. Roux has operated for cataract upon three brothers, aged from thirty to forty years, born in England. Their father and their grandfather had the same disease, and they had a brother much younger than themselves already affected with it.

there is every reason for believing that that is not a simple coincidence. Several examples of this kind are preserved in the thesis of Dr. Tartra. He relates from Ténon, who had been eyewitness of the facts, that a lady who was struck on the eye by a bottle-cork, had that eye next day affected with cataract: a potter entered into his oven while it was still hot, he came out of it with two ripe cataracts. Fabrice de Hilden has seen a lady of above fifty years of age, become blind in one night by the formation of two cataracts, without pain or inflammation, and that, after having wept for several days for the loss of one of her relations. A surgeon of Mayence relates the history of a man, in whom a cataract was suddenly developed after a repast at which he had got intoxicated. It is known, finally, that one of the accusers of the celebrated Desault got into a violent passion on learning that he had been restored to liberty; on the very instant one of his eyes lost the faculty of seeing, and next day it was remarked that he was affected with a cataract.

Dr. Carrou Duvillards has seen in three sexagenarian individuals, a cataract developed very rapidly after a blow from a bottle-cork; at the end of a few days the opacity was already perceptible; it became complete in the course of the year; the sight remained uninjured in the eye which had not been struck. He has seen the same accident occur in two women, of from twenty-five to thirty years of age, who had received, one a blow from a racket club, the other a blow from a billiard queue.

I have not met with a single case in which such striking circumstances as those of which I have just spoken, have preceded the commencement of the cataract. Of fifty-seven patients questioned in this point of view, the following are the only ones that have presented anything analogous.

1st. In a woman, of whom one of the eyes had already been affected with cataract, the second commenced to be weakened immediately after prolonged weeping; but a month afterwards, the blindness had not made great progress, and at that period it was operated on.

2nd. In a man, the sight commenced to decline some months after he had received a sufficiently violent blow to blacken the skin of the parts adjacent to the eye; but the progress of that cataract was slow.

3rd. A third had a fall upon the loins, immediately after which he caused himself to be bled several times, and kept his bed during fifteen days; two months later he awoke one morning, having the sight very much diminished, while on the day previously he saw very well.

4th. A fourth was bitten near the eye by a horse, which caused a wound, of which he suffered for fifteen days; from that period it seemed to him that that eye had become slightly weakened, but the real or

at least evident commencement of the cataracts did not take place for several years afterwards.

5th. A fifth, who was a public coach-guard, having one summer's day looked intensely at the sun, one of his eyes became rapidly weakened, and some days afterwards, he could no longer distinguish the light from the darkness.

6th. A sixth, finally, had received a splinter of wood upon one of the eyes, which remained red and painful for four or five days, became weaker from that moment, and at the end of three or four months was already lost. I have quoted these examples to shew that the cases in which cataract can legitimately be attributed to an accidental cause must still be rather rare, although assuredly nothing is more frequent than blows or wounds in the vicinity of the eye.

The 5th and the 6th example appear to me to be the only ones in which it can be admitted that the accident supervening a little before the commencement of the cataract cannot be altogether foreign to it. It must have been remarked, that in passing in review the different circumstances that may be considered as causes of the cataract, I have frequently confined myself to announcing the facts, without drawing any conclusion, either negative or positive. Relatively to sex, age, hereditary, &c., it has not been so, because in them there was no chance of error; but, could I legitimately say, even if I had had very high numbers, and very marked differences, that the cataract coincides particularly with such or such a temperament, with such or such colour of the eyes, or of the hair, that it affects particularly long-sighted individuals? From the fact of a great number of those whom I have observed, having been field labourers or old military men, ought I to conclude that it attacks *principally* those who are incessantly exposed to the sun or to the inclemency of the air? No, doubtless, I should not; all that is possible, but all that is very far from being demonstrated*.

It is not, indeed, from the absolute number of times that any circumstance presents itself before the commencement of a disease, that it is permissible to conclude that it is or is not the cause of that disease; it must, moreover, be known, whether in the proportion observed, it be not met with as frequently in cases in which there exists no morbid state. Thus, from there being found in a given number of patients affected with

cataract, three who have the hair black, for one having it white, forty having the sight long, for nine having it short, &c. &c., I shall beware of concluding that the disease is met with proportionally more frequently in black-haired individuals, than in those having the hair white; in those long sighted, than in those short-sighted, &c.; who knows, indeed, whether this be not the ordinary relation of black hair to white hair, of long sights to short sights? Thenceforth, from this ratio being maintained in the persons affected with cataract, it is clear there would be nothing particular to be concluded therefrom. There is something more, namely, that it may very easily happen that precisely the reverse of what it appears to be at first sight, may be found to be the truth. Thus, I suppose that in a given population, there are met with six individuals having the hair brown, for one with the hair white; then that in a certain number of cataracts, three be found with brown hair, for one with white hair; it must rigorously be concluded therefrom, that cataracts far more frequently affect persons with white, than those with brown hair. These reflections are fully applicable to the study of the influence of professions. Who can, indeed, say that the agriculturist is predisposed more than others to cataract? That there enter each year into the great hospitals of Paris, four persons affected with cataract, inhabitants of the country, for one inhabitant of the city, what does that prove, if the population furnishing the first be three or four times more considerable than that of Paris—if perhaps it be seven or eight times more so?

All these things are of the last evidence; so is there reason for being astonished at seeing the greater part of authors give their long lists of *causes*, without the least hesitation, without having the air, even of suspecting that they are neglecting precautions which are after all quite indispensable—happy, even when these pretended causes have existed a certain number of times, as simple facts of coincidence, and without even seeking whether they have had any real influence. Had the illustrious Corvisart analyzed his own work under this last point of view only, he would, doubtless, not have said that the tailors are very frequently attacked with aneurism of the heart, for he would have seen but a *single observation* in the whole volume, as relative to a workman of that profession.

M. Parent Duchatelet, in his excellent work upon the cause of ulcers is, to my knowledge at least, the only author who has clearly indicated and sufficiently developed this source of error, so is he extremely reserved in his conclusions, which are very limited; that is, unhappily, what must frequently enough happen when mere attention is given to produce things proved, than things that are possible—rigorous re-

* The fact of the equal frequency of cataract in the two sexes would tend even to prove that it is erroneously ascribed to the exposure of the eyes to the sun, to an ardent fire, the application of the sight to very brilliant objects, &c., considered as causes of this disease; it is manifest, indeed, that women are generally far less exposed than men to these diverse influences.

sult, than more or less hazarded inductions. That is, however, I think the route that must be followed without ever deviating from it, even at the risk of having applied to oneself, that more witty than just saying, that there are some folks who, from over prudence, dare not conclude that two and two make four.

Yet, in spite of the insufficiency of all these data for arriving actually at rigorous conclusions, I have not thought proper to pass them over in silence. This kind of research, notwithstanding its apparent barrenness, is in my opinion of a major importance. What is, indeed, wanting to enable us to obtain *legitimately* all the conclusions contained therein? There are wanting results of another kind, those of statistics—precious science, still of recent date, but which, perhaps, even owing to that, marches at once, and with a firm step, towards truths the most useful and the best determined. How many medical questions will there not be susceptible of a truly scientific solution, after statistics shall have furnished the indispensable bases of them? Can its aid be done without, when there is question of studying age, profession, habitation, kind of nourishment, customs, &c. &c.? Will it not be a sort of statistic, that may be called physiological or pathological, that recourse must be had to if it be desired to appreciate precisely the so frequently invoked influence of the temperaments of hereditary, and even of the different diseases one upon another? or, all that, being necessarily within the domain of observation—as all that must necessarily finally be known—is it not proper to assemble on the other hand materials, which, although useless at present, will not be the less useful hereafter?

—o—

CLINICAL LECTURES,

Delivered at the South-Eastern General Dispensary, Dublin.

BY DR. M. ADAM.

—

Pathology and Treatment of Diarrhœa and Peritonitis.

GENTLEMEN — At our last meeting we were engaged in the consideration of diarrhœa and dysentery, and after having taken a view of a few cases illustrative of both our diseases, which lately occurred among dispensary patients, we entered on the general history of the former affection. You may recollect, I pointed out to you some of the leading causes of diarrhœa, which it may be useful to recapitulate briefly; I endeavoured to explain in the first instance, how diarrhœa might arise from vicarious action—in other words, from a translation of a morbid or healthy action from a distant part to the intestines. 2dly, How it might be caused by ingesta proving irritating, either from un-

due quantity, improper quality, idiosyncrasy of constitution, imperfect digestion, or fœcal accumulation. 3dly, We alluded to morbid secretion either of the biliary fluid, or of the mucus of the intestines, as a frequent cause of diarrhœa. 4th, We also mentioned epidemic influence, that mysterious power of whose essence we are ignorant, but of whose effects we have had such melancholy experience, as occasionally giving rise to this affection, which may appear either uncombined with other diseases, or co-exist with a similar affection of the respiratory mucous membrane, or form the termination in many cases of an epidemic catarrh. 5thly, We described diarrhœa as in some instances emanating from a sympathetic influence exerted by the nervous system on the intestinal canal, as is exemplified when pure mental emotions, which of course act primarily on the brain, produce an increased secretion from the bowels, giving rise to diarrhœa. And lastly, We mentioned diarrhœa, as occasionally occurring as a symptom in the course of other diseases. I beg leave also to recall to your recollection, the importance that was attached to an investigation of the cause in every individual case of this affection; a correct knowledge of which, not only giving us more just ideas of the pathology of the disease, but also serving as an important guide in practice, without which, we should pursue empirical and often abortive attempts to combat symptoms, while we left the root of the evil unattended to, because unknown.

I shall now proceed to take a short view of the principal varieties which this disease may assume, and of the peculiar treatment most suitable to each. The first that I shall mention, is what has been denominated fœculent diarrhœa, in which the dejections are natural in appearance, but unusually loose and copious: this is the diarrhœa crapulosa of Cullen, and the diarrhœa of Dr. M. Good; it often arises from over-eating, or from diet of an irritating quality; it also sometimes occurs from fœcal accumulation, the consequence of constipation, and also often appears in the commencement of other forms of the disease. It is to be considered as an effort of nature to free the alimentary canal of matter irritating from quantity or quality; consequently, in the early stages we should not attempt to check it by opiates or astringents: we should rather assist nature in getting rid of the offending cause; while the stools continue fœculent in appearance and considerable in quantity, we should exhibit mild purgatives; castor oil in the first instance, is perhaps the most suitable, and if a second dose of purgative medicine is required, rhubarb with magnesia in some aromatic water may be given; by thus expediting the expulsion of the irritating cause, we both shorten the duration of the disease, and also diminish the chance of its becoming chronic, or terminating in colonitis or other forms of the affection. After the

operation of the purgative, if the diarrhœa still continues, and ceases to present a feculent appearance, we may then conclude that it is maintained by a morbid irritability of the mucous membrane, and at this period, we may give opiates with advantage, either in the form of Dover's powder, or the tincture in chalk mixture.

The 2nd form—bilious diarrhœa—is usually connected with an excited or inflammatory state of the liver or duodenum, causing an undue secretion of bile; the stools, at first feculent, afterwards present a bright yellow or green colour; in this form, local bleeding is useful before we exhibit internal medicines; after which, mild mercurials, such as the hydrarg. c. creta, or pil. hydrarg. combined with Dover's powder, may be given with advantage; demulcents, such as the infusion of linseed, may also have some effect in diminishing the irritation of the acrid bile, and towards the close of the disease, opiates may be exhibited with the best effects.

A 3rd form—mucous diarrhœa—has with some propriety been called a catarrh of the intestines; it may exist as a sporadic disease, but it more frequently prevails as an epidemic in conjunction with similar affections of other mucous membranes, and is occasionally attended with some degree of fever; it is characterized by the stools consisting principally of mucus, which is sometimes passed in large masses, or in flakes mixed with more liquid matters. Dr. Crampton observes, "That it sometimes assumes a more chronic or sluggish course in old delicate patients affected with dyspepsia; in such cases, both the stomach and bowels are often loaded with depraved mucus secreted in great quantity, and which appears to be the cause of the diarrhœa; in such cases the mucous membrane is sometimes found thickened and congested, and the follicles erected and patulous; and unless a suitable treatment is adopted, the disease degenerates into a permanently chronic state, probably attended with atrophy or dropsy." Our object in the treatment of this form of the disease should be to allay irritation by abstinence, demulcents, diaphoretics, either with or without opiates, confinement to bed, pediluvia, warm fomentations to the abdomen, &c. If these means fail, and much griping or tenesmus is present, Dover's powder and chalk mixture will be useful, or a starch enema with tinct. opii, may be given with advantage. Purgatives are, in general, improper.

4th form. Serous diarrhœa. The stools in this variety present a watery appearance; sometimes they appear almost limpid, or mixed with minute flakes or shreds; it may arise from the same causes as mucous diarrhœa, and seems to depend on a very irritable state of the exhalent vessels of the mucous membrane, which may in some instances amount to inflammation, though in others it appears to be connected with an atony or loss

of tone of those vessels, as was exemplified in our last lecture, when speaking of passive diarrhœa. Its treatment may be considered as essentially the same as the mucous species; diaphoretics, opiates, and astringents, will be proper; when it has assumed the chronic form, tonics may be used in addition to these means. I have been in the habit of employing the infusion of cascarrilla or columba; the decoction of logwood is also a valuable remedy in such cases; \mathfrak{z} i or \mathfrak{z} ij may be exhibited three or four times a day, and an opiate at night, or the opium may be combined with acetate of lead, with the best effects; in the latter stages of mucous and serous diarrhœas, or even in the early periods, when I have been satisfied that no inflammatory action or fecal accumulation existed, I generally use the following powders:—

R. Hydrarg. c. creta, Pulv. Cret. comp.;
Pulv. Doverii, $\bar{a} \bar{a}$ \mathfrak{z} i.

M. divide in pulv. vi.; sumat. i, ter quaterve, in die.

Isometimes of course vary the proportions of the ingredients according to circumstances; I know of no combination so generally useful; I have often found it stop the disease in a day or two; I recommend at the same time a diet of rice and milk, pediluvia, external warmth, abstinence from much bodily exertion, &c. &c.

Other forms of diarrhœa besides the four we have been considering, are mentioned by writers. Dr. Good describes one which he calls tubularis, in which membrane-like tubes, whitish, viscous, and inodorous, are discharged from the bowels; this substance consists of coagulable lymph, and is the result of a peculiar inflammation of the mucous membrane. The same author describes another form, which he calls chylosa, in which the stools present a milky appearance, which is probably owing to the absence of bile in the intestines, in consequence either of deficient secretion, or obstruction in its passage from the liver to the duodenum; when the treatment suitable to hepatic disease or jaundice will be required.

The disease called by old writers lientery, in which the food passes rapidly and little changed through the bowels, has been considered by Cullen and Good as a form of diarrhœa; it probably is connected with a deficient or altered secretion of the gastric juice, and also perhaps of the biliary fluid. It is an appearance which may occur in almost any form of diarrhœa, and can scarcely therefore be considered as a distinct species; for its cure it requires the treatment suitable to dyspepsia, conjoined with mild mercurials and alteratives.

Atonic or passive diarrhœa may supervene in the latter stages of almost any of the preceding forms. It is characterized by frequent dejections, accompanied with little or no pain, tormina, tenesmus, or other uneasy feeling; it continues for a considerable time,

and is attended with a weak pulse and more or less prostration of strength; the evacuations are sometimes partly *feculent*, but in most cases consist of the serous or mucous secretions of the bowels; it may sometimes be cured by a course of mild mercurials, combined with opiates, such as are the Hyd. c. creta, with Dover's powder, tonics, and astringents, as we before mentioned, such as calumba, cascarilla, decoction of logwood; and acetate of lead and opium will frequently be necessary.

I have now given you a short view of the different forms of diarrhœa, as distinguished by the appearance of the dejections, in which I have followed principally Dr. Crampton, who has given the best description of this disease which I have met with*. We have seen that the discharges from the bowels may be either *feculent*, bilious, mucous, serous, membranous, white or chylous, *lienteric* or consisting of unaltered aliment. But I should give you an incorrect idea of the subject, if I led you to suppose that these various appearances constituted in every case an essential difference in the nature of the morbid affection. Several of these appearances may occur either simultaneously or successively in the same case; thus, an irritation producing at first a *feculent* diarrhœa, may also cause an increased discharge of bile, mucus, or serum; or a diarrhœa, caused primarily by increased mucous secretion, may first be *feculent*, if there happen at the time of its attack to be much local accumulation in the large intestines, and may afterwards be bilious, from the liver participating in the morbid excitement of the mucous membrane; or if the biliary secretion happens to be the first that is morbidly increased, the irritation of superabundant bile in the bowels will stimulate the mucous follicles and exhalents to secrete an increased quantity of their peculiar products. However, in most instances one or other of these discharges will predominate, and it is of some practical importance to determine which is morbidly increased; by such inquiries you will be in general enabled to adopt a rational plan of treatment, and be prevented from the indiscriminate use of a certain favourite set of formulæ for every disease, which, though it may save the practitioner the trouble of thought, and be even successful in some cases, when the remedies happen to be suited to the nature of the disease, yet will be useless or injurious in many others. Thus, many persons are in the habit of prescribing chalk mixture and tincture of opium, in almost every case of purging; this, though undoubtedly a useful combination, when judiciously applied, will prove particularly injurious in certain cases; for instance, if the diarrhœa is the consequence of irritating

matter in the *primæ viæ*, what could be more absurd than to exhibit this medicine before the bowels had freed themselves of the offending matter? The effect obviously would be to diminish or suspend peristaltic action, thereby preventing the expulsion of the cause of the disease. On the other hand, in mucous and serous diarrhœa, when we have good reason to believe that the bowels contain little except their peculiar secretions, which continue to be poured out in consequence of increased irritability, purgatives, though useful in the former case, would be highly injurious in this, as they would only exasperate the irritability of parts already preternaturally excited. In diarrhœa connected with indigestion, stomachic medicines would be useful, but if the disease originated from increased irritability, or inflammatory action of the mucous membrane, their stimulant effects would be injurious. We see then the value of forming correct ideas of the nature of the different morbid actions which exist in the various modifications of what may be termed an individual disease. The word diarrhœa simply expresses an effect, in fact a prominent symptom, which may depend, as I have endeavoured to shew, on different, and even opposite conditions of the intestinal mucous membrane. What two pathological states, for instance, can be more opposed to each other, than mucous diarrhœa arising from increased vascular action, and passive diarrhœa caused by atonic relaxation?—the former, a state in which the functions of the parts are excited beyond their healthy actions, the latter a condition depending on debility. What two indications can be more opposite than the treatment in *feculent* diarrhœa, which demands the use of purgatives, and other forms which require astringents and opiates? These considerations are worthy of the closest attention from the medical student, and apply, not only to this, but to a variety of other diseases. A correct conception of the peculiar morbid action which exists in each individual case, should be the grand object which the practitioner ought to endeavour to attain; when he is right in this point he will experience comparatively little difficulty in the selection of suitable remedies; but in such investigations he should recollect that the same case may, at different periods of the same disease, bring a different and even opposite condition, and consequently require a corresponding change in the treatment.

I shall now, gentlemen, proceed to give you a short general history of dysentery, but before we commence the consideration of the causes, symptoms, varieties, and treatment of the disease, let us endeavour to settle what is meant by the term dysentery, or whether the more modern term *colitis*, expresses exactly the same morbid state. Cullen, who until lately was the reigning

* *Cyclopædia of Medicine*, Article, "Diarrhœa."

authority in nosological distinctions, defines dysentery to be a contagious pyrexia, with frequent mucous or bloody stools, the natural alvine evacuations being in general retained, accompanied with tormina and tenesmus. He conceives the disease to depend chiefly on a preternatural constriction of the colon, occasioning spasmodic efforts, which produce severe gripings, and which efforts, propagated downwards to the rectum, occasion there frequent mucous stools and tenesmus. His favourite spasm, which he so often assumes as the proximate cause of disease, he seems to conceive to be sufficient to account for the whole phenomena of dysentery. The evident symptoms of inflammatory action, the pain, frequent sensibility of the abdomen to pressure, sanguineous discharges, and accompanying febrile action, seem to have been entirely overlooked, or imputed to a wrong cause by this ingenious theorizer, as were also the more decided proofs of inflammation which *post-mortem* examinations disclosed. We see here an instance of the gross error into which an undue attachment to favourite theories may lead even a mind of the first order. Had Dr. Cullen reasoned impartially on the symptoms and morbid anatomy of dysentery, he could scarcely have come to this conclusion. Passing over minor authorities, let us consider the view which Dr. J. Johnson, of London, takes of this subject; he has had much experience of this disease, and his writings, deservedly popular, have much influence on medical opinion throughout the British empire. He supposes dysentery to depend primarily on obstructed perspiration and biliary secretion, in his work on the liver, and on tropical climates; that these are the two first links in that morbid chain which connects the remote cause with the ostensible form of the disease; he tells us, that the torpor of the vessels of the surface, causes an increased quantity of blood to be directed on the interior, while the blood circulating in the *venæ portæ*, is checked in the liver by a corresponding torpor in the secretory vessels of that organ: the consequence of this must be, an unnaturally great quantity of blood in the *cæliac* and mesenteric vessels; the perspiration being stopped, a vicarious discharge of mucous and acrid serum is thrown from the extremities of the turgid mesenteric vessels upon the internal surface of the intestines, which, by this time, are in a state of irritability; uneasiness in the bowels, frequent desire to go to stool, and mucous discharges, are the result. If the plethora be great, blood will be poured out from the mouths of the distended mesenteric vessels—hence inflammation and ulceration may ensue. If the cells of the colon contain hardened fæces, they will be grasped by the irritable circular fibres of the intestines, and rings or strictures will augment the tormina and griping in the bowels. Such is Dr. Johnson's view of the essence of this disease,

which may be shortly summed up in these words: Dysentery, according to him, arises from increased quantity of blood in the venous system of the intestines, caused by suppressed perspiration and biliary secretion, the discharges being efforts of nature to relieve the parts of their unusual load of blood. He considers inflammation of the mucous membrane, as a frequent effect, though not the cause of dysentery. This view is much nearer the truth than Dr. Cullen's doctrine of spasm; but Dr. Mason Good appears to me to have attained a more correct view of the true nature of this disease; he defines it to be inflammation of the mucous membrane of the large intestines, griping and tenesmus, frequent and often bloody dejections, the *æces* seldom discharged, and in small quantities; he tells us, that there always is some degree of inflammation in the colon or rectum, occasionally perhaps extending higher: an inflammation of a peculiar kind, which has a strong tendency, when violent, to run into gangrene, but when mild, exciting that increased flow of mucus which is common to inflammations of all mucous membranes. He divides the disease into two species; 1st. simple dysentery, in which the fever is slight and unperceived, the fæces when discharged, evacuated without considerable pain, of a natural quality, and affording ease. 2nd. Dysenteric fever, accompanied with pyrexia, great loss of strength and depression of spirits; the fæces, when discharged, of various colours and consistence, highly fœtid and mixed with putrid sanies, sebaceous matters, or membranous films—contagious. This appears to me to be a just view of the disease; both the symptoms during life, and the morbid appearances after death, prove that in dysentery there is always more or less inflammation of a part or the whole of the large intestine, sometimes attended with little or no symptomatic fever, in other instances accompanied with a decided pyrexia; in the latter form often epidemic to a wide extent, and sometimes, there is reason to suppose, contagious.

Peritonitis.—Peritonitis is the term applied to inflammation of that serous membrane which lines the interior of the abdominal cavity, and gives an external tunic to all its viscera. This affection is, when simple, perfectly distinct in its seat from enteritis or inflammation of mucous and other coats of the intestines, though the two diseases have been often confounded. The serous covering of the stomach or bowels may be in a highly phlogosed state, while the mucous membrane is unaffected; and even in some cases peritonitis induces the very opposite condition to inflammation in the mucous membrane, namely, a state of anemia, or diminished quantity of blood in its vessels; for it has been occasionally found that, when intense signs of inflammation have been detected after death in the peritonæum, the

mucous membrane has been remarkably pale. This is in accordance with the law laid down by Andral, that when an hyperæmia, or preternatural quantity of blood is determined to one organ or texture, it may cause the state called anemia or preternatural diminution of blood in the vessels of another; thus the inflammation of the peritonæum may cause the blood to abandon the intestinal mucous membrane and leave it exsanguineous, the blood flowing to, and accumulating in the inflamed part; this takes place in some instances, but the very reverse effect happens in others, which I shall hereafter illustrate. Simple peritonitis then is to be regarded as an inflammation of a texture distinct from that which is affected in enteritis, and we shall hereafter consider the criterion by which we are enabled to distinguish the one affection from the other during life; but first let us take a short view of the symptoms which peritonitis presents in the adult. Its great characteristics are abdominal pain, tenderness, and tumefaction, accompanied with more or less symptomatic fever, and disturbance of the functions of the stomach or bowels; it is true, these three symptoms may be present also in some cases of enteritis, but not to the same degree, nor are they so invariably co-existing as we find them to be in inflammation of the peritonæum.

Peritonitis frequently commences with more or less fever, perhaps with shivering succeeded by heat of skin, accompanied with a frequent small pulse; these symptoms may precede for some time any complaint of abdominal pain or tenderness; however, it is not uncommon for pain in the abdomen and increased sensibility to pressure, to be the first symptoms complained of. This pain generally becomes the most urgent symptom, and may assume various modifications; it is often of an acute lancinating character, sometimes limited to a small space, where it may continue unabated during the whole course of the disease; at other times it shifts its situation, and occasionally pervades the quarter part of the whole of the abdomen. It may be constant, or come on in paroxysms, which Dr. Abercrombie says, arise from the passage of flatus through the bowels. In some cases there is little or no pain except when pressure is made, and then the patient rather complains of an acute tenderness than actual pain; this sensibility of the abdomen to pressure is sometimes so exquisite that the patient cannot bear the weight of the bed coverings, and even endeavours to relieve the inflamed surface from the pressure of the abdominal muscles, by lying on his back with his knees drawn up. The respiration is frequent and interrupted, chiefly performed by the thoracic muscles, the descent of the diaphragm producing an aggravation of the patient's sufferings; consequently, full inspiration, coughing, sneezing, vomiting, or the evacuation of the urine

or fæces, aggravates the pain. Tumefaction of the abdomen is generally also present; this in the early stages, probably arises from distention of the intestines by flatus, but at the more advanced periods, is caused by effusion into the peritoneal cavity. The swelling is in general equal and regular, and accompanied with some degree of tension; along with these symptoms there is often present hiccup, nausea, and vomiting. The bowels are generally constipated, though occasionally relaxed. The pulse is frequent, from 120 to 130 in a minute, feeling contracted and firm, like a small whip-cord or harp-string. The tongue is covered with a whitish fur, and the thirst is often very great. As the disease advances the abdominal pain, tenderness, and tumefaction become aggravated, the face pale, features contracted and covered with a cold sweat, the pulse more frequent and weaker, and the patient sometimes dies in sixteen or twenty-four hours after the commencement of the attack, but in other instances the disease is protracted and does not terminate fatally till after thirty or forty days.

On the approach of death the abdominal pain generally ceases, the pulse becomes weaker, the surface generally, and especially the extremities become cold, the tumefaction of the abdomen increases, the face appears sunk and hollow round the orbits, and sometimes the contents of the stomach are discharged, apparently without the effort of vomiting; sometimes delirium, coma, or convulsions precede the fatal termination, though occasionally the mind is undisturbed to the last.

Such are the symptoms of a well marked case of peritonitis; in some instances, however, many, and almost occasionally all, the above signs may be absent; this constitutes the variety called latent peritonitis, which requires a good deal of discernment to discover during life. Acute peritonitis may end in resolution, effusion, gangrene, or by assuming the chronic form.

Resolution is indicated when the abdominal pain, tenderness, and fever subside, and the functions of the neighbouring organs are re-established; critical evacuations, such as diarrhoea, copious perspiration, or abundant urine, sometimes also mark this termination, the pulse becoming slow and soft, and the sleep quiet and refreshing.

The symptoms which characterize effusion, are a sense of weight and oppression in the abdomen, accompanied with irregular chills, softness of the pulse, paleness of the face, and coldness of the extremities; at the same time there is a diminution of the abdominal pain and tenderness.

Gangrene is a rarer termination; it is indicated by a small intermitting pulse, hippocratic countenance, sudden cessation of abdominal pain, and speedy death. When acute peritonitis does not prove fatal in the course of fifteen or twenty days, it usually

subsides into the chronic form, which is in many respects a peculiar affection, and on which I shall not at present dilate, as at some future period an opportunity may be afforded of illustrating this variety of the disease by some dispensary cases.

The above description refers to uncomplicated peritonitis in the adult, but it presents some peculiarities as it affects the child and puerperal female, on which I do not propose to enter, neither will our time allow us to go into a detail of the predisposing or exciting causes, which are generally speaking the same as other internal inflammations. My object is to present to your view the most important characters by which it may be recognized and distinguished from other diseases, preliminary to the exhibition of an individual case. I shall therefore say a few words on its diagnosis, principally in reference to other inflammations of the stomach and bowels. In gastritis the pain and tenderness are confined to the region of the stomach, the vomiting is more urgent and more easily excited by food or drink, and the thirst and desire of cold liquids more intense. When it happens, however, that the peritoneal coat of the stomach is exclusively inflamed, the difficulty of distinguishing the two affections will be greater, as all or the greater part of the above symptoms will be present; in such instances, an attentive consideration of the general history of both diseases, and of the succession of symptoms in the individual case, may assist our diagnosis.

In enteritis the sensibility to pressure is not so great as in peritonitis. The action of the diaphragm in inspiration or coughing does not produce so much suffering, nor is the pain so much aggravated by motion of the body. In peritonitis the pain is more superficial than in enteritis, is of a more acute character, and is not so often accompanied by vomiting or diarrhoea; this latter affection, jaundice, or dysentery, are not uncommon in enteritis but do not frequently occur in peritonitis. Rheumatism may affect the abdominal muscles; the pain in such cases is principally at their origin or insertion, shooting to the false ribs and spine of the ilium; these peculiar characters, together with the absence of fever, abdominal tumefaction, vomiting or constipation, will enable us in most cases to distinguish this affection from peritonitis.

Neuralgic pains sometimes attack the abdomen; they may arise from spinal irritation at the origin of those nerves which supply the anterior abdominal parietes. Their fugitive character, the absence of pyrexia, abdominal tumefaction, or disturbance of function, and the general history of the case, may sufficiently point out their nature; in such cases we should examine the spinal column, and if pain or tenderness is discovered at any particular spot, it will assist in confirming our diagnosis.

Hysteria occasionally simulates peritoni-

tis, but the temperament of the patient, the incongruity of the symptoms—for instance, great abdominal tenderness, with no fever or accelerated pulse, a hurry or labour of respiration, different from the short thoracic breathing of peritonitis, a sudden shifting and changing of the painful part, and sometimes the appearance of decided hysterical symptoms, will enable us in general to identify hysteria. Colic frequently presents severe abdominal pain and tumefaction, but may in general be distinguished from peritonitis, by the absence of fever, the suddenness of the attack, the state of the pulse, and the pain being generally rather relieved than aggravated by pressure. These are the principal diseases which may be confounded with peritonitis. Our time would not allow us to consider others, which may occasionally present some of the features of this disease; to enter into such a detail would require a notice of all the diseases to which the abdominal viscera are subject. The foregoing observations refer to simple acute peritonitis affecting the adult; but this disease may co-exist with other morbid affections of the subjacent viscera, or of more distant organs; the most common complication which occurs is that with gastritis or enteritis. This may take place in different ways; either the inflammation may have been primarily seated in the peritonæum, and afterwards extend itself by contiguity or continuity of substance to the intestines; or the intestinal mucous membrane may have been the first attacked, and the inflammation extend in a similar manner to the peritonæum; in either case the inflammation of the two textures may exist simultaneously; but in other instances, a metastasis or transference of morbid action from the one surface to the other may take place; the peritonitis may disappear, and immediately after, the mucous membrane may become inflamed; or the reverse may occur; the enteritis may subside, and peritonitis immediately after supervene. A case has lately occurred among our dispensary patients, illustrating the supervention of inflammation of the colon during the existence of peritonitis, which existed some days previous to the attack of the dysentery; the symptoms characteristic of inflammation, both of the serous and mucous coats of the intestines, continued to co-exist during the whole course of the patient's illness. The history of the case is as follows:—Eliza K., age thirty-five, a widow, sanguineo-nervous temperament, spare habit; on my first visit on Monday June 3rd, she complained of a severe pain in the abdomen, chiefly in the hypogastric and both inguinal regions, coming on in paroxysms of considerable severity, the pain continuing in a minor degree during the intervals. This pain is much aggravated by any motion of the body, especially turning in bed, coughing, full inspiration, or evacuating the urine or fæces; it is

also excited in an exquisite degree by the slightest pressure on the affected parts. She finds most ease from lying on her back with her knees drawn up; countenance contracted and expressive of suffering. The abdomen feels hot, but is not swollen; she also complains of some pain in the back when she attempts to stir, and of a severe headache. Pulse 90, small and contracted. Tongue a little whitish, urinescent. Catamenia regular. Bowels severely purged; had ten dejections yesterday and three to day, accompanied with tenesmus; fæces slimy, mixed with blood, sometimes whitish, at others greenish; no vomiting or sickness of the stomach. Took ill nine days ago with rigors, heat, pain and soreness all over the abdomen, vomiting and constipation. She was then leeches, stuped, and salivated, with considerable relief, but the above symptoms, though mitigated, still continued and became aggravated on Saturday, with the addition of the bowel complaint, which has continued till the present time; her gums are still sore from mercury. I directed eighteen leeches to be applied to the abdomen, the bleeding from the leech bites to be encouraged by fomentations long continued, and an enema of starch mucilage, with forty drops of tincture of opium to be given towards evening. The next day, Tuesday the 4th, I found her much relieved; the leeches had bled well, abdominal pain and tenderness much diminished, though it still existed to a certain extent; the purging had declined, but still continued frequent; salivation nearly gone; 8 more leeches were directed to be applied to the hypogastric region, and the following ordered:—

Rx. Calomel, gr. xii; Opii, gr. ii. M. Fiat massa in pil. iv dividend. sumat j 4tis horis.

On the 5th I found her considerably better; abdominal pain and soreness on pressure very inconsiderable; pulse weak, but it had lost that contracted character which it had on my first visit; some vomiting; bowels confined; she had taken all the pills; no pyalism. Contin. Pil. ut heri. Rx. Ol. olivæ, ℥ i; Sal. sodæ, ℥ i; Decoct. avenæ, ℥ xvi. M. Fiat enema statim injiciend. The abdomen to be fomented with warm flannels, sprinkled with turpentine.

On the 6th I found her much better; very little abdominal tenderness on pressure, and no paroxysms of pain; she can cough, turn in bed, and lie on either side, without exciting much pain. She had eight or ten dejections since I saw her yesterday, unmixed with blood, and nearly natural in appearance, attended with some tormina, but no tenesmus. Pulse 102, soft, weak; tongue a little red in the centre; no vomiting to-day, but a good deal yesterday; countenance much improved, having lost that contracted expression which her features exhibited the first day I saw her. Intermit. medicam.

Rx. Hydrarg. c. creta, gr. x; Opii, gr. ii.

M. in pil. ii, dividend. sumat j 4tis horis. Rice diet. Turpentine stupes to the abdomen.

7th. But one stool since yesterday, about two hours ago, solid, and natural in appearance, preceded by some griping pain. Slept well all night; abdominal pain and tenderness diminishing; pulse 100, soft. Rep. pil. i, h. s. et fatus terebinth.

8th. Has had a return of purging since yesterday; 13 stools, yeasty in appearance, mixed with some blood. Complains much of pains in the hips and back; but little abdominal tenderness; tongue white, reddish in the centre.

Rx. Pulv. Doverii, 3ss; Pil. hydrarg. gr. x. M. Fiant pil. viii, quarum sumat ij quartis horis.

10th. Took all the pills; no stool since Saturday; feels much better; still complains of pains in the hips; considerable pyalism; pulse 96, of tolerable strength; no vomiting; scarcely any abdominal pain or soreness.

Intermit. pil. Sumat haust ex oleo ricini.

12th. Nearly well; abdominal tenderness almost entirely gone; pulse quiet; functions natural. Intermit. med. Stupes to the abdomen at night: directed to attend to the state of her bowels.

This is a very interesting case when viewed in connexion with the subject which we have been discussing. It is evident from its previous history, that the patient had an attack of simple acute peritonitis nine days before my first visit: the co-existence of rigors, heat, abdominal pain and soreness, with vomiting and constipation, was sufficient to identify the nature of the affection. At this time she was leeches, stuped, and salivated, with considerable relief, by Dr. Houghton, but seven days after the commencement of the attack she had a return of the symptoms of peritonitis, probably from exposure to cold, or some other accidental cause, to which were added bloody stools with tenesmus, evidencing that the inflammation of the serous tunic of the intestines had gradually extended itself to the mucous membrane, and that a phlogosis of the two textures co-existed; for it was evident, I think, that the peritonitis did not subside on the supervention of the dysentery, as when I first saw her she exhibited, in addition to the bowel complaint, very decided symptoms of peritonitis in the lower part of the abdomen; she had pain in this region of a much more acute character than generally exists in mucous inflammations; it was aggravated by motion, coughing, or any other effort which excited the action of the diaphragm: this is highly characteristic of peritonitis, but is not commonly present in simple dysentery; the sensibility to pressure was very intense; this, it is true, is also the case in mucous inflammations, but it is more obtuse in character, and less in degree in such cases than in peritonitis. Her position,

INTRODUCTORY LECTURE

TO THE

COURSE OF CLINICAL SURGERY,

Now being delivered at the Hospital la Charité,

By PROFESSOR VELPEAU.

lying on the back with elevated knees, is also peculiar to the latter affection. There was no abdominal tumefaction, probably in consequence of the mucous inflammation affecting simultaneously a considerable portion of the large intestines, without being accompanied by any spasmodic constriction; the flatus, if it was generated, was therefore, it is most likely, discharged without accumulating so as to produce any abdominal distention. The pain in the back probably arose from the peritoneal covering of the bodies of the lumbar vertebræ and adjacent muscles being also inflamed. As the patient had been ill a considerable time, and her strength somewhat reduced by active treatment, I did not order general bleeding, though, under more favourable circumstances, I should have done so. I directed leeches to be applied to the abdomen, and the parts afterwards to be fomented for a considerable time. By this means blood was abstracted from the immediate vicinity of the inflamed parts, and was more likely to produce a favourable effect than if a greater quantity was abstracted from the system by venesection, without reducing the patient's strength so much. I also ordered an opiate enema, to quiet the tenesmus and purging.

The presence of salivation prevented me at this time from commencing the use of mercury. The next day I found her much better: the opiate enema had alleviated considerably the tenesmus and diarrhoea, but as there was still some abdominal tenderness present, I repeated the leeching, and as the mercurial action had subsided, I thought it advisable to renew it by the exhibition of calomel and opium. This I continued for some days afterwards, substituting the hydrarg. c. creta and opium when some pytalism began to appear, thinking that the calomel might be too irritating to the bowels, and that the hydrarg. c. creta would be sufficient to keep up the mercurial action which the calomel had established.

The treatment afterwards consisted in the continuance of the opiate and mercurial, the occasional use of mild aperients, by the mouth and anus, and the employment of turpentine stupes, as a substitute for blisters. This plan has succeeded to the utmost of our expectations, and when I last saw the patient I considered her as nearly free from all complaint. This case is instructive, both as exhibiting a specimen of peritonitis complicated with dysentery, and also as illustrating the efficacy of local depletion and the combination of opium and mercury in controlling intestinal inflammation.

At our next lecture, gentlemen, we shall conclude this subject by a general view of the treatment suitable to the acute form of peritonitis, and afterwards proceed to consider some other affections of the abdominal viscera.

GENTLEMEN—I shall proceed to show you that the best method to follow in surgery, ought to be likewise the best in medicine—or more fully to explain my ideas—that surgery cannot be separated from medicine, in no part, neither in the wards, in the lecture rooms, nor in clinical instructions, and that they ought both to be governed by the same philosophy.

Allow me to explain myself. In the present age, surgery is far beyond its etymology; it is no longer, as in former days, the humble servant of medicine. No person thinks in the present day of restraining it to the narrow circle of mechanical arts. Its province is so extended that it can be no longer bounded. It is true that manual operations always constitute its most apparent characteristic; but it is surgery, and not medicine, that now decides on the propriety and necessity of an operation. The word external pathology does not express it any better, for it seizes on the treatment of certain effusions, of certain collections in the head, in the chest, and in the abdomen, though they are internal diseases; whilst it abandons that of scarlatina, measles, urticaria, and pemphigus, which are however external diseases. The division of the healing art into *medicine* and *surgery*, does not really exist in nature. We can very well understand that certain physicians devote themselves specially to the practice of a particular class of diseases, that some of them attend only to those diseases that scarcely ever require the employment of mechanical means, or of local applications, whilst others practice quite the contrary; but in reality all that is arbitrary, and you will not find a lesion, called surgical, that will not in some points be complicated with a medical one, and in the same way there is scarcely a medical case that is not sometimes in need of the help of surgery.

Medicine is one, gentlemen; let us accustom ourselves to this idea. It may be hygienic medicine, surgical medicine, or pharmaceutical medicine, according to circumstances. Surgery is one of the most powerful resources of medicine, when it is clearly indicated; but it must not entirely depend upon medicine, nor can it ever with safety lose sight of it. Learn medicine then, if you wish to cultivate surgery with advantage; for to be a good surgeon you must also be a good physician. This assertion requires explanation.

The perfection of a surgeon is made to consist in using his instruments in the most graceful and the most rapid manner possible, in performing the most difficult operations in a few seconds, in dazzling the eyes of the spectators by the quickness of his movements, the regularity of his incisions, and the beauty of his apparatus. *Celerity and elegance* should be the law of each, the incontestible standard of the merit and ability of every surgeon. It is thus that non-professional persons judge, and this is also the mode of acting and judging followed by a great number of surgeons. You see them counting the seconds that elapse during an operation for the stone, for removing the hip or shoulder joint, and look for the applause of the audience when they have extracted a calculus, or removed a limb in as short a time as you would take to carve the wing of a fowl. Nothing can be more injurious than these pretensions. Surgery does not consist of legerdemain: *sat cito si sat bene*. *Extreme quickness, and elegance* are rarely united with *prudence and safety*. You have gained a minute, but your incision is too long or too short, too straight or too oblique; you have left more skin or less flesh than you had intended; in fine, the wound is not as favourable as it might have been.

Do not however think that I have any intention of advocating awkwardness or bungling in manual operations: I only mean to say, that to act rapidly and gracefully is more frequently dangerous than useful in surgery, and that a judicious slowness is in general safer for the patient. A bandage very quickly put on may please the eye, but it is not always well applied. Examine it, and you will see that it wants solidity; that it is too tight in one part, and not tight enough in another, and that many of the patients soon complain of it. The same observation applies with respect to cutting operations. *Very quick and PERFECTLY WELL* is almost as impossible in surgery as in every thing else. Besides, if a man who is obliged to submit to the knife, looks for one who will not uselessly prolong his sufferings, he should also seek one who will operate safely, and in that manner most likely to afford afterwards the most chances of success.

Thus, even in the performance of operations, art should give way to science; besides, is not that the least important point of surgical pathology? How many things must be considered before we operate on a patient! The first thing to be noted is, that all division of tissues is in itself a disease, and that the slightest laceration is a door opened to death; yes, gentlemen a door opened to death! In short, it is on the whole system of man on which we operate when we incise the weakest of his organs. The puncture of a vein may bring on phlebitis, and destroy the patient.

A leech bite may induce an erysipelas, and cause death. The incision of a finger often inflames the lymphatic vessels of the whole limb; the synovial membranes of the hand all the cellular inter-muscular tissue of the fore-arm, in such a manner as to cause the death of the patient. The point of a pin driven to the depth of half a line in any part of the arm would be sufficient to produce the same results. An operation on any part affects the tegumentary, the nervous, and the vascular systems. For, when the functions of the great wheels of organization are disturbed, who can tell where the evil will stop, or who can undertake to be able always to re-establish the normal state of the economy. An operation should never be performed without the most precise indications; without first having positively ascertained that the disorder which may ensue, will cause less danger than the disease that is removed. Another point should not be forgotten, it is that the lesion that you wish to remove is not a being independent of the being you endeavour to preserve. The disorder that it has produced may have caused other disorders elsewhere, and may have re-acted in turn over the entire. It may be only a visible branch of a tree that bears or that conceals a great many others. It is in vain that you would cut it; for, to succeed in surgery, you must be able to remove the whole disease.

You see then, that before taking the bistoury in your hand, you ought to calculate all the injurious influences that any operation may exercise on man in health; you must consider, moreover, the whole extent of the disease that you have to combat; all the organs, all the viscera, all the symptoms, must be scrupulously examined; you should be convinced that the disease, if left to itself, or if treated in any other manner, would more endanger the welfare of the patient.

Lastly, when the operation is completed, you have not finished. We no longer say, as in the time of Paré or F. Jacques, *I have operated on you, may God cure you*.

The formidable consequences that I shall hereafter mention, you must endeavour to prevent. When they supervene, you should perceive them at a distance, in order to combat them in time. You should know how to resist them by every possible means, and be able to pursue them to their inmost intrenchments. Then, gentlemen, you no longer act as surgeons; it is to medical knowledge and medical means, that you must most frequently have recourse.

These exigencies, which I am far from exaggerating, and which I can but glance at superficially, will sufficiently indicate to you, that in surgery, the art of flourishing the knife is neither the great object, nor the most difficult to learn. In a word, the talent of diagnosis treating the indications, a profound knowledge of medicine should predominate. Nevertheless, there is no reason why the use

of the knife should be despised. All things else being equal, the more you excel in it, the more successful you will be. It is a portion of science that should be cultivated with the greatest care, which it is dangerous to neglect; but then, it must not be at the expense of the other departments of science, nor should we use it to the exclusion of all the others. After having brought surgery within the pale of pathology, I hasten to add, that medicine would be wrong, in its turn, to diminish the importance of surgery. Surgery, taken in its natural and most extended limits, will be nothing less than effective medicine—that which we wish to apply to all diseases.

Surgery has had its epochs of timidity and audacity; we have seen it only approach the patients with the knife or the fire in hand, while at other times neither the one nor the other dared be employed. But in our days you see individuals who maintain that the true end of pathology is to reduce more and more the number of operations. Abernethy went so far as to declare, that every operation was a disgrace to surgery*. It is with this, as it is with facts: the dispute is about words, and not things. If surgery always consisted in mutilations, it would undoubtedly be a duty to diminish it; but this is not its usual character. The object is to know, that in a given disease, the employment of the knife, or of mechanical means, will cure better or quicker, or expose more or less to unfavourable results, than the hygienic or pharmaceutical means. It is neither temerity nor timidity, but a sound knowledge and prudence that are wanted in surgery.

But to resume. Clinical surgery ought to be studied in a different manner from theoretical. To separate the one from the other would be ridiculous: they are sisters, and should go together.

There must be facts in surgery as in every other science: to slight them would be absurd. But in order that facts may be good in surgery as well as in medicine, they must combine conditions so numerous and so difficult to discover, that they are very few in number, and we must examine them most rigidly, before assigning them a definite place in science.

Surgery is not a distinct science, but it rests continually on medicine, over which it sheds a lustre; it requires peculiar studies, which are also involved in difficulties.

Foreign Medicine.

MEMOIR OF DUPUYTREN.

(Continued).

So much for M. Dupuytren as a practitioner; let us now consider him as a teacher.

* Sir Astley Cooper declared, that the best surgeon was he who performed the fewest operations.—T.

When he took his seat in the amphitheatre of the Hôtel Dieu, he took upon himself great responsibility. He succeeded a professor whose chief fame rested on his ability as a teacher. M. Pelletan disappeared (for what reason it was not well known), from the place where the students so much liked to see him; and the latter were not much disposed to receive with indulgence the new comer, whose unexpected and unprecedented advent appeared to them irregular. Even before Pelletan himself, Desault had for a long time made French surgery shine with a splendour before unknown. It required more than ordinary resources to avoid being crushed by such predecessors. M. Dupuytren performed all that any one had a right to require of him; and if he did not hush all the voices that were raised against him, he at least reduced to silence those who only doubted his capacity. Since 1815 the surgical clinique of the Hôtel Dieu has lost nothing of its ancient renown. No other clinique in France can be compared to it, either for the number of its pupils, the abundance of its cases, or the talent of its professor. In fact, M. Dupuytren understands to perfection what clinical teaching demands, which is a very difficult attainment, judging by the small number of those who succeed in it. Clinical lectures in surgery, differ greatly from a course of surgical lectures. The subject-matter of a course may be distributed beforehand. The professor constructs for himself a regular plan, which he fills up with all the developments he thinks appropriate. He has time to mature his ideas, to systematize his theories; he can pass over in silence what he does not know, skim over that of which he knows but little, and dwell particularly on what he knows best. He has sufficient time to consult authors, to quote their opinions, and to corroborate his precepts by the examples of the masters of the art. In short, a course may be made, very much like a book. A clinique is a very different thing. The professor has here constant occasion to speak extemporaneously, because the matter of his lecture is not settled beforehand, but by the chance which sends to-day a strangulated hernia, to-morrow a fracture, and three or four different cases in the same day. Arrived with the pupils in the presence of the patients, it is necessary he should explain their cases, give his opinion, pronounce a diagnosis, and give his reasons for it, prescribe the treatment, and explain the motives for his prescriptions. His task consists, perhaps, more in actions than in words. Always on the alert, always overlooked, always accompanied by a crowd, whose every look is a question, he must satisfy all, he must reply to all. We thus perceive how it is that more practical knowledge, and more intellectual resources, are necessary for a clinical professor, than for him who delivers a course. He does not set himself at the bedside of the patient, learnedly

to develop fine theories, and to descant more or less eloquently on a prepared subject—by no means a difficult achievement for one who adds to solid information, some degree of literary taste and conversational powers. Here, on the contrary, theories which offer so many advantages to one who is giving a dissertation, are no longer worth anything. It is not now so much a matter of *science* as of *art*. The professor ought to speak not so much of *diseases* as of the *diseased*. He ought, in every individual case, to point out to the student all the peculiarities of such and such an affection, in such and such a patient, and thus to exercise him gradually in the practice of an art, which is not and cannot be learned from books. Now, the difficulty of this task is great; for the subjects under observation are continually changing, as I have already said. It is by no means impossible that a physician, altogether incompetent as a practitioner, but versed in the literature of the science, and endowed with a certain facility of address, might give a tolerable course of lectures. We have even at the present day, several books on practical medicine, written by men whom the sight of a patient disgusts, and who would not stoop to write a prescription; and these books enjoy a certain portion of reputation. But for a clinical course, practical talent takes the lead of everything; for the professor ought especially to preach by example. It is above all things necessary, in the case of surgery, that he should be a good operator: the interests of the chair and his own reputation imperiously demand it. We may add that a clinical professor, continually exposed to the controlling observation of those who see him act and hear him speak, ought, in order to maintain himself in that position, to be either a man of great merit, or a complete fool. We have living proofs of both members of this alternative, in the school of Paris.

Excellent as a practitioner, M. Dupuytren possesses what is really the most important of all the qualifications of a clinical professor; but with that first and capital requisite, he combines numerous others. A professor ought to speak with facility, and to have, in some degree, the talent of improvisatizing. He ought to be endowed with a memory sufficiently retentive to recollect all the particulars of his patient's complaints, and of the different remedial measures he has ordered. With a deep sense of what his situation requires, he ought to have sufficient command of himself to return every day to the same things he has said a thousand times, in spite of the ennui connected with the repetition. It is highly important he should recollect, that he has to do with inexperienced auditors, to whom things must not be said by halves; auditors whom it would often not be difficult to *dazzle*, but whom it is far better to *instruct*;—an end which patience alone can accomplish. Now, in all these respects M.

Dupuytren is well nigh irreproachable. We will not say he is an *orator*, in the ordinary sense of the word, for that would be matter of censure instead of eulogy; but we will say that, although a little verbose, and sometimes diffuse, he speaks in a manner which is altogether attractive and appropriate. His diction is not destitute of elegance. It displays indeed occasionally, when the subject requires it, a degree of literary elaboration which is not displeasing. There is in his words a polish and refinement, which are rarely met with in hospitals; but so far removed are his expressions from commonplace, that I believe he takes more trouble with his elocution than is generally supposed. But whatever may be thought of these observations, which relate only to accessories (though highly important), and the justice of which may be contested, I rely with confidence on a more solid and appreciable merit. This merit consists in an inexhaustible abundance of practical reflections of the highest interest, and an excellent memory, which furnishes in profusion curious analogies; in a facility of thinking and speaking, which enables him, in a very short space of time, to seize all that is important in any case, and to develop it in a satisfactory manner; and in an understanding sufficiently exercised to teach him to accommodate himself to his audience. The students understand and feel all this, though they might not be able to explain the motive which leads them to the Hôtel Dieu, rather than elsewhere. As for myself, instructed by personal experience, and by the numerous comparisons I have made, I do not hesitate to affirm my belief, that M. Dupuytren's clinique may be offered as a model of that kind of instruction. To learn what ought to be done, and what is necessary to success, we must go to the Hôtel Dieu; to learn what ought to be avoided, we must go to St. Come, and other places beside.

But the most brilliant qualities—sagacity in diagnosis, imperturbable sang-froid in operating, facility of elocution in teaching—does all this suffice to merit general esteem, and to obtain the suffrages of all? No; for with all this, his qualifications may not be complete. There is a good faith which is required of every eminent man, but especially of a clinical professor. By this good faith I understand that candid impartiality, and that praiseworthy modesty, which leads a man to “render unto Cæsar the things which are Cæsar's,” and to render homage to truth, wherever it may be found. This good faith does not permit us to conceal a fault, either from the fear of public blame, or from a wound of our self-love. It does not permit us to proclaim a success which does not exist; or to eulogize or depreciate a proceeding, not because it is good or bad, but because its inventor bears this or the other name. It will not allow us to avail ourselves

of another's goods (as Bouvart said) without leaving our acknowledgments for our creditors. It accepts what is good, from whatever quarter it may come; and never holds its tongue when an opportunity presents itself of speaking well of a neighbour. Without this good faith, the most eminent qualities may become the instruments of deception.

In surgery, as well as everything else, a little ambition does no harm. It is even praiseworthy and necessary, when united with merit; for without the powerful impulse of that passion, merit would be apt to loiter on the road; but there is no need that the passion should be always burning, when the reasonable and attainable end of the journey has been reached. If there existed a man greedy of renown and of domination, whose character offered, in all its degrees and shades, the destructive energy of ambition, the inflexibility of pride, the jealous irritability of self-love, a vanity extending to the minutest details; if he dared to pretend that in all the chairs and all the books of surgery in Europe, there was only one eminent name, and that name his own; if he should wish that, struck with mental sterility, his contemporaries should invent nothing, perfect nothing, *do nothing*, in short, but by his order, and in virtue of his approbation, and that French surgery should only be the surgery of his hospital; if he pretended to reign alone, in the Oriental style, absolute in authority, having at his command the voices, the pens, and the practice of all the other professors of his art; if he seemed to desire that the labours of his predecessors and his contemporaries should be reduced to nothing, in order to have it said that surgery began and ended with him; if, dissatisfied after all, he disdained the most flattering eulogies as insufficient, and considered himself ill-treated by the slightest criticism, because it seemed to cast a doubt on his great capacity; if, in fine, instead of encouraging dawning talent, he appeared to see with alarm in each of his colleagues a rival, ready to dispute with him the sceptre of surgery, and to supersede him in his brilliant post, by some manœuvre of a kind analogous to that by which he himself obtained it; such a man might obtain flatterers and slaves, as all power of whatever description will; but generous hearts will separate themselves from him, and will refuse him their homage.

Let us now return to the clinique at the Hôtel Dieu. That clinique, so brilliant in every respect, so profitable to the students, from the sources of instruction which it opens, is a school of which we ought to be cautious; for the truth is not always respected there. There, as elsewhere, faults are committed, but they are never spoken of; or, if they are avowed, it is only when they can be repaired by a decisive display of brilliant talent. There they are not so deficient in tact as to censure themselves openly; but they invoke the tes-

timony of the auditors—of the pupils; and they lay under contribution all the subtleties of diplomatic language, and their own powers of invention, in order to express a thing without saying it, and to make themselves understood without speaking. Who has ever heard within those precincts the name of any living professor cited, whether for good or ill? Nothing is denied; nothing is attacked; but everything foreign is buried in the deepest silence. Is a well attested success obtained? all the trumpets of the hospital and the Journals sound it out. The fact is proclaimed, and exposed in public to the light of day. Cases which have not succeeded are scarcely mentioned, or altogether forgotten. Does a patient upon whom an operation has been performed get well? he is borne in triumph to the amphitheatre, and the case is added to the long list of cures. Does he perish? he is never spoken of more; and the body is swallowed up, along with the truth, in the damp vaults of the Hôtel Dieu. Is it desirable to justify a diagnosis by a *post mortem* examination? if the inspection confirm it, the pathological appearances will be shewn to the people. If there has been an error, the preparation will be taken away inadvertently, or much disfigured by the inexpertness of the anatomist; and we may sometimes enjoy a little comedy, got up by two or three persons the day before, for the mystification of the audience. Why so many precautions? Wherefore so many paltry combinations? Wherefore? It is to avoid that terrible confession, "I have made a mistake!" These pretensions to infallibility, seconded by so much perseverance and by so many means direct and indirect, still better display the spirit of domination of which I have already spoken, and which can scarcely redound to the advantage of science. The Hôtel Dieu is not a school, but a government. There are some subordinate ministers, and a chief, whose will is the law. The amphitheatre is not a simple gymnasium, set apart for familiar conferences; it is a divan, in which men, more or less prostrated, listen in silence to the words which the master deigns to let fall from his lips. This crouching subordination of minds and of wills, to the mind and the will of one man, is painful to be seen; but it exists. There are, in some wards of that hospital, such genuflections and habits of silence and mystery, as put us in mind of a seraglio. The chief is never spoken to but when he asks a question; and the body of him who replies becomes gradually curved, as by a superior force, and under the influence of an awful regard. A direct question put to the master, would be considered an act of temerity, of which there are but few examples on record. Every one shrinks before him. Even men whose talents and honourable exertions have made them his colleagues in that hospital, lessened, eclipsed, or rather annihilated by his ascendancy, cannot, in spite of

themselves, maintain that footing of equality which men of science ought to preserve among each other. Almost confounded with the host of students who encumber the wards, they are but rarely admitted to a consultation with the chief; and even then, the part they play is so subordinate as to be pitiable. Equally perturbed whether he smiles or frowns, they lose three parts of their faculties.

I forbear to pursue a subject which would lead me much farther. Some will perhaps think this criticism objectionable, from its personality. I have considered that objection; but, indignant at that scene of despotism, I could not refrain from raising my voice against it. Those who do not know the first surgeon to the king, will charge me with imprudence and exaggeration; those who do know him, will give me credit for much moderation and forbearance. But, however this may be, it is not inappropriate to give expression here to sentiments which everybody entertains, but to which, from various motives, no one gives utterance. I know the adage which says, that the truth is not always to be spoken; but I do not admit it without restriction. I am neither the friend nor the enemy, nor the pupil, nor the flatterer, nor the colleague of the surgeon of the Hôtel Dieu. I have observed his conduct as a public man, and have stated freely the impression which has been left on my mind. Carping objectors may find something to quarrel with in my words, but I do not fear they will suspect my intentions.

M. Dupuytren has written only two or three works, of which the following are the titles:—1. *Propositions on some Points of Anatomy, Physiology, and Pathological Anatomy* (1803). 2. *Memoir on the Effects produced on Respiration by the Ligature of the Pneumogastric Nerves*. 3. *Memoir on the Fracture of the Fibula*. I am acquainted only with the last work, which is diffusely and heavily written. The first volume of the *Memoirs of the Royal Academy of Medicine*, which is about to appear, will contain, it is said, a long announced and long expected Memoir by M. Dupuytren, on *Artificial Anus*.

Reviews.

Rudiments of Physiology, in Three Parts.

Part I. On Organism. Part II. On Life, as manifested in Irritation. Part III. On Life, as manifested in Sensation and in Thought.

By John Fletcher, M.D. F.R.C.S.E.

Lecturer on Physiology, and on Medical Jurisprudence. Part. I. 8vo. pp. 155.

Edinburgh: Carfrae & Son. London: Longman & Co. 1835.

THE celebrated author of the work before us stands pre-eminent among modern physiologists, and we felicitate ourselves in

being the first to place a part of his erudite, comprehensive, and incomparable lectures before the medical world. When we commenced their publication, we were immediately opposed by rival journalists—the one publishing the lectures of M. Magendie, the other, since dead, those of Dr. Graves, of Dublin—but both very speedily abandoned their undertakings, as far inferior in every possible respect to the discourses which now form the substance of the present production. In proof of this statement, we shall insert Dr. Fletcher's preface, which modestly but forcibly shews that no British or foreign physiologist “gives such a grasp of the whole (of physiology), and that so continuously and with such direct reference to the business of particular physiology, as can be of any considerable service to the student.”

It would be a work of supererogation on our part, to give extracts from the elaborate production before us, as we have already published the whole of this part of the work in this Journal; and we shall therefore content ourselves with placing the preface before our readers. In our judgment, Dr. Fletcher's *Physiology* exceeds all national and foreign works of modern times, in research, erudition, science, and comprehensiveness; and will be a work of reference and standard authority. After this expression of our conviction of its superior merits, we need not state that we strongly recommend it to our readers. It ought to be placed by the side of Haller's, Blumenbach's, Magendie's, Richerand's, Bostocks, Tiedemann's, and Mayo's *Physiology*; indeed, it far surpasses most of them as a systematic work.

“The following work will contain, in a somewhat amplified form, the matter of the earlier part of a six month's course of lectures on physiology, which the author has for some years been engaged in delivering annually; and it is published principally for the purpose of obviating an inconvenience which he has every year experienced—the necessity either of treating in too cursory a manner of certain general subjects, a knowledge of which is quite essential to a full comprehension of any particular point of physiology, or of occupying a longer time with questions belonging equally to all the functions, than could be well spared from the detail of each. The ordinary works on physiology in our language commonly plunge almost immediately in *medias res*, dispatching the consideration of these gene-

ral subjects in some eight or ten pages—a space which is quite inadequate to communicate any available information; and of those works which treat expressly of these subjects—admirable as many of these are, and unwilling as the author of the following pages would be that his production should be compared with even the least meritorious of them, each in its own particular department—he still knows of no one which gives such a grasp of the whole, and that so continuously, and with such a direct reference to the business of particular physiology, as can be of any considerable service to the student. Authors always succeed in proving to their own satisfaction, if not to that of the public, that their lucubrations are a desideratum; and he may therefore be excused if he entertain this opinion with respect to the present undertaking, particularly after the repeated solicitations of his pupils that he would engage in it. That his book will be of material use to *them* he does not hesitate to believe, and he hopes that it may not be quite useless to others.

“It has been the uniform practice of the author, in treating in his lectures of each of the individual functions, to begin with a short description of the apparatus by which this function is performed in all tribes of organized beings, and afterwards to state the vital conditions necessary to its performance. Now it is impossible to speak of the structure of any individual apparatus or organ without referring frequently to the subject of organism in general, including the considerations of the general classification of organized beings, the character of their several organs, the properties and general distribution of their tissues and fluids, and the nature of the chemical principles entering, or supposed to enter into their composition; and it is equally impossible to treat of the vital conditions necessary to the performance of any individual function without making frequent allusions to the subject of life in general, including the considerations of the mutual relations of the functions, the nature and sources of irritability or vitality, of sensibility or of the faculty of thinking, and the character and mode of action of the various agents by which these vital susceptibilities are excited. It is of these general subjects then that the following work will treat, more or less fully according as they appertain more or less directly to the proper business of physiology. It will be divided into three parts: the first treating of organism in general, the consideration of which, as belonging to the proper business rather of phytozoology and zoology, of anatomy, descriptive and general, and of organic chemistry, than of physiology, will be comparatively summary, and in many parts little more than commemorative; the second treating of life as manifested in irritation, the consideration of which, as proper to physiology, will be

considerably more full; and the third treating of life as manifested in sensation and in thought, the consideration of which, involving, as it does, the business partly of physiology, and partly of moral philosophy, will be in the former relation ample, while in the latter it is more concise. The first and second parts are intended as introductory to a detailed description of what is called the organic functions alone, including respiration, circulation, deposition, absorption, assimilation, and generation; and the third as introductory to that of what are called the animal functions, including sensation, thought, and voluntary motion; and care will be taken that the order in which every fact is stated, and every allusion made, directly correspond with that in which these several functions will fall subsequently to be treated of. This must be the author's apology for adopting frequently a less lucid arrangement, and one perhaps less illustrative of the subject immediately in hand, than might have been followed had he had no ulterior object in view; and the same prospective purpose must also plead his excuse for introducing occasionally an apparent superfluity of examples, and these not always perhaps the best that could have been selected, had the point directly at issue been the only thing to be considered. In choosing such examples, while he has always brought forward as many as possible of those which he will have occasion afterwards to introduce in other associations, he has confined himself almost exclusively to these; so that the present work, although perhaps, considered *per se*, less perfect than it might have been without these encumbrances, will be, he hopes and believes, more conducive to his main object of rendering the general subservient to the particular. Students for the most part do not readily take up mere didactic precepts, nor long retain abstract conclusions which have been drawn for them by others; but if frequently presented with numerous facts, from which such precepts and conclusions necessarily flow, and these in various relations to each other, the wished for deductions are gradually forced upon them, and, so implanted, are retained with all the pertinacity of real or fancied discoveries of their own: they cannot be successfully led to the goal, but by the same road by which their instructors have reached it. The numerous references to delineations of the organs alluded to in the first part are intended principally as a guide to such students as may wish to consult the originals of the large diagrams in oil, which the author has for many years been in the habit of exhibiting in his lectures—a plan which he is proud to find so many other public teachers have since adopted.

“In entering upon the composition of the following pages, the author imposed upon himself two rules which he has never

infringed—the one, to confine the text to acts and arguments, without any interlarding of authorities or *ipsissima verba* of authors, all which will be found in the foot notes—the other, never to speak directly or indirectly of himself. By attention to the former of these rules, the philosophy of the science has been kept quite distinct from what may be called the literature of it—a plan in his opinion highly conducive to perspicuity; while by attention to the latter, the besetting sin of egotism, into which he might have been occasionally betrayed, from finding that not a few doctrines which he conscientiously believes were taught for the first time by himself have been since appropriated by others, has been effectually avoided.”

Elements of Bedside Medicine and General Pathology; with a Sketch of the Origin, Progress, and Prospects of Clinical Medicine and Surgery; Exposition of the Creeds of Materialism and Vitalism; a Confession of Mixed Medical Faith; the Art of Observing in Medicine, &c. &c. By J. Stewart Thorburn, M.D. 8vo. pp. 473. London: Longman and Co. 1836.

THIS is a complete history of clinical medicine, both ancient and modern, and of the various topics mentioned in the title page. The style of the work is too inflated, and often pedantic, as the terms, “bedside medicine, general disease-discourse, mixed medical faith, quarrying the chief facts, architecting a literary edifice,” &c. &c. amply testify. Notwithstanding such imperfections, the work proves the author to be a learned physician, and one intimately acquainted with antiquated and standard clinical medicine. In the first section he quotes all the eminent writers on the subject in this and other countries, of the past and present epochs, and traces clinical or practical medicine from the ancient Babylonians and Persians down to the present time. He contrasts it in the different ages and nations, and very ably criticises and exposes its imperfections. He compares it in this country and continental Europe,¹ exposes the defects and abuses in our hospitals, dispensaries, &c., and suggests means for improving the study of clinical medicine in its fullest meaning.

The second section of the work is entitled, “Exposition of the medical creeds of materialism and vitalism, and of vegetable,

brute, and human organization.” This part is most ably executed, and “matter-of-fact practitioners, hoaxing, forging, cooking and trimming, false facts, homœopathism, allopathism, antipathism, expectantism, eclecticism, Broussaism,” &c. are duly estimated, and some satisfactorily refuted.

The third section is “On the art of observing, and of conducting observations in medicine.” This is also treated with great ability and success.

The last part is quaintly headed, “Elements of general disease-discourse, or pathology, technically so called.” This section gives a clear exposition of nosology, etiology, symptomatology, and of the invasion, development, duration, and modes of termination of diseases, and of convalescence, relapse, and recurrence.

Such are the contents of the work before us. It must be obvious that the great variety of subjects discussed render an extensive analysis of the whole a matter of difficulty and impracticability to a hebdomadal journalist. He can only give a general opinion on the merits or demerits of the whole. In our opinion, the author has evinced great research and erudition in the execution of his task, and has added an interesting and instructive work to medical literature.

The Cyclopædia of Anatomy and Physiology.

Edited by R. B. Todd, M.B., &c. Part IV.

Dec. 1835. Published every alternate Month. Sherwood and Co.

THIS part equals the preceding ones in the excellence of its execution. The article Aves, by Mr. Owen, is perhaps the best in any language—Axilla, by Dr. Benson, is very creditably done—Axillary artery, by Dr. Hart—Azygos, by Dr. Harrison—Back, by Dr. Benson—and Bile, by Mr. Brande, deserve great praise—Bladder, normal anatomy, by Dr. Harrison, and Bladder, abnormal anatomy, by B. Phillips, F.R.S., are not surpassed by any modern surgeons—Blood, by Dr. Edwards, and Blood, morbid conditions of the, by Dr. Babington, are perfect descriptions.

We entertain no doubt whatever, but that this will become a standard work in medical literature. It has, even now, an extensive circulation, and eminently deserves it.

1. *Education Physique des Jeunes Filles, ou Hygiène de la Femme avant le Mariage.* Par A. M. Bureau-Riofrey, M.D., &c. 8vo. Paris: Dulau and Co. 1835.
2. *Physiologie du Mariage, ou Meditations de Philosophie eclectique sur le bonheur et le malheur conjugal.* Par M. de Balzac. 12mo. t. ii. pp. 596. Bruxelles.
3. *L'Art d'Elever les Enfants, considerations sur l'Education Physique et Morale, aux Peres et aux Meres.* Par M. Froissant, Professeur, &c. 8vo. pp. 264. Paris: 1835.
4. *Nouveau Traité d'Hygiène de la Jeunesse, suivi des Maladies les Plus frequentes à cet age.* Par M. Simon (de Mentz), D.M., &c. 8vo. pp. 447. Paris: G. Bailliere. 1836.

1. *Physical Education of Girls, or Hygiène of Woman before Marriage.*
2. *Physiology of Marriage, or Meditations on Conjugal Happiness and Misery.*
3. *Physical and Moral Education of Infants, addressed to Parents.*
4. *A New Treatise on the Hygiène of Infants, and on the most frequent Diseases at that Age.*

THE first work on our list is very ably executed, and contains a correct account of the subject of which it treats. The author gives the physiology of woman at the different epochs of life, the influence of external agents on her economy, her temperaments, habits, hereditary predispositions, development, deviations and deformations, the importance of physical education, and the hygienic precepts, at every period of life. The work will be interesting both to the general and medical reader.

The second production embraces the physiology and hygiene of marriage, and its influence on morals. It is popularly written, and perhaps more intended for the public than the medical profession.

The third work is superficial, and intended for the perusal of parents.

The fourth is an excellent and scientific treatise, but its contents might be advantageously compressed. The author gives a very minute description of hygiene of infancy and childhood, and appends a history of the most common diseases of these periods of life.

We need scarcely observe that the hygiene and pathology of early life deserve as much attention as those of any other period; and it is to be regretted that so few works of this kind are to be found in our language.

—o—

RECLAMATION OF DR. COLLINS—PURITY OF THE ELECTORS AT THE DUBLIN LYING-IN HOSPITAL.

To the Editor of the London Medical and Surgical Journal.

SIR—As I doubt not your object is to publish facts in the Journal edited by you, I beg you will insert this communication in reply to the following observations in your review of a Practical Treatise on Midwifery, lately published by me.

In mentioning the Dublin Lying-in Hospital, you state, "The chief physician is elected by a few voters; that there is no grosser job in the medical offices in the United Kingdom; that the individual is invariably elected by family interest or intrigue; incompetent persons get appointed, and up to this hour none of them was ever able to publish even so imperfect* a volume as the present." You continue, "the election is a farce played for the purpose of excluding talent; the best proof of the evil results of it, is simply this, that masters were appointed who did not possess the slightest claim to preferment, while the most competent have been repeatedly, or rather invariably excluded—witness the exclusion of Doctor Montgomery and others."

The above statement is as unfounded as it is unconnected with the work.

The governors of the lying-in hospital consist of sixty individuals, according to the charter of the Institution. The following is a list of the present Governors and Guardians:—

President—His Excellency the Lord Lieutenant.

Lord Primate; Lord Chancellor, V. P.; Lord Mayor of Dublin; Bishop of Kildare; Commander of the Forces; Dean of St. Patrick's; Archdeacon of Dublin; Duke of Leinster; Archbishop of Dublin, V. P.; Fredk. French, Esq., V. P.; Lord Maryborough; Rev. J. F. Robinson; Earl of Charlemont, V. P.; Earl of Belmore; Alderman Sir A. B. King, Bart.; Rev. C. C. Berrisford; Lord Ashtown; Earl of Leitrim, V. P.; John Joseph Henry, Esq.; Richard Manders, Esq.; Abraham Colles, Esq.;

* "This report of obstetric practice is the most valuable in the medical annals of this or any other country."—See Ryan's Midwifery, p. 225; on Dr. Clarke's Hospital Report.

Samuel B. Labatt, M.D.; Lord Bishop of Cork; Provost, Trinity College; Lord Langford; Robert Collins, M.D.; Wm. Rathborne, Esq.; Earl of Armesley; Rev. Dr. Stewart; Acheson Lyle, Esq., K.C.; George A. Grierson, Esq.; Rev. Thos. Goff; Edward Litton, Esq., K.C.; Alderman West; John Chambers, Esq.; Rev. W. G. Wakeley; Viscount Bangor; Honourable John Plunket; Rev. Sir F. L. Blossie, Bart; Rev. Charles Boyton; Rev. Dr. Ebrington; Sir J. K. James, Bart.; Rev. John M. Staples; Alex. Montgomery, Esq.

Where, I would ask, could more competent governors be found in any country, and how does this agree with your uncalled-for assertion? As to the master being *invariably* elected by family interest, &c., and the most competent candidates invariably excluded, this is equally correct with the "*few voters.*"

I am the only individual who was connected with any previous master. I had the *distinguished honour* of being *unanimously* elected, and, I fear not, the governors, my professional brethren, and the public, consider I discharged the duties of my office satisfactorily.

As to the incompetence of my predecessors in office, it is sufficient to mention Drs. Clarke, Ivory, Labatt, and Pentland, to place *this* on an equality with the errors before noticed.

With respect to the exclusion of the respectable physician you named, he *never* was a candidate for the office of master, *nor could* he, as he has not been assistant in the hospital.

I regret extremely, sir, you did not seek information from some friend qualified to furnish you with a just statement, previous to publication, and thus avoid maligning the character of an Institution and its principal officers, which in cooler moments, I have little doubt *you* will also regret*.

I have, in conclusion, to thank you for the early notice taken of my work, and although you state we differ in opinion in many points, I feel we are both at liberty to advance what, from experience, we conscientiously believe correct. You have inadvertently given the table from my work containing the *proportion* in which some of the most eminent practitioners use both *crotchet* and *forceps*, as if the *latter* instrument had *alone* been used; by looking to this, you will perceive the inaccuracy of the remarks made by you, page 692.

My object in giving the statement I have done, on the use of instruments (see p. 28), was to shew that the crotchet was used by many continental physicians, and also by some in Britain, as frequently as in our

hospital, and by others much *oftener*, notwithstanding the forceps being in *constant* requisition.

I shall feel obliged by your directing your attention to the result of the tedious and difficult labours in the hospital, and the cause of death in such as proved fatal, which perhaps might somewhat lessen the difference of opinion between us respecting the use of instruments. See pages 25, 26, 27, 31, 365, and 487.

Hoping you will receive this communication in a friendly manner,

I am, Sir,

Your very obedient,

ROBT. COLLINS.

Morrison Square, Dec. 30, 1835.

—o—

The London Medical

AND

Surgical Journal.

Saturday, January 9th, 1836.

PURITY OF ELECTION AT THE DUBLIN LYING-IN HOSPITAL.

"Oh! save me from my friends."

IN our last number we exposed the dexterous manualism of the Dublin College of Surgeons, and we supposed we had done with medical abuses for some time in the sister isle. But scarcely had we concluded, when we received a letter from Dr. Collins, late master of the Dublin Lying-in Hospital, purporting to be a refutation of some unpalatable truths, which were declared about elections at that institution, in our late review of his work. Our correspondent requests us to publish his communication verbatim, which we do unhesitatingly, though it was rather unreasonable to expect us to insert the names of sixty governors, who, with the exception of three, are non-professional, in proof that this number should not be designated a few voters, though it will appear by the sequel that the real electors at the Dublin hospital are no more than *three*.

Admitting the whole sixty to have voted at any election, which is extremely improbable, as some of them are peers, others prelates, &c., and others non-residents in Dublin, what are the

* On reference to the evidence before the Parliamentary Committee on Medical Education, you will find mine strictly accords with this statement.

remainder but a few voters, compared to the governors of similar hospitals, that amount to one or two thousand? As to their competency as governors, it has never been questioned by us, though as electors it reasonably might be. Thus, what do the whole sixty, excepting the three physicians, Dr. Labatt, Dr. Collins, and Dr. Colles, know about the competency, or fitness, or ability of a candidate for the important office of master to such an extensive institution? Are the fifty-seven not likely to support the friend or candidate patronized by the three medical governors, who might perhaps be aptly designated "a few voters?" Thus, Dr. Clarke was father-in-law to Dr. Collins at the time of his election; Dr. Labatt was successor and friend to the former; Dr. Colles their colleague as consulting surgeon for many years—all having, from their eminence, the greatest influence with the said fifty-seven governors, which secured their candidate, and would exclude any other in Christendom. If this system of election is not a gross job, and if family interest is not occasionally employed in the selection of the master of the Dublin Lying-in Hospital, language has lost its meaning. That Dr. Collins "had the distinguished honour of being unanimously elected," under such circumstances, is only a strong proof of the corrupt system of election, and the family interest to which we alluded. There were many eligible candidates as well as himself, who not only had been assistant physicians to the hospital, but stood as high as obstetricians as he did; for example, Dr. Johnson, the Professor of Midwifery at the Royal College of Surgeons, Dr. Breen, Dr. McKever, &c., &c., the seniors of the candidate elect; but they were not connected with Dr. Clarke, or the other medical officers, and therefore stood no chance against his son-in-law. Each of them had published some valuable report from the hospital, or some papers in the medical

press of Dublin, and every one of them was in extensive practice. In making this statement, we intend no personal disrespect to Dr. Collins; but it is necessary to advance it against his defence of the purity of election of the master to the institution above mentioned. It also proves a part of our original assertion, "that masters were appointed who did not possess the slightest claim to preferment, while the most competent have been repeatedly, or rather invariably, excluded—witness the exclusion of Dr. Montgomery and others."

With respect to the eminent physician just named, it is said "he never was a candidate for the office of master, *nor could he*, as he has not been assistant to the hospital." Here is another proof of gross jobbing. Dr. Montgomery is Professor of Midwifery in the Medical School of the Dublin University and College of Physicians, Physician to a Lying-in Hospital, an elegant scholar, a learned, eloquent, and experienced professor, a popular lecturer, a most judicious obstetrician, but he could not be candidate for the office of master to the National Lying-in Hospital, as he has not been assistant to it; which means, that he had not paid £250 or £300 for the latter appointment; and even if he had, he would probably want that family interest, and that long established friendly feeling which exists between the three medical governors, whose names were already mentioned, and lose his election as others had before him.

In shewing the evils of the mode of election of masters at the Dublin hospital in question, we gave one, among other examples, "that incompetent persons get appointed, and up to this hour none of them was ever able to publish even so imperfect a volume as the present." To this Dr. Collins replies by adducing the following extract. "This report of obstetric practice is the most valuable in the medical annals of

this or any other country." (*Ryan's Midwifery*, p. 225; on Dr. Clarke's Hospital Report).

Does our opponent in argument seriously mean to urge, as a satisfactory answer, that a single report in one of the periodicals is a refutation of our allegation, that none of the masters was able to publish even so imperfect a volume as Dr. Collins'? We really never knew before, that an isolated report, and a "Practical Treatise on Midwifery, containing the result of *sixteen thousand, six hundred, and fifty-four births* occurring in the Dublin Lying in-Hospital," were works of equal importance—or that one was to be considered a book at all.

Dr. C. proceeds: "As to the incompetence of my predecessors in office, it is sufficient to mention Drs. Clarke, Ivory, Labatt, and Pentland, to place *this* on an equality with the errors before noticed." Now, we beg to inquire what original treatise, or what benefit, have the annals of science derived from any one of the above physicians, with the exception of Dr. Clarke's very few reports? But we never said they were incompetent, except as monographic or systematic authors; and this we fearlessly repeat.

We call on our correspondent for the names of their works, and until these are furnished, our position is incontrovertible. These physicians attained to great eminence as obstetricians in private practice, after the termination of their respective masterships; but that has nothing to do with the question at issue. Dr. Collins asserts that our remarks on the hospital were unconnected with a review of a work, whose contents were derived from the institution. We cannot assent to his assertion. In the first place, he brought the establishment most prominently before the reviewer in his title page, and several times in the work. Again, the hospital is public and not private property, and every physician in Dublin ought, in

justice, to have as good a right to the advantages which it affords in private practice—and these are numerous—as any one of the former or future masters, who was or may be connected with it. In fine, it being one of the largest in Europe, its masters ought to contribute as largely as those of much smaller institutions to the advancement of science. Dr. Collins is in error in stating that the reviewer "maligned the character of an institution, and its principal officers," for the character of the former was never mentioned, and that of the latter was given with perfect accuracy and truth. It was merely urged, that the principal officers of the institution had not published works even equal to that which gave rise to these observations; and that is a fact which cannot be denied.

It is however the system of election for seven years, and the mode of election, that has in some measure disqualified former masters from following the example of Dr. Collins. At the end of seven years the master retires, just when his observations and experience ought to be rendered valuable to the poor, and beneficial, in his capacity of lecturer, to the advancement of obstetrics. He then acquires extensive private practice, and the scientific world loses all sight of him. He is in great repute with midwives, the female part of society, and the ignorant part of the profession, though he has not gained any reputation for talent, industry, or usefulness among scientific practitioners, unless, like our opponent, he places his opinions among the records of medicine. Were it not invidious, we might mention the names of masters of that Dublin hospital, which are wholly unknown to the profession, except in Ireland. Notwithstanding the defence of our correspondent, the profession in Dublin have long entertained the opinions we have expressed of the establishment to which they referred; as a proof of this we may mention, that

other lying-in hospitals have been opened of late years in Dublin, although the national one is fully adequate to the wants of the population of that city. The national institution is virtually closed against all who have not private and family interest, or who cannot purchase some of its appointments. There are many physicians in Dublin, who could give an ample history of the monopoly in this institution; and we hope to be favoured with such account.

We request some of them to favour us with the particulars of a few of the elections; the number of voters at each, the politics and religious persuasion of the candidates, and all other interesting information. Perhaps our correspondent, who thinks the election so fair and "such a distinguished honour," would transmit to us the above information—and no one could do it better; and also who were the other candidates, when he was unanimously elected. The concluding part of Dr. Collins' letter requires but very few remarks. He has not complained of the reviewer, further than about a table as to the frequency of the use of instruments, which was accurately copied from his work, and which was headed as given in it. If this required to be elucidated, by reference to another in back of the text, the fault was not the reviewer's but the author's, as no reference was made to any other.

With regard to noticing other parts of Dr. Collins' work, we may probably do so on some future occasion, when convenience may permit; but the author ought to know, that weekly journalists have very little space for elaborate and lengthy reviews, which are only suited to the pages of quarterly journals.

We might dilate upon the preceding theme, if we were disposed to be severe critics, but we have adduced sufficient evidence to prove beyond the possibility of doubt, that the election at the Lying-in Hospital of Ireland for chief Physicians is injurious to the poor, and to the

interest of several, while it is most unjust towards the members of the medical profession.

—o—

PROFESSOR OF SURGERY IN THE UNIVERSITY OF EDINBURGH.

WE are much indebted to our correspondent SCOTUS for his information relative to the late election of Professor of Surgery in the University of Edinburgh, which will be found in another of our pages. It is lamentable to observe the conduct of some of our contemporaries with regard to the candidates. The reason will be obvious after the perusal of the communications to which we refer.

—o—

SURGEONSHIP TO THE RICHMOND HOSPITAL, DUBLIN.

THE government appointment of Mr. Adams, the Assistant Surgeon to the Richmond Hospital, as surgeon, was judicious and just. There can be no reasonable ground of complaint on this occasion, while public charities are conducted on the present plan, as a gentleman who has acted for many years as assistant surgeon to an hospital, more especially when he is eminently qualified, has a strong claim to the next appointment. Mr. Adams is a distinguished anatomist and surgeon, a popular lecturer, and one who has published many valuable surgical essays in the Dublin periodicals. He was recommended to the government in preference to all other candidates, by Mr. Crampton, Mr. Carmichael, and Mr. Colles, the most eminent surgeons in the Irish Metropolis, and each belonging to different hospitals. The appointment reflects honour on the Irish executive for doing justice to a gentleman of opposite politics, and also on those who recommended him, and whose personal interests were naturally very different. We are glad to perceive the dawns of a better spirit among the medical profession in Ireland; and we trust that in future, the religious and

political opinions of an able and talented individual will no longer depreciate his merit, or impede him in his professional career.

—o—

MEDICAL ATTENDANCE ON THE SICK POOR.

To the Editor of the London Medical and Surgical Journal.

SIR—My attention having been for some time past, intensely drawn towards the subject of medical attendance on the sick poor, I have read with much interest, and not a little disappointment, the communications of your correspondents and your own editorial remarks thereon. My disappointment has arisen in consequence of my having found the subject treated (as it appears to me) partially, and by no means in that comprehensive manner which its importance, and the various and *seemingly* conflicting interests of the parties concerned, demand. I say *seemingly*, because I hope to be able to shew that they are not *really* conflicting. With these impressions, I am induced to offer some observations, as the result of my experience, which I hope may assist in throwing some light on the matter and afford some data for deciding upon the *proper* remedy for the evil justly complained of. But I may here remark, *in limine*, that it will be perfectly useless to point out either the evils or the remedy, while the profession continues such a rope of sand as circumstances and the chicanery of its ruling corporations have made it. *Union* has done much, and will do more, in politics, and unless the present state of affairs should excite an *esprit du corps*, in which our body appears to have been from time immemorial most lamentably deficient, the exposé now in progress will only put *new* weapons into the hands of those who profit by our disunion, and by enabling them still further to effect division among us, will put us at last completely in their power.

While deeply sharing in the indignation expressed in Mr. Verral's communications, I perfectly coincide in the opinion so forcibly urged by yourself, namely, that the members of the profession have none but themselves to thank for what has happened. Angry they may be, but ought they to be surprised if, having eagerly and with all the virulence and malice of party medical politics engendered by contested elections for parishes and other *charitable(?)* institutions, contended for the *honour* of the appointments, those who elect do estimate them at their own valuation, and taking advantage of the competition in the labour-market, do enforce the maxim, "*divide et impera*," most inexorably against them? And here I would remark that Mr. V. is scarcely just towards his junior brethren, when he accuses

them of undervaluing their time and talents so greatly, for the purpose of superseding their seniors in these offices, inasmuch as Mr. V. acknowledges to having been himself underpaid as well as his contemporaries; consequently the presumption is fair, that both he and they have heretofore been guilty of the same offence. "They who have glass windows, should not throw stones."

Again, Mr. V. in his too evident anxiety to inculcate those who now seek these appointments, and to exculpate those who already possess them, attributes motives inconsistent with his own statements and at variance with the facts; and Mr. Bottomley indignantly repudiates the charge of being influenced by the *indirect* advantages afforded by these offices, rather than by the amount of the salary; at the same time admitting that the latter "is not at all adequate to the very great charge and heavy responsibility attached to them." Now, sir, with respect to parish appointments, I am prepared to maintain that in *no* case is the salary in the remotest degree adequate to the duties which are *contracted to be performed*; that where the surgeon has to supply medicines, surgical instruments, &c., which is the case in almost *all* country parishes, the salary cannot by any possibility assist in maintaining a family, inasmuch as it is insufficient to defray the cost price of drugs alone; aye, even if salts and water, and quassia chips, with second editions of the vegetable infusions, &c., were all that the diseases of poverty required. No, sir, it is worse than useless, it is foolish and mischievous to blink the fact, that it is the *indirect* advantages obtained through the medium of these appointments, which cause them to be so eagerly sought for; it is the patronage, the introduction to *better* practice, the suspended orders, the midwifery fees, the inquest fees, &c. &c., the monopoly of which is secured to the successful candidate: and this is one of the causes in operation in producing "envy, malice, and all uncharitableness" among the profession. In proof of my assertion I need only point to the fact, that appointments to hospitals, dispensaries, and other similar institutions to which *no* salary is attached, are not less the subjects of eager and unprincipled contention among medical practitioners. I say *unprincipled*, because I *know* that in the degrading practice of canvassing for these offices, all manner of electioneering tricks are resorted to to obtain the start of the rival candidate, to depreciate his abilities, and to bring *all* kinds and degrees of *influence* to bear upon the electors. Until the profession learns to respect itself, it will look in vain to be respected by the world. I have omitted to mention above, another advantage which a monopoly of these appointments gives to the individuals possessing them, namely, the facility of obtaining pupils with large premiums, to whose inexperience the practitioner too fre-

quently entrusts the task of discriminating between strangulated hernia and cholic, between Epsom salts and oxalic acid, in reference to his pauper patients, while his own time and *experience* are so much better employed in pocketing the fees and flattering the vanity of some purse-proud and gouty Parvenu or hereditary, hypochondriac aristocrat. The injury both to the "morale" as well as to the "physique" of the profession, of which we are only now beginning to be sensible, the neglect of the poor, of which some strong case is occasionally brought to light, but the ten-thousandth part of the *systematic* extent of which is never publicly known, as well as the ultimate cost to the public, but to which no allusion has hitherto been made, are all, more or less, to be traced to the before-mentioned monopoly.

It is evident, by Mr. V.'s own showing, that the guardians acting under the New Poor Law Act, have generally taken existing contracts for their guide; and although the cases cited by him are bad enough, I have no doubt that others might be found in which the medical officers, if they are not actually gainers, are at all events less of losers by the change.

Having extended my observations as far as I can, with any reasonable hope of their insertion in your excellent periodical, which I have taken ever since it assumed its hebdomadal form, I shall now conclude. In my next, I shall be prepared to enter more into detail, and shall most probably take that opportunity of indulging in a little jocularly at your expense, on the subject of the "maggot" in your head respecting "experience."

In the mean time, wishing you success in your efforts to effect a radical reform in our medical institutions,

I remain, very respectfully, your's,

ISAAC AARON, M.R.C.S.

Birmingham, Dec. 22, 1835.

—o—

PROFESSORSHIP OF SURGERY IN THE UNIVERSITY OF EDINBURGH—MALIGNITY OF THE MEDICAL GAZETTE.

To the Editor of the London Medical and Surgical Journal.

SIR—The independent and liberal manner in which you have always conducted your valuable journal, convinces me that the appeal I am about to make to your justice will be attended to. I am the more induced to make such an appeal, from the fact of your having, in your leader of last week, spoken so favourably of the appointment of Sir C. Bell to the Chair of Surgery in the University of Edinburgh. No one is more willing or more anxious to give that truly great physiologist and surgeon all the honour his merits will entitle him to, than myself. But, sir, there is another question involved in

this appointment; a question which, as it has been taken up not only by the medical, but the public press, should not be passed by lightly. It is that question, sir, which regards Mr. Liston as a candidate for the office to which Sir C. Bell is appointed; and the only fact in dispute is this—Could Mr. Liston have obtained the appointment, had he wished to do so, or could he not? Now, sir, the case stands thus—the *Courier* newspaper (London) states that Mr. Liston never did intend to accept of such appointment; and that when a proposition was made to him, by a highly respectable portion of the influential members of the town-council, to stand as a candidate, that he positively stated that he would "not leave London for any situation that could be offered him." This is fact, or falsehood. The editor of the *Courier* states, that he has seen documents which will prove it fact. You also state in your journal, nearly in the same words as those used in the *Courier*, the decision Mr. Liston had come to. I consider, then, that you also must have seen such documents, or you would not so positively state the circumstance. This is one side of the question; the other side rests mainly on the speech of the Lord Provost at the nomination of Sir C. Bell; in which the worthy magistrate states—that when the appointment was offered to Mr. Liston, he did not know there was any other individual between that gentleman and the chair. Now, did the Lord Provost know of Mr. Liston's having declined the honour of being elected? this is an important point—for on it the whole matter hinges; and one question put to the worthy magistrate, if answered, will put the matter to rest. Did he (the Lord Provost) fear, that, if it was generally known that Mr. Liston had refused the appointment, that Sir C. Bell would not have accepted it after such refusal? There is something more, sir, which requires mentioning regarding this dispute. The *Medical Gazette* has spoken of the article in the *Courier* as having been written by an indiscreet friend of Mr. Liston's; but, sir, did not the editor of the *Medical Gazette* strangely overlook, or wilfully mistake facts: he must have been strangely ignorant, indeed, on this matter, if he did not know that the article in the *Courier* was an answer to one which appeared in the *Scotsman* on the subject; and in which paper (or report contained in it) the dispute was foolishly begun by the friends of Sir C. Bell. But, sir, there appears to me to be a more indiscreet enemy to Mr. Liston, in the editor of the *Medical Gazette*, than an indiscreet friend to him in the *Courier*. I must confess I cannot see the indiscretion of defending the reputation of a gentleman, when that reputation is unjustly assailed. Perhaps the editor of the *Medical Gazette* is of a different opinion; he is certainly fond of wrangling—like Orlando, he is never happy if not tilting; or perhaps we might more justly

compare him to Don Quixote, so dreamy and so muzzy, and yet so "indiscreetly" valiant withal! The editor of the *Medical Gazette* states that Mr. Liston never could have obtained the appointment to the professorship; and makes such statement, too, knowing of the article in the *Courier*—thereby giving that journal the lie, and, of course, yours also. *His* lies are, however, so palpable, that he will never be suspected of having written a farce that was performed with success some years ago at the English Opera House, entitled, "He lies like Truth." With regard to the anonymous letters said to have been circulated in Edinburgh, disparaging to Sir C. Bell, and the effects of which were counteracted by the distribution of extracts from the *Medical Gazette*, I have only to say, that it was an excellent scheme of the worthy editor's, by which he might advertise his journal—

"We made the giants first, and then
We slew them."

Now, sir, I appeal to your justice for the insertion of this letter. I do it the more readily from this fact, that you have always given Sir C. Bell the honour that is justly due to him—that in your late *leader* you spoke of his appointment with great satisfaction; therefore, neither you or myself can be suspected of wishing to detract from the merits of that truly great man, but that our object is truth.

Yours, truly,

Edinburgh, Dec. 24.

SCOTUS.

—o—

THE CHAIR OF SURGERY IN EDINBURGH.

To the Editor of the London Medical and Surgical Journal.

SIR—As an addendum to my last, perhaps you will be good enough to insert this note. Your worthy contemporary, the *Medical Gazette*, in the last Number, has given what he calls "a last word touching the Chair of Surgery in Edinburgh." The veracious Journalist, finding he had got in the wrong box, and that his bullying and blustering were properly appreciated, tries to sneak out of the matter, as one might expect such a person would. Sterne used to say, that when he "could not fight with the *devil*, he used to run away from him." But, he of the *Gazette* has tried the battle, and, having got well drubbed, sneaks off, firing a shot, as harmless as his shots generally are. He says, "We conjectured that some unauthorized individual had asked Mr. Liston to become a candidate, and he, knowing how matters stood, very wisely said he would not. It now appears that Mr. Dick was the individual. *This is the whole of the matter.*"

Now, as it happens this is not "the whole of the matter," but it is that part of it which

might serve Master Greenhorn's malicious wishes. The other part, which gives a rather different look to the matter, is simply this—Mr. Dick is the convener of the Town Council of Edinburgh, in whom the appointment to the surgical chair is chiefly vested. Let me ask the hireling scribe a question. Was it likely that the convener of the Town Council would write to Mr. Liston, offering him the appointment, if authority was not given for that purpose? Here then ends the matter, which stands pretty much thus: that the *Medical Gazette* has eaten its own words; the best proof of this is a reference to the three last numbers of that veritable organ of monopoly; the malignity displayed in the articles regarding Mr. Liston is so glaring, that it deserves only to be mentioned that it may be despised. I need not state that Mr. Liston is lecturer at St. George's; the *Gazette* man is in the opposition school—*Jam satis.* Yours, &c.

HISTORY OF MEDICINE IN CHINA.

THE following is an account of the medical writers and doctrines, as they have existed and do now exist in this mysterious empire. It is the work of a writer in the "Indo-Chinese Gleaner," a periodical that appeared at various dates in the years 1817 and 1822 inclusive, and conducted by the indefatigable missionaries in that quarter of the globe; and among others by the celebrated Dr. Morrison. The work is exceedingly rare in this country, and this joined to the curious nature of the subject, renders all excuse for extracting the article unnecessary.

"We feel particularly happy in giving publicity to this paper, for two reasons: the first is, that the subject of Chinese medicine has not, that we are aware of, been laid before the British public. The second is, that the paper appears to have been read before a select number of gentlemen in China, who have, it would seem, formed themselves into a Society for the purpose of investigating the natural history, &c. of that country, and from whose united researches, much new information may be expected. We cordially wish them success. We shall rejoice in their every step in the path of science. We shall have great pride in giving publicity to any documents they may wish to be generally known; and it may be satisfactory to our medical readers to know, that we have reason to expect a series of papers on the subject of this one, which we shall, by the earliest opportunity, lay before them."

"Gentlemen, the Chinese, whom I venture to pronounce the most unique, and the most original people at this day on the face of the earth, look at medicine in two points

of view, a favourable one, and an unfavourable.

"1. The sincere, diligent, candid, and benevolent practitioner, who toils for the health of his neighbours, and fellow-countrymen, they regard as holding a place equal in importance to that of the virtuous minister of a powerful monarch, who is a blessing to the empire. On the other hand, he who has no higher motive than his own emolument, and who from his ignorance, or his fool-hardiness, as often kills as he cures, they regard with sovereign contempt, and feel ashamed that such men should be called by the same name as the sincere votaries of the healing art, who by a very appropriate and honourable distinction, they call *jìnshùh*, 'the benevolent art.' The ideas I have thus put into English, are taken from the preface of a work in forty volumes, compiled by the united efforts of about a hundred persons, connected with the Imperial College of Physicians at Peking, during the reign of the late decided and prosperous monarch, known by the name or rather title of *keen-lung*, which, being interpreted means, 'celestial glory.' This book, which is the latest national work in China, on the subject to which this paper has a reference, was published about A.D. 1740.

"2. There is an individual and private work, in eleven volumes, printed not more than fourteen years ago, entitled *E-shoo-hwuy-tsan*, 'a comparative compendium of Medical Books:' this is the latest publication which has any pretensions to particular notice, that I have seen. In the year 1819, being desirous of procuring information on the Chinese notions of diseases and their cure, I bought all the books on medicine which were to be found in the populous and opulent city of Canton. They amounted to 892 volumes. I need scarcely add, as my other avocations are well known to you, that I have not yet been able to examine the contents of these books, to that extent which I could have wished; or rather, did and still do wish to effect.

"3. I shall this day furnish you with a few general notices on the history of Chinese medical practice; and at the same time would observe, that I by no means anticipate very important and useful discoveries from the Chinese in this department of human knowledge; for, since the genius of Bacon threw open the gate of experimental science, the European mind has outstripped all that ever preceded it, in the accuracy and the extent of its knowledge. However, you are not unacquainted with my maxim, which with reverence I adopt from an inspired and a divine author, viz. that 'it is more blessed to give than to receive.' I know it is a much more ungracious task to teach than to learn; for the assumption of superior knowledge, however justly it may be claimed, commonly offends one's pride; whereas, he who becomes a scholar flatters

our vanity: this is a difficulty in our way; but, I would ask what honourable and benevolent course is not attended with difficulties? Let us therefore resolve to go onward.

"4. In the case of men so remotely situated, and of such a different speech, and discordant manners, and habits of thinking, as Englishmen and Chinese, a most discouraging difficulty *in limine* is, how to understand each other on physical and medical facts and theories; therefore, as I have before hinted to this Society, great patience is necessary in our pursuits; and one must learn a great deal of nonsense, in order to be able to refute it.

"5. The imperial work above referred to, is entitled *E-tsung-kin-keen*, 'a Golden Mirror of the most approved Medical Practice.' All books in China referring to medicine that could be procured by purchase, or by loan, were collected, and traditional popular MSS. were sought by the order of government. In four years it was completed. In this work it is maintained, that in the remote ages of antiquity, medicine, and the affinities and correspondencies in nature, were better understood than at any subsequent period.

"Chinese writers attribute the ascertainment of the properties of herbs to *Yen-te*, the illustrious monarch, an antediluvian personage, in their annals placed about 3000 years before our era. This illustrious King *Yen-te*, is otherwise called *Shin-nung*, which appellation means, 'Divine Husbandman.' About the same time lived; another king, *Heen-yuen*, and a statesman, named *Ke-pih*, who, with the monarch just now named, formed by their personal efforts a sort of Royal Society, for physical and medical research in China; and in allusion to them, medicine is sometimes called 'the art of *Ke-heen*.' To *Ke-pih*, the origin of *Tszechich*, i. e. 'impuncture,' is attributed. There are two fragments, yet extant, attributed to *Ke-pih*, and which, (according to the imperial editors, and other writers) are the most ancient notices in China, concerning the cause and cure of diseases.

"6. The first of these fragments is called *Lingchoo*, 'the intellectual hinge,' perhaps meaning, that turning point, that crisis, which determines the connexion, or the final separation of soul and body. The other fragment is entitled *Soo-wan*, 'plain questions,' and refers to, or contains the result of certain consultations between *Heen-yuen* and *Ke-pih*, on *splanchnology*.

"7. Both these medical fragments are given in the work published fourteen years ago, by a private hand, to which I referred in the beginning of this paper. They are considered more ancient than the classical books, collected and edited by Confucius; but how their authenticity and genuineness are traced I know not. The style of these, like that of several other ancient medical

writings, is obscure, and abstruse to modern Chinese students. In these fragments, the circulation of the blood is recognized; whether in the form of a note or not, I am not prepared to say: however, there is little doubt, that as early as the days of Galen, the Chinese believed, and taught, and acted on the belief, that the blood, and a certain animal spirit, or subtile aura, circulated, or went round and round the human body, without intermission day or night, as long as life continued. But, up to the present time, I believe, they are ignorant of the manner in which it does perform its circuit, and of the structure of those canals, the veins and arteries, which convey it.

(To be continued.)

MEDICAL BOTANY.

PLATE XII.—STYRAX OFFICINALE.

Off.—The balsam, called Storax.

This tree grows in the Levant, Italy, and France. The storax flows from wounds made in the bark, in countries where the heat is sufficient; for neither in France nor in Italy does it furnish any. Storax occurs in three forms. The best kind, *St. in granis*, is in grains, either distinct or slightly agglutinated, of a yellowish or reddish-yellow colour, about the size of a pea, as soft as wax, tough, and having the smell of the finest vanilla. It is probably the product of spontaneous exudation, and is not now to be procured. The second kind is in masses (*St. in massis*), of a clear brown or reddish colour, less translucent, resinous, pieces agglutinated by a clammy substance. This is also rare, and now occurs in bladders. Formerly it was sent packed in the leaves of a reed, and hence called *Styrax calamita* or *canaliculata*. It likewise has an agreeable smell like balsam of Peru, an aromatic balsamic taste, and is inflammable. The third kind, which almost alone occurs in commerce, and is sold as *St. calamita*, is common storax, *St. vulgaris*, *Scobs styracis*. It is totally different from the preceding. It consists of large, light, compressed, clear brown, round or shapeless masses, which externally are not unlike peat turf, easily friable. It is evidently a compound of sawdust and other foreign substances with genuine storax, or is the residuum of black Peruvian balsam after decoction. When good, it should, by pressure between two hot plates, yield a fluid brown resin, smelling like storax.

Storax has an agreeable smell and an aromatic taste. Neumann got from 480 grains, 360 alcoholic, and 30 of watery extract; and inversely, 120 watery, and 240 alcoholic. In distillation it yielded benzoic acid. It is therefore a balsam, or natural combination of resin with benzoic acid.

Medical Use.—It is employed for perfuming wax lights, or for fumigations.

Leeches.

M. Noble, head physician to the hospital at Versailles, has invented a successful plan for breeding leeches in a reservoir made for the purpose. A quantity of potters' clay is put into the vessel, in which they deposit their cocoons, and in which they shelter themselves from cold and storms.

ESSAY

UPON SOME POINTS OF THE HISTORY OF CATARACT;

*Thesis presented to, and sustained before, the
Academy of Medicine of Paris.*

By THEODORE MAUNOIR,
OF GENEVA,

*Doctor of Surgery; Member of the Medical
Observation Society.*

TRANSLATED

By ALEXANDER THOMSON, M.B.
Of St. John's College, Cambridge.

"Observer la nature, rassembler beaucoup de faits pendre leur ensemble pour principes Qui sommes nous pour nous détourner de cette voie."—BICHAT, *Œuvres Chirurg. de Desault*.

2. Commencement and Progress of the Disease.

THE commencement of cataract may be slow or rapid, occur in both eyes simultaneously, or in a single eye, be sensible to the patients, or altogether unperceived, &c. &c. Let us study these different points of view.

In the greater number of cases cataract commences slowly; the patients perceive that their sight declines, they see objects through a slight mist, and most frequently perceive that this disturbance of the vision is owing to the weakness of a single eye, while the other is still perfectly healthy; that is what has occurred in 52 of 60 patients; in the other 8, to whom 2 must be added, who were operated on in 1830, and indicated the facts without its being demanded of them, the commencement occurred in a more or less abrupt manner. The first was a man of 57 years of age, writer in an office; he went to bed one night after his usual labour, without having remarked the least weakening of his sight; the next day, on awakening, he could scarcely see sufficiently with it to find his way: both eyes were equally affected.

The second was a military man of 42 years of age, who, when marching from Valence to Paris, had his sight very good; in the space of one night, and without any known cause, it became very indistinct.

A third, a field labourer, aged 62, perceived one morning that he saw the objects as it were surrounded by a mist; he was certain that the day before he had nothing similar. Both eyes were equally weakened; however, it was only two years afterwards that he ceased to be able to conduct himself alone.

The fourth, whom I have elsewhere mentioned, was a coach guard, who, at the age of 65, lost the sight of his left eye in the space of some days, after having gazed intently at the sun.

A fifth was a soldier, aged 59 years: his case was similar to the third.

The sixth presents a case rather curious. A journeyman, aged 47 years, one day, in the streets, perceived, for the first time, that his sight was doubled; he shut his eyes alternately, and discovered that the right eye was completely lost; the left was very good. Three years later, while he was occupied in reading a journal, his second eye, which had in no way declined, became all at once so weakened that he was unable to finish his reading. Five or six weeks afterwards he could no longer see his way.

The seventh was a French captain of the empire, aged 62 years. One morning he felt intense itching in one eye, which lasted almost incessantly for three days, and obliged him to rub it forcibly. At the end of the third day the sight of this eye was gone: the other eye declined five years later, and was lost in two months.

The eighth was a gate-keeper, 50 years of age. One of his eyes had been slowly affected with cataract for about four years back, but the other was so good he was in no way uneasy about it. One Sunday, after a walk, he went to bed as well as usually; the next morning he could no longer distinguish more than light from darkness, and the contour of large bodies, but without being able to guide himself.

Of 26 women, forming part of these 62 patients, two only have presented analogous particulars.

In one, aged 35 years, the first eye became slowly affected with cataract; two years afterwards the other declined rapidly, but the patient could guide herself for four or five months afterwards. In the other,

who was a sempstress, aged 28, the first eye was likewise slowly lost. About three years afterwards this woman, after having, according to her custom, sewn all day long, perceived that her sight declined rapidly in the evening; the next morning she no longer saw sufficiently with it for sewing: three or four days afterwards she could no longer recognize her relations, and at the end of a week she could not see her way.

It is worthy of remark—

1st. That in these ten cases two only relate to women, although the number of these be not very inferior to that of men.

2nd. That of these ten patients two only had exceeded 62 years, four were between 50 and 60, and four under 50.

3rd. In three cases the commencement has occurred in a rapid manner in both eyes at once; six times, on the contrary, only one eye has been lost rapidly; in the seventh patient the commencement has been equally abrupt in both eyes, but at three years' interval.

4th. Finally, this kind of commencement has not appeared to have any unfavourable influence upon the definite result of the operation; indeed, of fourteen cases operated on, nine have been with complete success.

Cataract generally commences by affecting one eye: this has occurred in 63 patients out of 72. The right eye has been the first attacked in 35 cases, the left in 28. In nine cases, on the contrary, both eyes became weakened at the same time. Finally, it sometimes happens that persons affected with cataract have not perceived the loss of the first eye until, on accidentally closing the other, they discovered the more or less complete loss of the faculty of seeing. This mode of commencement is not even very rare: it has occurred in the ninth part of the cases in 72 patients. It is a thing at once worthy of remark, and difficult to comprehend, that some individuals will immediately perceive a trouble in the vision, from the fact alone of one of their eyes commencing to be weakened, while others do not even suspect that on one side their sight is completely lost.

There is a point, the discussion of which naturally finds its place here. Can cataract frequently remain limited to one eye during many years, and even during the whole life? or when its existence is on one side, is there a greater chance that the second eye will be more or less rapidly affected by the same disease?

The solution of this question, which at first seems only curious, may however become of the highest practical interest. Indeed, were it demonstrated that, in certain cases, the prevention of a second cataract could be accomplished, or a spontaneous cure could be obtained when it is commencing, by the fact alone of having operated upon the first eye affected, it is con-

ceivable that it would be very important not to observe the rule generally given, of not undertaking the operation until both eyes be affected with cataract. I know that this spontaneous cure of cataract is doubted by most surgeons; but it must be said that they very rarely find themselves in favourable circumstances for verifying the fact, since there are few who consent to operate on one eye before the second be affected. Opinion is not, however, unanimous upon this point; thus Wenzel has seen a person already aged, who, operated on successfully for one cataract in the right eye, would not have himself operated on for the other. Twenty years after he met with this same person, and was astonished to learn that he distinguished equally well with the left eye. This person related to him that the faculty of seeing had returned *progressively* to this eye without the employment of any means. He observed, however, that the left pupil was a little yellowish and opaque at its superior part. The same author asserts that he has moreover seen similar facts. Saint Yves mentions the case of a man wounded in the right eye; a short time afterwards this eye was affected with cataract, and the left eye soon shared the same fate, but the sight was re-established spontaneously when the right eye had been operated on. Finally, an English author of our days, Mr. John Bowen, in a small work, in which he proposes a new method of operating, declares positively that a diseased crystalline cannot be too soon operated on; "since," says he, "cataract of the second eye may be prevented by operating early on the first." He mentions, in support of his opinion, the example of a monk, on whom he operated at Rome, on the right eye, for cataract of six or seven years' duration; the opacity commenced in the left eye; it disappeared entirely after this operation, which was perfectly successful. The same author also relates a passage of Wardrop, which seems to him to confirm his views. "There is," says this last, "a disease of the eyes frequent among horses; it has the appearance of a specific inflammation—it attacks first one eye, then soon afterwards affects the other, and sooner or later destroys vision. Some veterinary surgeons know that if the eye which is the first affected come to suppurate, and to be destroyed in its orbit, the disease does not at all attack the other eye, or that it is arrested if it has already been declared therein; consequently, they have adopted the method of destroying at once the diseased eye, in order to save the other. They accomplish this object by piercing it with a nail, or by introducing quicklime between the eyelids."

I have not myself seen anything relative to the subject of which I am speaking; what I have just reported, I have done so in order to shew that it is *possible* that one day it may be important to know what chances there

are of having two cataracts, when one has already formed. I shall recur to this last question.

The answer generally made to it is the following:—When one eye is affected with cataract, the second eye is *most frequently* affected with the same disease. I am far from denying the fact; but I maintain that it is not so easy to establish as may at first be thought. Indeed, it may very well be objected, that if so many double cataracts are seen in the hospitals, and even in persons of the higher classes, it is so because in the greater number of cases the individuals who preserve one eye healthy do not seek the succour of surgery; and what would seem to favour that opinion is, that those even who have two cataracts, frequently do not apply for advice until their sight is weakened so as to hinder them from following their usual occupations—that is to say, that very frequently they have kept a cataract on one side for a longer or shorter time, without thinking of having it removed. Why should it not be the same, it may be said, with a great number of individuals who remain all their lives affected with cataract of one eye?

I am about to state what I have observed upon this subject, and what are the reasons which, according to my opinion at least, may lead to the belief that the general opinion is indeed the expression of the truth. Of 69 subjects who were received at La Charité during the autumn of 1832 and the spring of 1833, in order to undergo the operation for cataract, *one only* was affected with this disease on one side. It had existed for at least thirty years, and he had only thought of coming to seek advice because some slight spots had for a year back been developed upon the other eye, and slightly troubled his vision. Of 52 other patients who were operated on in 1830, ten were only affected on one side; unfortunately, I have not, in the ten cases, indicated what was the state of the other eye. In a *single one*, it is said expressly that one of the eyes was perfectly healthy, but the other had been affected with cataract only for a year back. Something analogous existed probably in one, or perhaps two, other patients. I must state, however, that of this I have no certainty. Thus, then, in 121 subjects, there have been found but two who very certainly had but a single cataract; again, it was only in one of the two that this affection was of a very remote date.

But the objection made above, representing itself here, other means of determining what is in reality the relation of double to single cataracts must be sought for; or, if it be considered,—1st. That in 72 subjects in whom it has been possible to fix the commencement of cataracts, there are 9 in whom that commencement has occurred in both eyes at the same time.

2nd. That in 8 only of these 72 subjects

one of the eyes was already completely lost without the knowledge of the patients, when they perceived that the second eye was declining; and that, consequently, it will be only in these eight patients that it may be strictly supposed that the first cataract has existed *alone* during a very considerable time; a thing which is neither proved, nor even probable, from what follows:—

3rd. That in all the others the second cataract has commenced some weeks, some months, or at most from three to five years after the first; that in two only it has commenced ten and twenty years later.

4th. Finally, that for 47 individuals in whom it has been possible to determine with some precision the time elapsed from the commencement of the first cataract to the moment in which the patient was incapable of guiding himself, the whole of that time, as I shall state farther on, has only been of five years and one month. If, I say, all these circumstances be brought together, we shall be induced to conclude that a first cataract (or, if it be wished, the cause that has produced it), has appeared to have almost constantly an influence so approximate upon the state of the other eye, that it is little probable that a cataract will be met with *single* for many years together, since, when there are two, they have generally succeeded each other after a rather short time. Nevertheless, that this kind of round-about solution is far from being correct, I admit; an appeal from it must be made to direct observation. However this may be, one thing is worthy of observation, that there is a remarkable difference between cataracts, which nobody will deny very frequently attacks both eyes, and other diseases which seldom affect more than one organ. What more rare, for instance, than to find cancer attack both the breasts or testicles? And yet is not the similarity of organization and of functions as complete between the two breasts and testicles as between the two crystallines? Is not the exciting cause of cancer as deep-rooted in the organization, when once developed, as that of cataract?

Progress.—There remains little for me to add upon the progress of cataract; it has been constantly slow and uniform, except in some cases already mentioned, in which it has been as rapid as the commencement of the affection had been abrupt.

The patients generally perceived the mists surrounding them become thicker, little by little, and without sudden changes, until at length they could no longer guide themselves. Sometimes the disease, after having commenced slowly, has made rapid progress in a few days, or even in the space of a night. Thus, in the case of a man whose eyes began to be weak at 59 years of age, cataract had increased so slowly that after five or six years he still could guide his

self; then, without any apparent cause, and in the space of a night, the blindness became complete.

In the case of a woman, of whom I have already spoken, an erysipelas of the face appeared to very much accelerate the progress of the disease.

In a third, finally, the commencement and the progress of the two cataracts had been slow; she still saw well enough with one eye to undertake a journey alone, on foot, of five leagues, after which the cataract made such progress, that at the end of three days it was necessary to lead the patient to her home.

3. *Symptoms and Diagnosis.*—The symptoms of cataracts are well known; however, as some are not generally agreed upon, I shall examine them in detail. Besides those drawn from the inspection of the eye, others are found in the sensations experienced by the patients.

SECT. I.—Thus, a uniform mist, which incessantly becomes more dense, envelops every object, and terminates by hiding them completely from the sight, is constant in all individuals affected with cataract.

SECT. II.—But, in more than three-fourths of the cases, other sensations are joined with this. Thus, in 59 persons affected with cataract, 13 only had never perceived anything but that uniform mist; the other 46, on the contrary, had had very various illusions; they used to see coloured ribands, diamonds, flashes of lightning, flames, brilliant luminæ, brilliant rings, serpents appearing to crawl before them, sometimes at the commencement, in a transient manner, sometimes at a more advanced epoch, and sometimes during several years successively. But, of all these illusions or imaginations, as they have been called, by far the most common was the frequent, or even continual presence of one or several black flies, vaulting sometimes before one eye, sometimes before both. In 33 of the 46 subjects in question, that sensation existed alone, or united with some of those that have just been indicated. I have inquired whether they did not depend upon the spots, the various striæ that are seen, as I shall state hereafter, frequently marked enough upon the opaque bottom of the pupil; but that is an explanation which it has been absolutely necessary to renounce, as two-thirds of the subjects who had experienced these sensations had cataracts completely uniform in aspect.

It would be very useful to study carefully, in a great number of individuals attacked with blindness, all these visual sensations of which the cause is unknown; perhaps it would be the means of arriving at the best sign of recognizing the disease, when the examination of the eye is insufficient, and for removing all doubts. Indeed, opinions are far from being unanimous upon

the differential characters of amaurosis, for instance, and of cataract, in the difficult cases. Thus it is that professor Marjolin, in the article *Amaurosis* of the *Dict. de Médecine*, says, that vision being better laterally than in front, is a sign peculiar to cataract, since persons affected with amaurosis do not see better, in whatever position the object may be. On the contrary, Beer and Richter (quoted by S. Cooper) pretend that in amaurosis it frequently happens that the patient can still see in a determinate position. Richter goes further; according to him, as it is the centre of the eye that appears the most frequently affected in the *gutta serena*, it happens that the greatest number of patients, having a commencement of amaurosis, always see the objects better situated laterally than those placed in front.

SECT. III.—I cannot say what happens in amaurosis; I have not observed a sufficient number of them; but what is certain is, that in cataract it is by no means rare to meet with this symptom spoken of by Professor Marjolin, and which, moreover, is well known. It must not, however, be believed that it can very frequently be determined; many patients have not directed their attention to this, and can give no indications upon the point. Of 46 persons affected with cataract, 23 were in this state, of the other 23, 15 had very well remarked, that there had been a period at which they had distinguished lateral objects much better than those directly in front of them; 8, on the contrary, have affirmed that they have frequently tried every species of position without any success.

SECT. IV.—There is another kind of sensation stated by some authors to be peculiar to persons affected with commencing amaurosis; that is, seeing artificial light, and very much enlightened objects, as it were, surrounded by a rainbow aureola; it is likewise being affected with double vision (*diplopia*). I do not know what occurs in amaurosis, but at least those phenomena do not exclusively belong to this last affection: they are met with, though rarely, in cataracts. Thus, of 25 patients questioned on this point, 3 stated that artificial light appeared to them surrounded by rainbow colours; and assuredly none of them was amaurotic, for the extraction of the crystalline restored them to their sight, at least on one side. In almost all, the flame of a lamp appeared to be a very voluminous globe of fire.

SECT. V.—Nine of them experienced other sensations besides; some, in place of one light, used to see two or a greater number; others, round the principal light, which appeared to them very large, used to perceive a multitude of small flames, which seemed to proceed from it; in one of them, the flame of a lamp appeared to be multiplied 20 to 30 times, when he was remote

from it, but it again became single as soon as he approached it; finally, one man, when he looked stedfastly at the moon, thought that he saw several luminous globes, and an artificial light did not produce an analogous effect on him. It would be curious to try whether the same sensations exist in the amaurotics, and in what proportion they are met with.

SECT. VI.—It is known that the subjects affected with cataract present this peculiar phenomenon, at least, in the early periods of their disease: they see better in a rather obscure, than in a brightly illuminated place, before the rising and after the setting of the sun. This fact is very well explained by keeping in mind the changes that occur in the dimensions of the pupil. In persons affected with cataract, just the same as in individuals whose eyes are perfectly healthy, the pupil contracts when the eye is exposed to rather a vivid light; it dilates, on the contrary, in the opposite circumstances. Or, the thickness of the crystalline diminishing in a very rapid manner from the centre to the circumference, and the opacity in cataract being generally less at the periphery than at the centre of the lens, it is clear that the images of bodies must arrive much more readily to the bottom of the eye if the luminous rays fall upon the crystalline nearer to its circumference. But this phenomena of dilatation and contraction of the pupil, which are constant in the individuals affected with cataract, while it very well accounts for what they experience in passing from a vivid light into a place comparatively dark, seems to me to be a rather powerful objection against the species of intimate dependance generally admitted between the iris and the retina. Indeed, if it be true that in the normal state of the organ of vision, one of the functions of the iris be to contract the pupillary opening proportionally to the quantity of light received by the retina, in consequence of a sort of consensus between these two membranes, the first regulating constantly and solely its movements according to the wants and the impressions of the second, how happens it that in cataract, a disease which in no way changes the normal state of the retina and of the iris, which only interposes between them an opaque veil, how, I say, happens it that this sort of consensus, this species of intelligence of the iris is so perverted that the movements of that membrane are no longer regulated by the impressions received by the retina, but only according to the quantity of light that it receives, since it contracts in daylight, so as to annihilate altogether the faculty of vision? This objection seems to me to be so forcible, that until further elucidated, I should prefer admitting that in the normal state the iris can move not only under the dependance of the retina, but likewise under the direct influence of the light that strikes upon itself.

This mode of considering it accounts both for what passes in cataract and for what occurs in the natural state. I know it may be objected that in amaurosis the iris is most frequently immoveable, and seems, by this state of paralysis, to follow the state of paralysis of the retina; but the objection exists, I believe, more in the words than in the things. What proves that amaurosis is in all cases a paralysis, properly so called, of the retina, and even that the disease is seated in the retina? Absolutely nothing; it is declared that there is paralysis of the retina, because the transparency of all the media of the eye is seen to persist, while the sight is abolished. But why may not the cause of the disease have acted primitively upon the ophthalmic ganglion, and the branches of the fifth pair, as well as upon the other nervous parts of the apparatus of vision? Moreover, is not amaurosis very frequently seen as a symptom of a material appreciable lesion of a limited portion of the cerebrum or even of the cerebellum, without the least change being found either in the retina or in the optic nerve? How, in these cases, does the retina paralyse the iris, since it is very manifest that the cause of blindness exists in the nervous centres and not elsewhere?

Finally, there is no need of having observed a great number of amaurotic cases to know, that the sight may be totally annihilated while the iris preserves the integrity of its movements. I shall again remark, as proof of the possibility of the independence of the retina and of the iris, what occurs when extract of belladonna is applied upon the eye: the pupil dilates, remains immoveable; and if the dose of the topic has not been sufficiently considerable to procure drowsiness, the sensibility of the eye to light is by no means diminished by it; this is a palliative means, which has been recommended for rendering the sight momentarily more distinct, in the case of commencing cataract. I recur to the subject which has drawn me into this digression. If, in the greater portion of persons affected with cataract, the sight acts more distinctly in obscure places than in the broad daylight, particularly in the commencement of the disease, yet the thing does not always occur. Thus, of 55 subjects, 45 have declared, that from the commencement of the affection, they had seen better in an obscure place, than in a place strongly lighted; in a small number, this difference has ceased at the end of a certain time; or even the reverse has occurred; but the greater part, at the period when they were operated on, still presented this peculiarity. Of the other 10, 4 have affirmed that they had not at any time seen better in the shade than in the sun; 6 finally have declared that they had always seen far better when they were exposed to a broad day light, or even in full sun light, than in the opposite circumstances. The last fact,

though difficult to comprehend, is not the less certain; I have employed the greatest care in determining it. It will, moreover, soon be seen that some doubts may be raised upon the simplicity of cataract in two of these cases.

CLINICAL LECTURES,

Delivered at the South-Eastern General Dispensary, Dublin.

BY DR. M'ADAM.

Pathology and Treatment of Dysentery.

GENTLEMEN—Towards the conclusion of my last lecture, we entered on the consideration of dysentery. I endeavoured, in the first instance, to convey a clear idea to you of what was to be understood by the term; in other words, to determine what morbid action existed in this affection, and in what texture it was seated. I mentioned Cullen's view of its pathology, who conceived the disease to depend chiefly on a preternatural constriction of the colon, occasioning spasmodic efforts which caused the gripings and tenesmus in this disease; this view, I think I proved to you to be partial and erroneous, to be in fact mistaking an effect for a cause—a very common error in medical reasonings. Yet you may recollect, I observed that an acquaintance with this, as well as with several other erroneous theories broached by ingenious and original thinkers, is not without its use; our being aware that it is refuted by more enlarged observation, will prevent our falling into a similar mistake; and an acquaintance with the theory, impresses on our memory an important feature in dysentery, namely, the occasional existence of spasm or spasmodic constriction, which, undoubtedly, is present in many cases, not indeed as the first cause, but as an effect of the irritation produced on the muscular parietes of the large intestines by the inflammation of the contiguous mucous membrane, and perhaps in some instances by the partial propagation of the phlogosis to the muscular coat. Having dismissed Cullen's theory, we next mentioned Dr. Johnson's, who conceived dysentery to be caused by a preternatural quantity of blood being determined to the venous system of the intestines, in consequence of the suppression of the perspiration and biliary secretion; and that the discharges were efforts of nature, to relieve the congested parts from their unusual load of blood. I observed that this view was near the truth; it is probably an accurate account of the pathological state of the parts in the incipient stage of the disease: the first deviation from a healthy condition of the intestinal mucous membrane in dysentery being probably what Andral calls an hyperemia, or an increased quantity of blood in the vessels of the part; and thus is

most likely caused, at least in a great degree, by a suppression of the cutaneous and biliary secretion; but it appears to me, that this in itself is not sufficient to cause dysentery. The vessels of the mucous membrane might be gorged with blood, and relieve themselves by intestinal hæmorrhage, as occurs in melæna or in hæmatemesis, or might establish hæmorrhoids or other vicarious discharges, yet neither melæna, hæmatemesis, or hæmorrhoids, are dysentery. Dysentery is something more than a mere hyperemia of the mucous membrane: it is accompanied with re-action, altered secretion, and more or less fever; in fact it is a true inflammation of the mucous membrane of the large intestines, exhibiting the constitutional, and as far as we can detect, the local symptoms of inflammation during life, and presenting the usual effects of inflammatory action on mucous membranes after death. We came, therefore, to the conclusion that Dr. Mason Good was correct in his definition of dysentery.

You may recollect in my first lecture, I mentioned that the term colonitis had been recently applied to dysentery, which expresses the nature of the disease much more correctly than the latter word; but it appears to me that Cullen and other writers who used this term, employed it in a more restricted sense than is at present understood by the appellation colonitis. By dysentery, Cullen and his followers meant a certain group of symptoms, viz. mucous or sanguinolent discharges, the fæces being retained; and by the term colonitis, we understand an inflammation of the mucous coat of the colon, which is not necessarily, though it may be generally attended with dejections of this character, nor are the natural fæces always retained. The fact appears to be, that when the whole or the greater part of the colon is simultaneously inflamed, a discharge of its contents will most usually take place, though the reverse may happen and the inflammation may suspend secretion and peristaltic action; but when in dysentery, the lower part of the colon and rectum are the only portions inflamed, we shall have in general mucous stools, urgent tenesmus, and retention of the natural fæces. The fact is, the two words mean essentially the same disease, but dysentery has been more frequently applied to that form of colonitis, in which the lower portions of the large intestines are principally affected, and the fæces retained. Having settled this point, I beg leave to revert to what I said in my first lecture relative to the pathology of diarrhœa; I stated that its slightest and simplest form consisted merely in *increased secretion and quickened peristaltic action*; that a more severe degree of the same morbid state produced *permanent morbid irritability and altered secretion*; and that a still more intense grade of the same affection of the mucous

membrane constituted true inflammation with its products, blood, pus, or lymph; and that this latter stage is the disease we usually call dysentery. Diarrhœa and dysentery we find thus to merge into each other, and it is impossible to define exactly the line that separates the most severe form of diarrhœa from the mildest degree of dysentery. I may be thought guilty of some repetition in this short retrospect, but I am anxious to convey a clear idea to the mind of the junior student, of the manner in which gradations of the same morbid action give rise as they advance to different symptoms, and constitute often what nosologists are pleased to call different diseases. I shall now proceed to give you a short outline of the history of dysentery, and afterwards make a few observations on its treatment. The disease is divided into three species; 1st, simple dysentery; 2nd, dysentery accompanied with fever; 3rd, dysentery complicated with other diseases.

The simple form is sometimes preceded by slight rigors followed by heat of surface, thirst, and other pyretic symptoms; but not unfrequently it commences without any fever. It often begins with a common feculent diarrhœa, which gradually assumes the form of dysentery; at other times the peculiar symptoms of the disease appear at the very onset, followed by some degree of fever; and in a third class of cases the attack is preceded for several days by wandering pains in the bowels: it is probable that when it begins with a discharge of natural fœces, a large portion of the colon is simultaneously inflamed; when it commences with mucous stools without natural evacuations, that the lower portion of the colon and rectum are first attacked; and that when wandering abdominal pains are the first symptoms, that the intestinal mucous membrane is generally in an irritable or phlogosed state. In whatever manner it commences, its peculiar characters soon manifest themselves; one of the most remarkable of which is, frequent and distressing tenesmus, and after long continued and painful straining, nothing but a little mucus mixed with more or less blood is voided: the patient suffers much from these reiterated and ineffectual attempts to evacuate his bowels, which are often attended with acute pain in the abdomen and griping; these symptoms are generally exasperated during the night, and attended with more or less symptomatic fever, and sometimes with vomiting: there is, occasionally, permanent abdominal pain and soreness on pressure, though this is by no means constantly present. The urine is scanty and high-coloured, sometimes passed with pain and difficulty, and delirium in some instances occurs. It is of importance to attend to the appearance of the alvine discharges, which vary considerably in character; 1st, we have fœces of natural quality; 2d, scybala; 3d, mucus; 4th, blood;

5th, fleshy or sebaceous matter; 6th, membranous shreds; 7th, pus. These, of course, do not all occur in the same case; scybala, mucus, and blood frequently appear together, though sometimes the two latter only are present; we shall consider each of these discharges separately.

1st. *Fœces of Natural Quality*.—These, as we have before mentioned, frequently appear in the early stages of a case of dysentery, in which when fully formed, the other discharges are the only matters passed. They are also frequently voided towards the termination of an attack of this disease, and their return is to be considered as a favourable sign, the griping and tenesmus abating or wholly disappearing at the same time. But besides being often the beginning and end of this affection, the natural fœces in some instances continue to be passed through the whole course of the disease; this is the simple dysentery of Dr. Good, which is only attended with slight fever, with some degree of tormina and tenesmus, and perhaps a little mucus and blood. It is to be considered as a mild inflammation of the colon, with little or no spasmodic constriction, the presence of which retains the natural fœces.

2nd. *Scybala*.—These are small hardened lumps of fœces moulded into globular masses in the cells of the colon. They are by no means constantly present; I have met with cases of some severity, where I could not discover them, and Dr. Cheyne, in his History of the Dysentery which prevailed in Dublin in the year 1818*, states, that in no instance could he detect them, though every other variety of excrementitious matter was seen in the stools. They generally appear only in those cases where the fœces are retained, and they indicate that spasmodic constriction of part of the colon exists. Their expulsion, whether affected by nature or art, is productive of relief to the more urgent symptoms of tormina and tenesmus.

3rd. *Mucus*.—This is a very frequent appearance; sometimes it forms almost the only evacuation in dysentery—when it constitutes the dysenteria alba or morbus mucosus of the old writers; but it more generally is mixed with blood, or with other evacuations; it is to be considered as the result of increased secretion, produced by the mucous follicles of the intestines participating in the inflammatory irritation of the membrane in which they are seated.

4th. *Blood* is a frequent appearance in dysenteric stools; its quantity varies very much: sometimes it is only in streaks, mixed with fœces or mucus; in other cases it is passed in large quantities, forming almost the entire of the matter voided. It has been supposed to be always the consequence of ulceration; this is the case in some instances, but it may be also the result

* Dublin Hospital Reports, vol. iii.

of various other morbid states. In some instances it is produced by exhalation from the overloaded vessels, or is the consequence of the abrasion of the mucous coat, and consequent rupture of minute vessels; or it may proceed from the bursting of small arteries or veins, from over-distention and increased action; or, according to Sir John Pringle, the blood may flow from the debilitated mouths of the vessels while open, on the internal coat of the intestines. We thus see that intestinal hæmorrhage may arise in this disease *from simple exhalation, from abrasion of the mucous coat, from ulceration and consequent erosion of vessels, from simple rupture of vessels, from debility and atonic relaxation of vessels, without rupture.*

5th. *Fatty or Sebaceous Matter.*—Certain substances, compared by different observers to fat, suet, cheese, or lumps of flesh, are occasionally voided in dysentery; it is probable that in different cases they assume all these various appearances; their origin is obscure, but it appears most reasonable to suppose that in some cases they are the result of a peculiar diseased secretion; in others, they may be some portions of undigested aliment, or be some of the other productions of the disease, such as blood, mucus, or lymph, solidified and condensed in consequence of being retained in the cells of the colon, and compressed there by spasmodic constriction.

6th. *Membranous Shreds.*—I have occasionally seen these substances in dysenteric stools; they resembled small portions of cuticle. They have been supposed to be abrasions of the mucous coat, but others think them to be inspissated mucus; it appears to me more conformable to analogy to consider them to be coagulable lymph, the result of inflammation, and in this respect identical with the membranes expelled from the trachea and bronchia in croup, or from the intestines, in that form of diarrhœa denominated tubularis by Dr. Good.

7th. *Pus* is sometimes voided in dysentery; this is frequently, though not necessarily, a consequence of ulceration, as we know that purulent secretion may take place from a mucous membrane, without any solution of continuity.

Besides the results above mentioned, the fæces in dysentery may assume various other appearances. They may present a drab colour or resemble starch, or be of a light or dark-green, or present the appearance of sanies. It would be a useless task to consider all the varieties which the alvine discharges may exhibit in this disease; but it is well to be aware of the principle, as a knowledge of them is not only of use in illustrating the pathology of dysentery, but may also assist us in our prognosis and diagnosis, and afford, in some cases, an important guide in practice. For instance, feculent stools in the early part of the disease, would indicate the propriety of pur-

gatives; in the latter stages their appearance indicates a relaxation of spasm and a restoration of healthy action to the intestinal canal. Scybalæ point out the presence of partial spasmodic constriction, and would suggest the propriety of opiates and emollient enemata, followed by purgatives. Mucus in large quantities would evince considerable irritation of the mucous membrane, and lead us to suspect that the natural fæces were retained by spasm. Copious discharges of blood will sometimes require the use of astringents, which are not at all proper in the early stages of the disease, or indeed at any time, unless when the hæmorrhage is excessive, and evidently connected with atonic relaxation. It is obvious, therefore, that a close attention to the appearances of the discharges is not unworthy of the physician, who should not despise any means in his power that may assist him in forming a more correct judgment of the nature and suitable treatment of the diseases which it is the business of his life to alleviate or cure.

Many other symptoms may exist in dysentery, besides those we have considered. Dyspnœa is sometimes present, and is occasionally caused by the co-existence of peritonitis. Great distention of the abdomen occurs in some cases, and may arise from the same cause, or from the mere loss of tone of the muscular parietes of the intestines, and the generation of flatus. Very great thirst occasionally prevails, and probably in most instances is connected with an inflammatory state of the gastric mucous membrane: vomiting may take place, the matter ejected being either bilious or stercoraceous. It has been well observed by Dr. W. Philip (On Febrile Diseases, section on Dysentery), "that by an attention to the local symptoms of dysentery, we may sometimes determine what part of the intestines is affected. If the small intestines be the seat of the disease, the pain is often very acute, and twisting round the navel; the sickness and vomiting, and the pain and flatulence of the stomach, are more urgent than when the disease is confined to the large intestines; the fæces are not passed immediately after the griping, and the blood is mixed more intimately with the other parts of the stools. Hiccup, when it occurs at a late period, is a bad sign, but when early and obstinate, we may suspect that the inflammation is seated pretty high in the abdomen; when the disease is seated in the large intestines, the pain is more obtuse; when the stomach and smaller intestines are much affected, there is in general more sickness than griping, and when in the large intestines, more griping than sickness." The worst cases of dysentery sometimes prove fatal in a few days, during which the patient is reduced to the last stage of debility. If he lives many days, the emaciation is extreme. It may prove

fatal, either from the patient's sinking from mere debility, or the inflammation terminating in gangrene; or perforation of the parietes of the intestines may be caused by ulceration, and a rapid and fatal peritonitis be induced in consequence of the escape of the contents of the bowels into the peritoneal cavity; but more frequently the symptoms become mitigated, and the disease subsides into the chronic form. An unfavourable termination may be expected when the debility is extreme; the pulse feeble, the extremities cold, the tongue furred and brown, or glazed, red, and aphthous, the stools dark-coloured, and extremely offensive, the skin cold and clammy, with partial sweats, the face hippocratic;—such a group of symptoms indicate gangrene. A favourable result may be hoped for when the fever is mild, the appetite in some degree continues, the abdominal pain, tenesmus, and frequent inclination to go to stool diminish, natural evacuations appear, and the skin becoming soft and moist.

Such are the principal phenomena which simple dysentery presents, but this disease may be complicated with fever or other affections: even some degree of symptomatic pyrexia generally attends the simple form. Sometimes a real idiopathic fever co-exists and may even precede for some days the local symptoms. Many respectable authorities consider this form of dysentery contagious, especially its combination with typhus. Dr. Harty asserts that simple dysentery is never contagious, nor its combination with remittent or intermittent fevers, but only when complicated with typhus. Others have supposed that the contagion may arise from the effluvia of the feces, which they conceive may even excite a real typhus without any affection of the bowels; but Dr. J. Johnson, of London, asserts that he has seen dysentery in every possible situation—in the east and in the west, in the north and south, in public and private practice, in fleets and camps, and that he never saw a single instance of contagion. In my more limited experience, I never could trace a single case of dysentery to contagion, and I have met with the disease pretty often within the last five or six years. I do not however mean to assert that it may not occasionally assume this character, especially when combined with typhus; this may be probable, though I do not think it proved beyond a possibility of doubt, because it may happen that dysentery may be epidemic at a time when typhus prevails, when of course we shall have many cases where the two affections co-exist without its necessarily following that the former was derived from contagion. We know also that, when an epidemic prevails, certain organs will be peculiarly susceptible of disease, even in persons in apparent health. If, then, the epidemic influence should affect the alimentary canal when typhus is raging,

it is extremely probable that a large proportion of the cases affected with the latter disease will have the fever, as it were, determined to those parts; in other words, have inflammation excited in the intestinal mucous membrane.

Dysentery may be combined with different grades of inflammatory fever, according to the season of the year, and many other causes. The symptoms, of course, will be modified by the nature of the accompanying pyrexia; the local symptoms will be nearly the same, with some aggravation. It is not, however, my design to go into a consideration of all these complications, my object being to give you a short history of the common sporadic dysentery. This disease may also be combined with agues, inflammation of stomach, or other abdominal viscera, and not unfrequently with peritonitis. Of this latter complication I have a case at present under treatment, which I hope to present to your attention at our next lecture.

I shall now give you my view of the treatment of dysentery, which I shall deduce principally from my own experience.

The indications are obvious enough, and are these:—

1st. To reduce the inflammatory action in the affected parts.

2nd. To allay the fever, if considerable.

3rd. To evacuate the bowels, and restore healthy secretion.

4th. To soothe irritation and alleviate urgent symptoms.

I have seldom met with cases of dysentery which required general bleeding, but such do occasionally occur; and we may conclude it to be necessary when the pulse is full, or small and contracted, the attending fever of an inflammatory type, the stools consisting chiefly of bloody mucus, and the abdominal pain constant and much aggravated by pressure. A moderate bleeding of 16 or 18 oz. in such cases produces the best effects: it relieves the pyrexia, abdominal pain, and soreness, and causes the bowels to expel a large feculent stool, when, previous to the venesection, even purgatives failed in bringing away anything like a healthy evacuation. Another benefit is also obtained: both the bowels and the system are rendered more susceptible to the action of remedies, consequently, if we want to salivate or purge our patient, our desire will be greatly facilitated by the previous bleeding; the good effects, then, of abstraction of blood are threefold, viz.:—

1st. It lowers vascular action, and consequently relieves the fever and local inflammation.

2nd. Resolves spasm and enables the bowels to expel their contents.

3rd. Renders the patient more easily affected by either constitutional or local remedies.

In most cases local bleeding will be suf-

ficient, and is preferable when the febrile excitement is not very high, or the abdominal pain and tenderness not very intense. It is indicated if the abdomen is permanently tender on pressure, and some pain is felt there in the intervals between the attacks of griping and tenesmus. In such cases we shall derive much benefit from the application of from 10 to 30 leeches to the abdomen, followed by fomentations continued for some time; after which, we may apply a warm poultice to the parts. The leeches may be applied a second or third time, if the abdominal pain and soreness is not removed by the first application.

In by far the largest proportion of cases, however, little or no abdominal pain or soreness is present, except during the paroxysms or griping; in such circumstances, bleeding or leeching may be dispensed with; and our object should be to evacuate the bowels, restore healthy secretion, allay irritation, and relieve urgent symptoms. The medicines which I have been in the habit of using for these purposes, are mercurials combined with opiates, alternated with mild purgatives, fomentations, aperient and opiate enemata.

The combinations of mercury and opium which may be most advantageously employed are, 1st, blue pill and Dover's powder; 2nd, blue pill and watery extract of opium; 3d, calomel and opium; 4th, hydrarg. c. creta, with Dover's powder, or opium.

Any of these combinations will be more or less useful in the majority of cases; but the practitioner should always endeavour, after having ascertained the nature of the disease, to discover the peculiarities of each individual case, and to modify his remedies, so as to suit these peculiarities; this is one of the great distinctions between the scientific physician and the empiric: the latter has a certain set of medicines for the removal of certain diseases, which he employs indiscriminately, and it is a chance whether he does good or harm; but the former is aware of the infinite shades of variety which the same morbid affection presents in different individuals, and studies to vary his remedial means so as to suit these modifications. Generally speaking, blue pill and Dover's powder may be given advantageously in dysentery, in the following proportions:—
Rx. Pil. hydrarg. $\mathfrak{d}\mathfrak{j}$; Pulv. Doverii, 3 ss m. in pil. xii æqual. dividend sumat ii, 4tis 6tis vel 8vis horis. This combination is adapted to restore healthy secretion, allay irritation, and re-establish the action of the skin; but in some cases, where the stomach is very irritable, Dover's powder may be objectionable; in such instances the blue pill and watery extract of opium will be the most suitable. In other cases we may wish to bring the system quickly under the influence of mercury: then calomel and opium will be preferable; from gr. xii to gr. xx of calomel may be combined with from

gr. iii to gr. iv of opium, and divided into four or six pills, one of which may be given every four or six hours. Again, the bowels may be in a very irritable state, and I have known calomel, or even blue pill, disagree; we may substitute the hydrarg. c. creta, of which we may give $\mathfrak{d}\mathfrak{j}$ or 3 ss. in divided doses, in the course of 24 hours, combined with the same quantity of Dover's powder; or, if pills be preferred, we may combine each dose of the mercurial with from gr. ss. to gr. i of opium. Whatever form we employ, we may continue the mercurial and opiate; either until the system is affected by mercury, or until the local symptoms are relieved, and natural evacuations are established.

Suitable purgatives will assist much in accomplishing these objects. Castor oil, in doses of from half an ounce to an ounce in mint water, if the stomach will bear it, is perhaps the best; but it occasionally causes vomiting or griping: in such cases, I have been in the habit of giving an ounce of the phosphate of soda, in chicken broth or gruel, or small doses of the sulphate of magnesia in mint water, or the tartarized soda in saline draught, or cream of tartar, which is much recommended by Dr. Cheyne. These medicines will be materially assisted by occasional enemata of tepid gruel, mixed with olive or castor oil. By some or other of these means we should endeavour to procure one or two dejections every 24 hours. The opiate and mercurial should be given in repeated doses during the afternoon and night, and on the following morning we should intermit their use for five or six hours, and endeavour to move the bowels by the means we have just mentioned. In this manner we give the patient a chance of a good night's rest, undisturbed by the operation of the purgatives, and also afford the mercurial time to act on the secretions. After pursuing this plan of treatment for 24 or 36 hours, I have in general observed all the symptoms to become mitigated, and healthy fæces begin to appear; and when this is the case, we may expedite matters by a moderate dose of rhubarb and sulphate of potash, after which we should continue the mercurial and opiate in diminished doses, and attend to the state of the bowels for some time after all urgent symptoms have subsided.

The diet should consist of small quantities of farinaceous substance: in the latter stages rice is the most suitable, and the patient may allay his thirst with whey, barley water, or imperial, according to his taste.

Besides this general plan of treatment, peculiarly urgent symptoms may require our especial attention: vomiting is often very troublesome; it may depend on sympathetic irritability of the stomach; in such cases there will be no epigastric pain or tenderness on pressure, or it may arise from gastritis co-existing with dysentery, when pain and soreness on pressure will be detect-

ed in the region of the stomach. Sympathetic vomiting may be relieved by saline draughts, with tincture of opium, or by a blister to the epigastrium; that arising from gastritis will require leeching and blistering, and the other treatment suitable to inflammation of the stomach.

Tenesmus is one of the most distressing and constant symptoms of dysentery: I have known nothing more effectual for its relief, than an enema of from 30 to 60 drops of tincture of opium in two or three ounces of starch mucilage; it sometimes acts like a charm, and gives the patient a good night's rest; but it will not always succeed, and when it fails, a few leeches applied to the verge of the anus, will often be attended with the best effects; this tenesmus appears to be owing to an highly irritable or inflammatory condition of the lower portion of the rectum; in giving opiate enemata, therefore, in such cases, we should administer them in very small bulk, otherwise the stimulus caused by the distention of the intestine will only excite its contraction, and cause the expulsion of the enema, before the opiate has time to exert its sedative influence. This is a point of some practical consequence; the quantity should seldom be more than two or three ounces, which will be often retained when an enema of five or six ounces would be expelled. Gripping is often troublesome, and may be relieved by cloths wrung out of hot water, or decoction of poppy heads, or dry warm flannels sprinkled with spirits of turpentine; I seldom use blisters in this, or indeed in any other abdominal disease. I think, in general, they may be dispensed with; their application deprives us of a valuable means of ascertaining the degree of sensibility of the abdomen to pressure, which is such an important guide in practice; and if they should cause strangury, it would prove a distressing complication, especially to a patient already labouring under an abdominal disease, and might cause an extension of the inflammation to the bladder. The turpentine fomentation may be managed so as to produce a considerable rubefacient effect, and is much preferable to blisters.

These are the symptoms which most frequently demand particular attention. In the latter stages of the disease debility may supervene, and require the use of wine and other tonic remedies; or the sanguineous discharge may be in great quantity, attended with considerable weakness and other symptoms indicating an atonic state; in such cases astringents may be necessary, and the acetate of lead and opium, as before recommended in diarrhoea, may be useful. I shall not enter into the consideration of the treatment of chronic dysentery at present, as I think it probable that cases illustrative of this form may present themselves to your notice before the end of this session. What I have been just stating refers principally to

the common cases of acute sporadic dysentery of this city, of which I have had most experience, and which we not unfrequently meet with in our dispensary practice. I have now a very interesting case under treatment, of dysentery complicated with peritonitis, which I shall present to your attention the next time that I have the pleasure of addressing you; on which I will make a few comments, and also take a short view of inflammation of the peritoneum.

—o—

THE CONNEXION OF PHYSIOLOGY AND PATHOLOGY.

A Paper read before the Medical Society of the London University.

THE object of this paper is to shew how far disease may be considered as originating, or at least making its progress in obedience to certain laws impressed on our nature for the well being of the species at large.

There are those who, unwilling to ascribe anything to chance, consider bodily affliction or diseases as visitations from the Almighty, and prejudice leads many to ascribe to Divine agency that which is in fact the work of man. For it is not by any imperfection in the primitive fabrication of the human body that we are subject to disease, neither is it by any direct dispensations of Providence that we suffer them; but it is by man acting contrary to the dictates of reason, and seemingly striving to subvert the operations of the physiological process, that disease is engendered. Hence man, in his condition of natural liberty, is comparatively free from disease; whilst, under the restraints of an over refined civilization, or in the enjoyment of pernicious luxuries, the number of his ailments become prodigious. The wild beasts, ranging at large after their natural habits, preserve their community from disease; but, incarcerate them, and so deprive them of their proper exercise, or debar the cow from its proper pasture, and you soon have them die of phthisis, of which fact the London dairies in the one case, and the Zoological Gardens in the other, afford ample testimony. Now, the notion of ascribing disease to the direct operation of Divine agency, does appear to me as absurd as the ancient doctrine of the heathens, in which they were considered to be sent down to the earth from Jupiter, enclosed in a box entrusted to Pandora, and subsequently let loose by Epimetheus.

But, waiving the consideration of the causes of disease, it is in the progress of them that we are most clearly enabled to trace the working of the laws of physiology; and in order to do this, as it was impossible to embrace the examination of all the diseases of structure in a paper confined within the limits usually assigned to the papers of this Society, I was necessarily compelled to

make selection of those which seemed best adapted for the elucidation and proof of the argument, that the forms and the nature which disease assumes depends entirely upon physiological laws.

I have taken induration as the first subject for consideration, because the first physiological change perceptible in the ovum is the increase of consistence.

Induration.—The only change comprehended under this head, which can be said to constitute a simple disease, is that of bulk. Under change of bulk is included hypertrophy and atrophy, and changes in the quantity of the fluids of secretion and nutrition, as conditions which are not unfrequently accompanied with an increase of consistence of the otherwise natural and healthy texture of organs. Hypertrophy, however, is the only state in which increase of consistence can be regarded as a simple disease, inasmuch as it does not depend on the presence of a foreign product; the increased consistence in such case being a consequence of a superabundant molecular deposit of nutritive matter of a homogeneous kind, in a tissue, and arranged in a normal order. But that an increase of consistence depending on these circumstances should follow, it is not necessary that it should be accompanied by any change of bulk of the organ in which it is observed; for there may be hypertrophy without change of bulk, from the mode in which the additional deposit takes place. The most remarkable examples of morbid increase of consistence depending on an augmentation in the quantity of healthy solid material which enters into the composition of organs, are met with in those which are naturally soft; as in the medullary and cortical substance of the brain and spinal marrow, in the lymphatic and salivary glands, and in the cellular and muscular tissues, and even in those tissues which are naturally firm and hard, as the fibrous and osseous in which the induration is sometimes extreme. The brain has not unfrequently been found increased to twice and even thrice its natural consistence; that of glandular, cellular, fibrous, and muscular tissues become so hard that they occasion a particular grating sound when cut; and the walls of some hollow organs, naturally soft and flaccid, acquire such a degree of firmness that they preserve, when empty, a globular or cylindrical form, and spring up with considerable force after sudden pressure, and parts of bones acquire that degree of hardness that it has been called *eburnoid* or *ivory-like induration*. The state of induration which we have been considering in the solids, whereby their consistence is increased, applies also to the fluids of nutrition and secretion. The various degrees of fluidity which these products are found to possess appear, in fact, to present us with some of the most simple forms under which the various degrees of consistence of matter can

be subjected to our senses, at least in so far as regards the materials of organic composition. Various degrees of fluidity of the blood are observed, from a watery thinness to a state of inspissation approaching to coagulation; which last is perhaps a manifestation in an extreme degree of one and the same property. It is indeed highly probable that the consistence of blood depends principally on the fibrine which it contains, and may vary in degree with the quantity and quality of this important constituent—an opinion the truth of which appears to be proved by the fact that coagulation of the blood is no other than spontaneous solidification of the fibrine. The opposite state, or extreme fluidity, produced by frequent hemorrhage, or bloodletting, reduces this fluid to the consistence of serosity, chiefly by the removal of the greater part of its fibrine—a further evidence of the influence which fibrine exercises on the consistence of the blood. The consistence of the blood is always increased by whatever reduces the velocity of the circulation below the healthy state. The blood that first flows from a vein in phlebotomy is not only dark but thicker than that which escapes some time after, on account of its having been brought to a state of rest by the constricting force of the bandages, and as the buffy coat is generally increased under similar circumstances, it would appear that fibrine had already assumed a disposition to coagulation; for cessation in the motion of the blood, even when limited in duration, is always accompanied by a tendency to separation in its constituent parts, and to coagulation of the fibrine. Hence it follows that ligatures, tumours, and other mechanical obstacles, situated in various parts of the body, and certain adynamic states, as local and general debility, which retard or arrest the motion of the blood, occasion, in the manner just stated, inspissation and coagulation of this fluid—effects which often lead to other diseased states, that sometimes terminate in death.

Insipissation of the bile is a common occurrence, particularly in the gall-bladder; there, as in the blood-vessels, the transit of the respective fluids must be more or less impeded by such a change. The formation of gall-stones appears in some instances to depend chiefly on this condition of the bile, which being thus prevented from passing along the ductus communis choledochus, undergoes the chemical changes necessary for the formation of these accidental products. It will be interesting now to trace the correspondence between these pathological changes of consistence, and certain corresponding physiological conditions, in order to shew that the connexion of physiology with pathology is so great that they are in fact identical processes; for instance, at the different periods of life, infancy, manhood, and old age, the consistence of the various tissues of the body, and consequently

of organs presenting great variety. In the first they are soft, spongy, largely imbued with fluids, easily torn and broken; in the second, firm, more compact; the fluids are less abundant, and the solids resist considerable efforts to tear or break them. In the last period, the proportion of fluids is still less, and the solids have arrived at their maximum of density and cohesion, so that the degree of softness or induration, *equal to that which characterizes even the extremes of certain pathological states, constitutes the peculiar character of certain parts at the different periods of life.* Thus, the brain of the newborn infant, the mucous membrane, and even the muscles of organic life, are so soft as to be ruptured or broken down into a pulp by a slight degree of pressure or traction, just as we find to be the case in softening of these parts from disease in after life. On the other hand, in advanced life the cellular tissue, membranes, particularly serous and fibrous, the muscles and tendons, bones, the brain and nervous system, and particularly the uterus and ovaries, acquire a degree of hardness equal to that which is known to be produced by certain diseases.

The changes of consistence which are observed to take place under these different circumstances, although sometimes great in degree and extent, are nevertheless to be regarded as physiological conditions, and which mark in a particular manner the intermediate stages and extremes of life. Thus, when the phenomena of organization are about to manifest themselves in the impregnated ovum, nothing is discovered but a colourless liquid; organs, when first perceived in the embryo, are a mere jelly, and during their development, and in proportion as they approach to the perfect state, do they acquire a gradual increase of consistence. This progressive increase of consistence keeps pace with their development, and does not acquire that degree which belongs to each tissue or organ in particular, until it has arrived at a perfect state of formation. Now, we cannot but perceive here, that the degrees of consistence must serve some important end; that even the almost fluid state of parts is not to be looked upon as a mere consequence, either of an entire want or of an imperfect state of organization, but that it is a condition of organs, or of the materials of which they are composed, subservient, if we may so speak, to the elementary acts of life; a condition which facilitates the transitions of form which organs must present before they can attain their more permanent and perfect state. By means of this condition of organs, whether transitory or permanent, nutritive elements subservient to growth and development, find a nidus fitted for their reception, and fluids every facility for passing in whatever direction they are wanted; organs are moulded to the forms of the parts destined to receive and protect them; and

numerous relations of bulk, position, and situation, &c., are reciprocally adjusted between the containing and contained parts, as the changes which they undergo may render it necessary, in order to maintain the integrity and to secure the well-being of each. When, then, we meet with examples of pathological induration, we may, I think, regard them but as the result of the operation of a physiological law, necessary to enable the ovum to arrive at maturity, and the various tissues to assume their proper degrees of consistence as life advances.

Transformations.—All the simple tissues, except the muscular and nervous, are subject to the ascending and descending transformations. As to the mode of their production, they originate in all parts in a process similar to that which presides over normal tissue, therefore they must be under the same laws. Some of the transformations of accidental tissues which occur just as in naturally existing tissues, depend on accidental circumstances: thus accidental cellular tissue must remain as such when formed in the larynx, and is not exposed to motion. But when formed on the surface of the pleura or peritoneum, when constant motion occurs it becomes serous. If placed where its secretion escapes, it becomes mucous, and if in the situation of the head of a dislocated bone it assumes the character of a synovial membrane, of cartilage or of bone. Therefore the nature they assume depends on that of the function they are called upon to perform. They are regulated by the same laws as those of normal tissues; they are not transformed except under the same circumstances as the normal tissues are, as physiological phenomena: thus, accidental cellular tissue is produced by changes in the coagulating lymph. Soon after its effusion, coagulating lymph assumes a reticular appearance: it is cellular, and the cells are filled with albumen. The coagulated lymph is most frequently effused on free serous surfaces: cellular and mucous tissues are as often inflamed, but instead of coagulating lymph, we hear more frequently of pus; or the lymph is absorbed, and therefore no accidental tissue, is found. As to accidental serous tissue, it differs from cellular tissue only nominally; for, normal or anormal, they both consist of the same materials, in the one case cellularly arranged, in the other laminated. The function of both is to connect and facilitate the motion of contiguous parts, and both secrete the same fluids; hence they replace each other with much facility. The circumstances determining its *transformation* into mucous tissue, are similar also to those which regulate the *formation* of this tissue in the development of the embryo. And should that tissue be exposed to the influence of the atmosphere, that condition alone is sufficient to make it acquire the properties of cutaneous tissue. So also the further transformations

into the fibrous, cartilaginous, and osseous textures, are but so many instances of changes in the ascending series precisely corresponding to what is observed during the progress of the fetus towards maturity; there is not therefore a distinct and separate law which presides over the anormal production of these tissues, and another different law which regulates the original formation of them in the healthy subject; no—the same law manifests its operation in both cases, and that law is a property impressed upon certain forms of organized tissues, rendering them capable of assuming a different disposition, in proportion as they are called upon to perform different functions—a general physiological law.

The new Formations.—Scirrhus or Carcinoma and Tubercles.—Mr. Abernethy referred all adventitious formations to the coagulable part of the blood as their origin, and fixed their seat in the cellular tissue, the parenchyma, and on the surface of organs. This plastic substance was supposed by him to be effused in one or other of these situations, to become organized, and to derive the materials of its subsequent growth from the vascular system of the surrounding parts.

The principal varieties of cephaloma are derived from the appearances which the carcinomatous substance presents either in different organs or in different stages of its development. When it presents the appearance of firm coagulating lymph or fibrine deprived of the red colouring matter of the blood, possessing an uniform and fibriform or lobuliform arrangement, with a certain degree of transparency and vascularity, Mr. Abernethy gave it the name of *common vascular or organized sarcoma*. If uniformly disseminated throughout the texture of an organ, so as to transform it into a substance resembling a section of a mammary gland, the application of *mammary sarcoma* was given it by Abernethy; when in colour and consistence similar to the substance of the brain, *medullary sarcoma*.

As to the cause of the deposit assuming one or other of these varieties, no distinct line of separation can be drawn between them; for the carcinomatous deposit when first formed, and indeed frequently for a considerable length of time after its formation, does not furnish us with any signs which shew that it will or will not become organized. Numerous examples have been met with by Dr. Carswell, of scirrhus, medullary sarcoma, and fungus hæmatodes, as they are commonly called, originating in the same morbid state, and passing successively from the one into the other in the order in which I have named them. Indeed, all the varieties are often met with, not only in the same individual, but even in a single organ.

The blood-vessels which enter into the composition of the carcinomatous matter,

vary greatly in number, and sometimes also in bulk. In cephaloma or fungus hæmatodes they present that peculiarity of distribution always more or less conspicuous in newly formed blood vessels; that is to say, the ramifications of which they are composed communicate with a common trunk at its opposite extremities, in the same manner as the hepatic and abdominal portions of the vena porta do with this vessel; they appear to be formed apart from the vascular system of the surrounding tissues, as they can be seen forming from small specks of blood situated at the centre or at the circumference of the carcinomatous mass, in the form of striæ or slender streaks of blood, and gradually assuming a cylindrical arrangement and ramiform distribution, and thereby constituting the proper circulation of cephaloma. The communication which exists between these vessels and those of the organ in which the carcinomatous substance is contained, is frequently very imperfect—a circumstance which, together with the delicacy of their structure, renders them extremely liable to congestion and rupture. The blood-vessels which are seen in scirrhus appear to be no other than branches of those which belong to the neighbouring tissues, and which have become enclosed within the substance of which its several varieties are composed. Thus we have two varieties of blood-vessels—the proper and collateral—and many of the now remarkable phenomena which present themselves during the progress of carcinomatous formations depend on changes which take place either in the proper or the collateral circulation. Thus the shade of colour will depend on the degree of facility with which the circulation is performed; and an imperfect communication between these vessels will give rise to congestion, which may cause rupture of the vessels, and internal or external hemorrhage. In the former case the carcinomatous substance is seen to acquire a rapid increase of bulk proportioned to the extent of the effusion, and when examined afterwards, is found to be infiltrated with blood, or broken down and mixed with clots of this fluid, and irregular masses or layers of fibrine; thereby producing, when the tumour possesses the cerebriform character, appearances very similar to those observed in the cerebral apoplexy after cerebral effusion, and showing that the deposit is but fibrinic. If the obstacle interrupt *entirely* the circulation in the tumour, nutrition ceases and death ensues in all those parts of it from which the obstructed vessels proceeded; the termination of carcinoma in mortification from obliteration of its veins is far from being a rare occurrence.

The next new formation which presents itself for consideration is tubercle.

Tuberculous matter is a pale yellow, or yellowish grey, opaque, unorganized substance, the form, consistence, and composi-

tion of which vary with the nature of the part in which it is formed and the period at which it is examined. It is found in the mucous tissue of organs, on serous surfaces, and, though rarely, in the blood.

The most important fact connected with the composition of tuberculous matter is that, either from the nature of its constituent parts, the mode in which they are combined, or the condition in which they are placed, they are not susceptible of organization, and consequently give rise to a morbid compound, capable of undergoing no change that is not induced in it by external agents. When the process of softening takes place in the tuberculous matter, it is clear, from what was just stated, which is on the authority of Dr. Carswell, that it cannot be, as Laennec believed, owing to any change originating in this morbid product. Besides, in man's organs it is in a state of fluidity, and does not require to undergo the change in question. When the tuberculous matter has become firm, from the resistance afforded to its accumulation, or the absorption of the fluid parts, it generally is, at some future period, converted into a granular-looking pulp or grumous fluid of various colours, from the admixture of serosity, pus, or blood, which have been effused or secreted by the tissues subjected to its irritating influence. As to its nature, its presence in the blood throws considerable light on that subject. It very rarely occurs that tuberculous matter can be detected in the blood contained within its proper vessels, but it is frequently met with in this fluid in the cells of the spleen. This organ is particularly favourable for ascertaining the presence of the tuberculous matter in the blood. Its spongy texture admits of the *accumulation of the blood* in such quantity that the tuberculous matter can be seen forming in this fluid at some distance from the walls of the cells in which it is contained. Thus we can see the blood coagulated in one cell, coagulated and deprived of its red colouring matter in another, and in a third converted into a mass of solid fibrine, containing in its centre a small nodule of tuberculous matter. It also sometimes happens that the blood is effused in consequence of rupture of some of the cells of the spleen, and an opportunity afforded of witnessing its successive or or simultaneous *conversion* into fibrine and tuberculous matter.

Thus, then, we have three morbid products, scirrhus, cephaloma, and tubercle, all mere modifications of fibrine—the latter not susceptible of organization, and acted upon by external physical causes, the two former susceptible of organization, either by the prolongation into their substance of the vessels of the affected parts, or by the establishment of a new set of blood-vessels, just as in the physiological process of cicatrization you may have union by the first intention, or union by the second intention, viz. the effusion and subse-

quent organization of fibrine, either by the prolongation of the vessels of the part, or by the formation of new vessels, and their subsequent union with those of the wounded part. *It is just in the same manner, also, that various parts of the body are first organized in embryo.* The first state of all parts is that of being fluid and inorganic, the formation into vessels being a subsequent stage of evolution; for in the ovum of recent vitalization—in an egg, for example, of 24 hours' incubation—grooves are seen to form in the matter forming the disk of the area umbilicalis, which grooves gradually grow red, so as to constitute vessels for containing and circulating a specific animal fluid; trunks are eventually formed for the branches, and at last the great central engine of the circulation, the heart, is added to the trunk: new parts are formed from materials within reach, as supplied by the adjacent structures already fabricated; and thus the several organs of the new animal make their appearance in a certain determined and beautiful succession.

So that, granting the deposition of scirrhus, cephaloma, &c., to be but the effusion of fibrine, the gradual organization of them is a process strictly identical with that which, presiding over the primitive materials of generation, builds up the rudiments of the embryo, preserves its structure, by the process of nutrition, as long as life continues, and obviates the effects of casual mutilation as far as that can be accomplished by means of reproduction: a physiological law therefore essential to the development, growth, and preservation of the animal body. And I may remark, that even the occasional termination of scirrhus in mortification, from obliteration of its vessels, bears an exact resemblance to the sloughing off of the extra-abdominal portion of the umbilical cord from the same cause—a truly physiological process also.

So that if we divest our minds of the idea that those new formations are *not analogous* to any texture of the body, and adopt the more probable opinion of Mr. Abernethy, that they may all be referred to the fibrine of the blood as their origin, the physiological laws which regulate their progress and course become obvious.

(To be continued.)

Reviews.

On Dropsies connected with Suppressed Perspiration and Coagulable Lymph. By Jonathan Osborne, M.D., President of the King and Queen's College of Physicians in Ireland, &c. 12mo. pp. 64. One plate. London: Sherwood and Co. 1835.

THE author of this little work commences by
ropsy attended with suppressed

perspiration, and coagulable urine, *Renal Dropsy*. He justly gives the merit to Dr. Bright, as having first traced this disease to the kidneys. He acknowledges that he was extremely sceptical on the subject after the publication of the splendid work of that author, and closely investigated the disease for eight years in the clinical hospital of Sir P. Dun. He was at length convinced, by his observations in hospital and private practice, of the accuracy and importance of Dr. Bright's conclusion. He observed the same results in several cases, without a single exception. He therefore calls upon any medical reviewer "to deny their truth in as far as he can do so by the aid of actual observation." The author further informs us, that he has succeeded in producing general perspiration in two cases of diabetes, and he appeased the appetite and thirst with extract of liquorice, until health was restored.

He has ventured to propose the term *anidrosis*, "as designating that peculiar disease of the skin, which consists in its not perspiring;" and he has done this deed with fear and trembling, no doubt, of the classic-loving editors of a moribund periodical. According to them, he ought not to have infringed on our peculiar privilege of manufacturing new terms, but he, as their president, will be pardoned by his worthy colleagues.

Dr. Osborne is evidently a physician of great discernment and judgment, as clearly appears by the faithful observations contained in the work before us. He details thirty-six cases of dropsy which were caused by disease of the kidneys. He gives an account of the experiments of Dr. Wells and Dr. Blackhall, which proved that in many cases of dropsy, the urine coagulated by heat, that there was evidence of inflammatory action, and that in such cases bleeding was productive of very great benefit. The result of these observations led to the employment of the term inflammatory dropsy. Dr. Crampton of Dublin was the next writer on the subject, and then followed Dr. Bright, Dr. Gregory, Dr. Christison, and now our author. The two last named physicians adduced eighty-seven cases in support of Dr. Bright's conclusion. Nevertheless, all the facts have been doubted, and the objections are thus examined and answered by our author.

"The facts produced in opposition, so far

as I have been able to collect them from the article *Dropsy* in the *Cyclopædia of Practical Medicine*, and from Dr. Copland's Dictionary, are the following:—

"1st. That coagulable urine has occurred in adults who appeared to enjoy good health, and also in children.

"2nd. That in some persons it can be produced by taking pastry, or other indigestible articles of diet.

"3rd. That Dr. Darwell has adduced an instance of a woman who died from disease of the heart, and in whose lungs there were scattered tubercles, in whom the kidneys were found in Dr. Bright's first stage of disease, although the urine did not coagulate.

"We shall consider these statements in their order:—

"1st. The continuous secretion of coagulable urine by an individual, who, notwithstanding, remains in the undisturbed possession of health and strength, would prove, either that the secretion was not the result of disease, or that, if so produced, the disease must be unimportant, and inadequate to the production of any sensible disturbance of the functions. Whether such an instance as this can be produced or not, it is impossible for me to say; but I may be allowed to state, that in a considerable number of trials I have not found one example; and experience enables me to assert, that many instances may be found of coagulating urine, which appear to be cases of health, but which an attentive examination would prove to be connected with disease. I may adduce, as a specimen, the case of a young man, who, about a year ago, had palpitations, and œdematous swellings, for which his medical attendant prescribed bleeding and other remedies, with good effect, and then sent him to the country for the restoration of his health: he was lately brought to town, preparatory to the resumption of his ordinary avocations. He made no complaint, the palpitations and swellings no longer existed, and he believed that all his ailments were at an end: but the eye of his anxious mother perceived that there was still something wanting to perfect health, and he was submitted to my examination. His appearance was healthy, his appetite and sleep natural, and the only circumstance which affected him was an anxiety as to the motions of his heart, in consequence of the opinion which his former attendant had entertained, of its being the seat of an organic disease. The heart's action, however, was natural: there remained then no complaint. I requested that a specimen of his urine should be brought, and, on observing its pale and cloudy appearance, tried it by heat, and found it to coagulate. Hence was opened a new field of inquiry; and it appeared that this young man, who, to a superficial view, would have appeared healthy, had a sensation of a dull weight in his loins, was in the constant habit of passing troubled

urine, with dense mucous clouds, had dry skin, which never perspired except after the most fatiguing exercise, and altogether afforded complete evidence, that the kidneys were in the state which has been described by Dr. Bright.

"It is true that in fevers, and other inflammatory diseases, an albuminous deposit is obtained on adding a saturated solution of corrosive sublimate. This urine is high coloured, and abounds in urea, yielding abundant crystals when treated with nitric acid, without requiring any previous evaporation. No coagulation, however, is effected by heat, unless it be so long continued at the boiling point, as to evaporate a large proportion of the water. There are also some individuals, who secrete constantly urine of this description, and in whom it may be traced to a habit of drinking very sparingly, by which a concentrated urine is produced. That a greater quantity of albumen in the urine is required to produce coagulation by heat, than by corrosive sublimate, is manifested by the following experiment:—I procured some urine secreted by an individual under these circumstances, which threw down an abundant coagulum to corrosive sublimate, but not to heat; and I found that an addition of a fortieth of its quantity of serum caused a cloudiness scarcely perceptible, a considerable time after it had commenced boiling, and that nearly twice that proportion was requisite to enable it to form a coagulum. Thus it appears, that such a proportion of albumen as may coagulate with corrosive sublimate, may be consistent with health, but that the quantity producing coagulation by heat is so much greater, as to require a diseased state for its production.

"The albuminous urine observed in children is very probably of frequent occurrence, which yet does not diminish the importance to be attached to it in the case of adults. The urine of children is at all times different from that of adults, in the proportion of its constituents. The quantity of urea and of uric acid is much less; and those are the deficiencies which are usually connected with albuminous urine in the adult. Hence we must not admit the value of albuminous urine as a symptom of a certain disease in the adult, to be diminished by the fact of the same being often secreted in infancy. The secretion is so different, that what is healthy in the adult would be esteemed morbid in the child, and consequently no comparison can be instituted between them.

"2nd. Here, however, we are met by the alleged fact, that certain healthy individuals are able, at any time, to produce a secretion of urine, coagulable by heat, merely by taking pastry, or certain other indigestible articles. Now this fact, if worth any thing as an argument, amounts only to this:—'Coagulable urine is not an indication of the presence of a certain disease of the kidney, because it

may be produced by eating indigestible substances.' In this proposition it is assumed, first, that the transient appearance of coagulable urine is the same thing as the continuous secretion of it, which alone constitutes the indication of the organic change of the kidney, of which we are treating; and, secondly, it assumes that this pathological phenomenon can only be produced in one way; and that, by showing that one way, it is proved impossible that it can be produced in any other. According to this mode of reasoning, we might prove that tenesmus is not an indication of dysentery, because it can be produced by aloetic purgatives; or that coma is not a symptom of apoplexy, because it can be produced by drinking spirituous liquors.

"3rd. Dr. Darwall's case of uncoagulating urine, in connexion with the first stage of diseased kidney, as described by Dr. Bright, carries no weight as an objection. The first stage of the disease is with difficulty distinguished from the natural state, and is most likely to be confounded with, and appears almost identical with, that paleness of the kidneys, spleen, and liver, which occurs in scrofulous cases. And this was evidently a scrofulous case, as appears from the presence of tubercles in the patient's lungs, as stated by Dr. Darwall.

"Those are all the adverse facts which I have been able to collect. But I find, with regret, that by some this important discovery has not been resisted by facts, but depreciated by loose observations, which deserve animadversion, when we consider the injurious effect which such may exercise on the progress of medical science, not so much with reference to this individual question, as to the investigation and settlement of medical questions in general. The truth of the statements made was not impugned; the extent of the field of observation—Guy's Hospital, and the Royal Infirmary of Edinburgh—has not been denied; the number of the observations recorded must have been admitted to be greater than has, within many years, been brought to bear distinctly on any one individual proposition in medical science. And yet all these circumstances were dismissed with the trite remark, that *further observations are required*; a remark which is as applicable to the discovery of the circulation, as to the question before us. By this remark we might throw an air of doubt over the best established propositions. It is so easily made, and, withal, so true when applied to every subject, that it is impossible to prove its impropriety. To this, however, has been joined the observation, that the writers, and the writers' friends, have not had opportunity to observe the connexion, and, therefore, they do not only disbelieve it themselves, but call upon others to do so, without producing a *scintilla* of evidence whereon to ground our disbelief, except the fact that *they* have not had, or have not availed themselves of, the opportuni-

ties of examining the question by the test of a sufficient number of experiments. This must forcibly remind us of the village lawyer, who, when his client had been convicted of stealing a sheep, by the positive testimony of three witnesses who saw him steal it, replied, that that evidence went for nothing, inasmuch as he could produce many more credible witnesses who did not see him steal it. Thus, because those gentlemen have not seen the connexion between coagulable urine and diseased kidney, we are not to be permitted to credit the evidence of those who have seen it; and all the facts before us—the result of long and laborious inquiries on this subject—are to be dismissed with the unmeaning, because universally applicable aphorism, that *further observations are required!*”

Dr. Osborne goes on to state that the number of cases of coaguable urine which fell under his observation was thirty-six, and in nine of these there was disease of the kidney; “while the remaining cases prove the existence of the same disease, so far as it is susceptible of proof by similarity of symptoms; of course of collateral circumstances, and by *adjuvantia* and *lædencia*; and I can with truth aver, that I have witnessed many more cases which are not sufficiently detailed for the present occasion, but which without any exception, corroborated the truth of Dr. Bright’s proposition.”

Our author has treated several cases of dropsy without coaguable urine, and in which the kidneys were healthy; and in no instance has he met with coagulable urine without diseased kidneys, or healthy kidneys with coagulable urine. He proposes the following method for examining the urine:—

“The examination of the urine in this disease must be conducted according to one fixed rule, otherwise we shall constantly meet with apparent contradictions. The urine should be that which is passed in the morning before breakfast. It should not be examined till it has cooled. It then is usually of a pale citrine colour, semi-transparent or translucent, but not transparent like healthy urine; and at the bottom of the vessel there is an opaque, whitish cloud, consisting of the mucus of the urinary passages, and differing from healthy mucus by its greater density and opacity; while in other cases it differs from the healthy state by containing no mucous cloud. On heating this urine, in a spoon, over the flame of a candle, white coagula are formed in those portions of the fluid next the metal, long before the heat has advanced to the boiling point: and when the heat is continued afterwards, the coagula become more

firm and distinct. The lesser degrees of coagulability are signified by its not taking place till the fluid has boiled, or till some of it has been evaporated; by no coagula forming, and the fluid being rendered merely turbid; and, lastly, by throwing up a froth when boiled, which appears to be produced by the smallest quantity of albumen that can satisfactorily be tested by heat.

“I may here mention, incidentally, that I use this mode of examining urine in other diseases besides dropsy, and without any expectation of meeting albumen. When urine with a copious sediment occurs, and it is desirable to ascertain whether it consists of uric acid and the urates, or of the earthy phosphates, I pour off the clear urine, and heat in a spoon the sedimentous urine which remains at the bottom. If the sediment consist of uric acid and the urates, it becomes perfectly clear before the heat is raised to the boiling point; and the sediment is restored to exactly its former state on cooling. If the sediment consist of the earthy phosphates, no such changes can be produced.

“The quantity of urine in this disease is variable, being not remarkable for scantiness, as is the case in other dropsical diseases. On the contrary, in most cases it is nearly equal to the drink, and in some cases exceeds it, approaching in this respect to the diseased secretion of diabetes.

“The state of the skin is one of the most important facts connected with the disease. In all my cases perspiration was extinct, except in a few in which it occurred in the head, or in a transitory manner in the palms of the hands. When the perspiration was restored, in every instance a removal of the dropsical swellings immediately followed. As this part of the subject, however, leads directly to the plan of treatment which I have to recommend, and which differs from that hitherto adopted, I shall postpone this, along with the consideration of the other symptoms of this remarkable disease, to the next opportunity.”

There is a very valuable practical remark made by Dr. Osborne, to which we beg to direct the reader’s particular attention.

“The result of my observations has been, that this peculiar disease stands in an intimate relation with the suppression of the healthy discharge from the skin, its connexion being so constant, that they may be fairly presumed to stand in the relation of cause and effect.

“The force of the circulation in this disease appears to be depressed by the action of some specific agency not as yet ascertained. The surface and extremities are uniformly cold—the latter being either livid or pallid; and, on reviewing my collection of cases, I find that in all of them the pulse was low, undulating, and ranging from sixty to ninety, except when they were complicated with in-

inflammations; and that in those cases it was considerably less frequent than usual.

"The perspiration was either completely extinct, or confined to occasional breakings forth in the head or chest, the palms of the hands, or soles of the feet. The skin was dry and shining, harsh to the touch; and, on examining it with a lens, the usual eminences belonging to the orifices of the follicles were no longer to be found, and the orifices themselves were hardly perceptible, except when they appeared like black dots, in consequence of being filled with the residue of old secretions.

"Whenever general perspiration came on, either spontaneously, or in consequence of medicine, then the cases always terminated favourably."

The next frequent case is the abuse of diuretic drinks and medicines. Our author observed that certain diuretics, when long continued, diminished the urine, and that the secretion became nearly suppressed; and these cases were characterized by coagulable urine. He observed some cases, however, in which the urine was diminished without its being coagulated. The late Dr. Gregory, of Edinburgh, had attested this fact in numerous instances.

Before we give Dr. Osborne's mode of treatment it is necessary to mention, that out of eighty cases of dropsy with diseased kidney, treated in Edinburgh, forty-five died; while of thirty-six cases, Dr. Osborne lost only nine. This is a most remarkable difference, and leads us to quote the practice of our author in detail, for the instruction of many of our readers, as well as the benefit of humanity.

"When a patient was placed under my care, with general œdema, coagulable urine, and dry skin, I directed him to be kept in bed, in order to maintain warmth of the surface, which is usually disposed to be cold. It has happened frequently that, by external heat alone, an improvement both in the quantity and quality of the urine, and a material subsidence of the œdema, have taken place. The first medicine ordered was usually a purgative; and in the choice of this, in order to avoid ambiguity as to its mode of action, I abstained from the use of all those articles which are reputed diuretic; such as compound of jalap, or supertartrate of potash; and I generally employed the senna mixture.

I then commenced a diaphoretic course, by administering foot baths, hip baths, or general baths; the last either of water or of vapour, according as they appeared to agree best with the individual case, at night at the hour of going to bed. The patient also took at night eight grains of Pulv. Jacob. ver. 4.

of Pulv. Ipecac. c. Opio, and 10 grains of Confect. Aromat.

"The usual drink was barley water. In case, however, of tendency to stupor, or headach, the Dover's powder was omitted, or given in smaller doses. In one case, in which no perspiration was produced by the above and other means, it followed the use of the following mixture: \mathcal{R} . Aq. Acet. Ammon. \mathfrak{z} iv. Sulphur. Subl. \mathfrak{z} j*. Vini. Ipec. \mathfrak{z} j. Ext. Opii. \mathfrak{z} gr. ij. Aquæ Fœnic. dulc. Syrup. Sacch. empyreumat. utriusque \mathfrak{z} ij., one ounce to be taken every hour.

"When the vapour bath was not attended by perspiration, from want of reaction on the part of the patient, he was directed to take, while in it, two drachms of the Tinct. Guaiaci Ammoniat.; when, however, (as sometimes happened), both vapour and water baths produced coldness of the extremities, they were discontinued. It is to be observed that the drops of moisture which are condensed on the surface of the patient's body, while in the vapour bath, are often mistaken for perspiration. The occurrence of the latter can only be determined by ascertaining if the skin becomes moist after the patient has returned to the bed, which should, in every case, be warmed for his reception.

"When there was a continued tendency to coldness of the surface, unaccompanied by feeble action of the heart, the diaphoretic preferred was Tinct. Guaiaci Ammoniat. \mathfrak{z} ij. Sulphuris Loti \mathfrak{z} j. Mist. Camph. \mathfrak{z} j. Sp. Piment. \mathfrak{z} ss., or the following: \mathcal{R} . Carbon. Ammon. \mathfrak{z} ss. Mist. Camph. \mathfrak{z} vj., an ounce to be taken every two hours. In connexion with these remedies, administered in the evening with a view to procure a perspiration during the hours of sleep, warm applications were kept up during the day, and frequently a succession of bags of hot salt was maintained, when the heat of the extremities could not be otherwise preserved. When perspiration was restored in one part of the body, as in the trunk, but not in the limbs, the latter were rubbed several times during the day with an infusion of two drachms of bruised mustard seeds in distilled vinegar, with Naphtha, or some other suitable stimulating embrocation.

"Having never failed in removing this kind of general dropsy whenever the entire surface of the body was restored to a perspiring state, it is not surprising that I should bestow the utmost attention on this part of the treatment. In a great number of cases, and especially those connected with bronchitis, the patient took three times daily, an ounce of the following mixture: \mathcal{R} . Balsami Copaibæ \mathfrak{z} j. Misc. Gum Arab. \mathfrak{z} ijss. Sacch. q. s. ft. Emulsio, Adde Aquæ Cinnamomi Mist. Camph. utriusque \mathfrak{z} ij.—The use of this was first suggested by the appearance of the mucus in the urine, which in almost every case

denoted irritation in the urinary passages; and in chronic bronchitis, with scanty and opaque secretion, there is no more valuable remedy. Copaiba has been set down in the *Manuals of Materia Medica* as a diuretic; but I never recognised this effect from it, except through its agency in diminishing irritation in the urinary passages. When given to patients who were kept under the influence of external heat, it always acted as a diaphoretic, and was peculiarly valuable in answering the indications usually co-existing in those cases.

"Next in importance to the restoration of the function of the skin, and indeed in most cases expedient, as contributing to that great object, was blood-letting. It will be recollected that in Dr. Blackhall's work, and in the papers by Dr. Wells, and by Dr. Cramp-ton, before the disease had been as yet traced to the kidneys, there was a considerable body of evidence to prove the advantage of bleeding in cases of dropsy with coagulable urine. The circumstances which appeared to me to afford the strongest indications for general blood-letting were, 1st, the peculiar full and undulating pulse, which resembles that so commonly occurring in nephritis; 2dly, the co-existence of inflammation of other parts; 3rdly, pain or weight in the region of the kidneys; 4thly, the appearance of blood in the urine. The blood drawn was not usually buffed; but the serum, in almost every case, was turbid, and especially, but not exclusively so, when the bleeding was performed within a few hours after a meal. In some cases cupping, or leeching, over the loins was resorted to, when there were some of the indications now mentioned; but when general blood-letting was forbidden by general debility, or other circumstances. Counter-irritation over the region of the kidneys, is a practice which requires some caution in a disease attended with such languor of the capillary circulation, and in which there may often be danger of the formation of intractable ulcers. Yet the application of moderate-sized blisters to the loins is a very suitable irritant, and calculated to promote the action of the diaphoretic medicines. The best mode of applying these is by lint steeped in tincture of cantharides, and covered with oiled silk. This has the advantage of superior cleanliness, of quicker action, and of not tearing the cuticle. Those vesications may be dressed with iodine ointment, or be healed rapidly by means of simple dressing, and thus a rapid succession of irritants be maintained."

The purgatives most commonly employed were senna mixture, castor oil, or rhubarb and magnesia; and some of these were given early in the morning, so that their operation might have terminated before the diaphoretics were employed in the evening. This is

judicious and excellent practice, and is generally overlooked.

When slow arachnitis supervened, and this was a frequent consequence, calomel was freely administered.

Iodine was also employed under the following circumstances.

"In two cases the general œdema was removed under the use of iodine (a grain and a half with three grains of hydriodate of potash dissolved in a pint water, given in the day-time). As, however, both these patients were kept in bed, and by means of external heat a restoration of perspiration had been effected, they cannot be adduced as evidence in favour of the action of iodine in the disease. The object which I had in view in using it was to ascertain how far it would act in causing absorption of the morbid structure developed in the kidney. During the time of the residence of those patients in the hospital, the coagulability of the urine diminished very much, but did not disappear altogether; its colour and transparency were, however, completely restored. Had they been content to have remained longer under the treatment, it is probable that a total absence of albumen in the urine might have been witnessed. In the majority of the other patients, dismissal from the hospital took place when the same degree of improvement had occurred in the urine, but before a total disappearance of albumen had been obtained; and as soon as the œdema was removed, the patients generally thought themselves cured, and became anxious to leave the hospital as soon as possible."

It is important to know that individuals who are cured of the form of dropsy under notice, are very liable to relapse, more especially in cold weather.

"Individuals who have been thus relieved from dropsy by a restoration of the functions of the skin, are liable to relapses if exposed to cold, so as to produce a return of the cutaneous obstruction. Hence they ought to wear flannel next the skin, and to make a timely use of baths and frictions, in case of dryness of the surface recurring. For those in affluent circumstances a residence in a warm climate cannot be too strongly recommended. If the muscular forces permit, exercise should be used till the effects of it are perceived on the skin; and, as œdema of the legs may recur, in consequence of the previous distention and subsequent relaxation of the cellular texture, it is expedient to wear bandages on the legs, until the ordinary vigour of health has for some time been established."

When renal dropsy was complicated with other diseases, Dr. Osborne employed a modified plan of treatment, but one in strict

accordance with his conclusion. His observations are so deeply instructive, that we feel it our duty to cite them.

"When combined with bronchitis, the use of Copaiba, as already mentioned, appeared of the most decided advantage. In dry bronchitis the following mixture usually caused free expectoration:—℞. Gum. Ammon. Gum. Arab. Sacchar. alb. singul. ʒij. Bals. Copaib. ʒss. Aquæ Cinnamomi, ʒiv. A tea-spoonful to be taken every hour and a half. In some instances in which the Copaiba produced nausea, it was superseded by the tincture of cubebs, a medicine which, although totally differing from it in botanical and chemical relations, yet agrees with it in medical as well as sensible qualities. When expectoration continued to be copious for a long time, without any benefit resulting therefrom, and the principal distress arose from its quantity impeding respiration, then, in conjunction with the diaphoretic course, the administration of acetate of lead, one grain, and watery extract of opium, quarter of a grain, four times daily, caused a diminution of expectoration, and, at the same time, diminution of irritation in the air passages. The application of leeches externally to the larynx, the number varying from two to eight, is a most important part of the treatment of bronchitis. The good effects of it are not confined to the larynx, but are apparent also in the unloading of the mucous membrane of the bronchial tubes throughout their entire extent, causing a more immediate cessation of cough, and relief of dyspnœa, than any remedial measure which I have had an opportunity of employing. In addition, blisters should be applied to the upper part of the sternum, and under the axillæ. I have generally used also, in these cases, frictions to the back, and sides of the chest, with the stimulating embrocations already mentioned applied several times daily. Under the use of these and other similar applications, I have frequently had the satisfaction of believing not only that the bronchitis was at an end, but that portions of emphysematous lung were restored to a healthy state. If asked for the evidence of this latter fact, I answer, that regions of the thorax, which had an unnaturally clear sound on percussion, and yet no audible respiration, or which presented the dry crepitus, and clear sound of emphysema, were, when subjected to this treatment, found gradually to resume the respiratory murmur of health, while the peculiar dyspnœa, characterized by longer expirations than inspirations, was at the same time removed, or notably diminished.

"When irritations of the stomach or bowels occurred, they were met by nearly the same treatment as if the disease now before us was not present. Leeches placed over the affected organ, with warm applications externally, and a diet consisting of rice, or

arrow-root, frequently removed them in a few days. A tendency to dysentery, which is one of the most frequent forms of this complication, and which commences by tenesmus and general excitement, was most speedily removed by an enema of four grains of nitrate of silver, dissolved in eight ounces of distilled water, followed in three hours afterwards by the starch enema, with tincture of opium. The first is retained only a few minutes, but the last generally remains several hours, and the irritation is then at an end. Although the efficacy of these measures, no doubt, depends much on the promptitude with which they are applied, yet they have been found not to fail even in long protracted cases of chronic dysentery, when aided by other appropriate treatment.

"When combined with pericarditis, the internal use of tartar emetic, in addition to topical and general blood-letting, produced a great increase of urine, with amendment of all the symptoms; while a decrease occurred on two several occasions, in which it was for a time superseded by squills. In valvular disease of the heart, and, especially imperfect closure of the aortic valves, the patient, in addition to the diaphoretic treatment, took a mixture of a small quantity of tincture of digitalis, with carbonate of ammonia, camphor, and Hoffman's liquor. This combination was intended to act as a sedative to the heart, and, at the same time, as a stimulant to the circulation through the capillaries. Whether it acted in this way or not, may be questioned; but it was certainly followed by warmth of the extremities, diminution of the violent action of the heart, a sense of general relief, and a capability of sleeping with comfort at night.

"The measure, however, which appears to me of the highest importance in diseased aortic valves, is the establishment of a large issue over the region of the heart. On some future occasion I shall bring forward some faithfully reported cases, which prove that organic disease of the valves is capable of great amendment, if not of complete cure, by this and other counter-irritants, aided by the administration of suitable internal remedies.

"General œdema, with coagulable urine, and obstructed perspiration, is not unfrequently accompanied by effusion of serum into the peritoneal cavity. This when not considerable or of long standing, disappears along with the general swellings.

"When, however, ascites has formed either in consequence of chronic peritonitis, or induration of the liver, then, although the general swellings have been removed, we have still to deal with a refractory, and often intractable complaint. In addition to the means which are usually adopted, viz. courses of mercury and purgatives, I am enabled, from experience, to suggest some other measures, to the employment of which I must

attribute the fact, that within the last four years I can recollect only one case in which tapping was performed in my hospital wards, while previously it was a frequent operation. These are the repeated application of leeches to the rectum, so as to unload the vessels of the vena portæ. The applications of various stimulants to the abdomen, as 1st, an ointment composed of equal parts of iodine, mercurial, and cantharides ointments. 2ndly, A paste formed of Spanish soap, spread upon linen, and sprinkled over with muriate of ammonia immediately before being applied; which, by the chemical decomposition that ensues, and the consequent gradual extrication of ammonia, produces heat and redness. 3rdly, Sinapisms, suffered to remain till the pain becomes urgent. These have the advantage of healing with great rapidity. 4thly, Frictions of six or more drops of croton oil. These are, however, rather uncertain: in some individuals producing no effect, and in others followed by erysipelas, extending beyond the seat of the application. 5thly, A mixture composed of one part of tincture of digitalis, and two of aquæ muriatæ calis: a teaspoonful to be rubbed on the abdomen, morning and evening. This compound appears to excite the absorbents, and increases the discharge from the kidneys, but does not produce any sensible redness of the skin. The application of these counter-irritants and excitants of the absorbents may be continued, when the administration of mercury and of drastic purgatives has become no longer advantageous, or indeed safe. It is certain that by these latter remedies the distention of the abdomen may frequently be diminished to a certain extent—but beyond this it is extremely difficult to proceed. Whenever the peritoneum has engaged in the process of morbid secretion, and the cavity of the abdomen has remained distended a certain length of time, it obstinately perseveres in retaining a certain quantity of fluid. The urgent and continuous use of the powerful remedies now mentioned, in such cases, is then not only abortive, but, sooner or later, causes irritation and ulceration of the bowels: and the patient sinks in consequence. It is therefore preferable, in those refractory cases, when the swelling no longer diminishes under the employment of internal medicines, to abstain altogether from their use for a time, and to rely on the application of counter-irritants and bandages, together with regulated courses of diet, and changes of air, until the patient's vital forces are recruited, so as to enable us to make fresh efforts to dislodge the fluid.

"When noises resembling the ringing of bells in the ears, wakefulness, delirium, stupor, or headach, come on, then, if there is increased heat of the head, blood must be taken either from the temporal artery, or by means of leeches applied to the temples, or behind the ears. Calomel must be freely

given, and followed by brisk purgatives. If those symptoms continue, it will be necessary to apply sinapisms to the nape of the neck, and to persevere in the use of mercurials. These symptoms, which are always of formidable import in dropsies, and peculiarly so, because usually neglected, and erroneously supposed to belong to the disease merely as symptoms, may, under this treatment, be very generally averted; and it would be acknowledged, from an examination of the fatal cases recorded in my table, that, though the patients died immediately from the affection of the brain or its membranes, yet in most, if not all of them, peculiar circumstances existed, which had the effect of disarming the remedies now mentioned of their usual powers, and which, in those particular instances, rendered the disease necessarily mortal."

We have now given a full account of the work before us, and we are convinced that every one engaged in medical practice, will freely acknowledge that it is replete with useful and instructive information. It reflects the greatest credit on its author, as a truly scientific and judicious physician, and as an ornament to the profession to which he belongs. His treatise is modest and unassuming, and abounding with faithful observation, which will materially conduce to the alleviation of a very fatal form of disease. We now insert his conclusions.

"1st. That it is always connected with disease of the kidney, which, when sufficiently advanced, is marked by the deposition of a greyish structure, impermeable to injections, within the substance of that organ.

"2nd. That the suppression of perspiration is the most general cause of this disease; and the long-continued excitement of the organ by spirituous liquors, or diuretics, the next in order of frequency and importance.

"3rd. That the most successful treatment consists in the restoration of the functions of the skin; which being accomplished, the disease, if free from complications, never fails to be removed.

"4th. That bleeding and purgatives are also suitable remedies; while diuretics are either injurious, or, if removing the swellings for a time, tend ultimately to cause a return of the disease, under a more aggravated and intractable form.

"The constancy with which either this disease or diabetes is preceded by a continuous repression of perspiration, renders it expedient that this state of the skin should be considered as a peculiar disease; for which purpose it may be called *Anidrosis*. The use of forming this designation is, to direct the attention of practitioners to a morbid state, which escapes observation

because not signalized by pain, but which is not only a disease in itself, but leads to many other and fatal diseases."

In conclusion, we are bound to observe that Dr. Osborne has evinced an intimate knowledge of medical science in this little treatise; he is, in our opinion, a most judicious practical physician, and is eminently qualified to fill the high station of President of the Dublin College of Physicians.

—o—

A Practical Treatise on Urethritis and Syphilis: including Observations on the Power of the Menstruous Fluid, and of the Discharge from Leucorrhœa and Sores, to produce Urethritis; with a variety of Examples, Experiments, Remedies, and Cures; a New Nosological Classification of the various Venereal Eruptions, illustrated by coloured Plates, and exemplified by numerous Cases; and a proposal of a Substitute for Mercury. By W. H. Judd, M.R.C.S. Surgeon in his Majesty's Fusileer Guards, &c. 8vo. pp. 568. Numerous coloured Plates. London: Highley. 1836.

THE author of this work has had the most ample opportunities of studying the diseases of which he treats; as it has been his duty for nearly twenty years to examine several hundred patients daily, for the purpose of detecting the incipient symptoms of Syphilis or Urethritis. He now publishes the result of his observations, and confirms them by numerous cases. The following is his arrangement:—

PART I. Urethritis Venerea.—The author asserts that urethritis, or elytritis (vaginitis) venerea, may cause ulceration within the urethra or vagina, or that these may be caused by the pus of a venereal pustule; that the time of the appearance of both after connexion is the same; and lastly, that both are caused by the same infection. Secondly, that pustules or abscesses in the urethra or vagina, induced by urethritis, occasionally produce secondary venereal symptoms; and that a sore in the vagina from this virus produces a venereal pustule in one party, and urethritis in another, or both occasionally in the same individual. Lastly, that the two poisons are identical.

Thus our author attempts to revive the exploded opinion of Hunter, of Travers, and of some few military surgeons. He

does not refer to the opposite conclusions of M. Ricord, which we published in this Journal, or to those of Dr. Wallace, both of which prove beyond the possibility of doubt, that a venereal sore cannot produce urethritis venerea, (vulgo gonorrhœa) or *vice versa*. M. Ricord examined with a speculum numerous women who were said to have caused syphilis in one individual, syphilis and urethritis in a second, and the latter in a third person; but he invariably detected a venereal sore in the vagina or uterus with elytritis; and, after a multitude of experiments and observations, arrived at the conclusion, that the poisons of syphilis and blennorrhagia or urethritis were not identical. We are not aware, up to this hour, that the speculum vaginæ is employed in our lock and other public hospitals, though it is manifest that, without examining the vagina and os uteri, no one can safely conclude whether ulcers exist or not in those parts. Now it does not appear that Mr. Judd has employed this indispensable and certain mode of diagnosis; and, therefore, we think his conclusions less satisfactory than those of M. Ricord and Dr. Alexander Thomson, who have tried it in a vast number of cases.

The question is one of great importance: it is whether mercury is necessary for the cure of gonorrhœa or not? A preponderating majority of the profession reply in the negative, and practise accordingly—and our author ranks amongst them.

Mr. Judd next gives a minute anatomical description of the tegumentary system, preparatory to the pathology of its various eruptions; and in this he has displayed great ability. This part of the work will be perused with advantage by every student and practitioner.

PART II. On the Origin and Nature of the Venereal Disease.—The author evinces great research in this section. He shews that sexual diseases existed 1450 years before the Christian æra, and that contagious forms are described in Leviticus. He adduces many statements to prove that animals, without contamination, produce secretions that are poisonous to themselves and others. He next reviews the question of identity of the venereal poisons.

The succeeding chapter is the mode of action of the poisons on the organs, and in-

cludes a lucid pathological account of all the symptoms of syphilis.

The author then describes the various forms of syphilitic eruptions, illustrates each by coloured engravings, and classifies all in a new arrangement. He gives a multitude of cases in this section.

The following chapter is on inveterate secondary symptoms, and is extremely well executed. The succeeding chapter is on the influence of mercury, and on a new remedy when this has failed, which is the hydriodate of potass in doses of five grains twice or thrice a day.

Such are the principal features of the work before us. Though we do not agree with the experienced author on the identity of the virus of urethritis and of syphilis, we have no hesitation in pronouncing his treatise a very valuable one. His classification and illustrations of venereal eruptions render the work entitled to great praise, for this subject had long required elucidation. This treatise is a valuable addition to medical literature.

—o—

A Treatise on the Diseases of the Eye and its Appendages. By Richard Middlemore, M.R.C.S., Surgeon to the Birmingham Eye Infirmary, &c. 2 vols. 8vo., pp. 1600. London: Longman and Co. 1836.

THE work before us consists in the course of lectures on the diseases of the eye, which are annually delivered by its author at the Birmingham Eye Infirmary. Few of the Council of the College of Surgeons would suppose that a provincial contemporary was equal to the task of competing with themselves by publishing a work which is fully equal to any one of their productions, and far superior to most of them. We always contended that medical science was not confined to the metropolis, and that many of our provincial brethren had cultivated it with as much assiduity and talent as the law-makers of Lincoln's Inn Square. Mr. Middlemore is entitled to much credit for the great research and personal observation which appear in his voluminous and valuable work. He offers ample evidence of having maturely and faithfully studied all the diseases of the organs of vision, and of having treated them with as great success as other recent authors on the subject. He

candidly and fairly criticises all extant works, and supplies the many defects and imperfections with which too many of them abound. It was scarcely to be expected that a ponderous treatise on the diseases of the eye would so speedily follow the publication of those of Mackenzie and Lawrence; and especially from the pen of a provincial surgeon. We cordially congratulate him for so successful an achievement. This work will be one of standard authority and reference.

Guy's Hospital Reports. No. I. Edited by George H. Barlow, M.A. & L.M., Inceptor Candidate of the Royal College of Physicians; and James P. Babington, M.A., Member of the Royal College of Surgeons. 8vo. London: Highley. 1836.

THE medical officers of our large hospitals and public charities have long been reproached for their negligence, in not publishing clinical reports of the many important diseases which daily came under their treatment. A new æra dawns on us at the commencement of the new year, for London Hospital Reports have at length appeared in the republic of medical literature. We have now on our table, St. Thomas's, and Guy's Hospital Reports, and we hope the other institutions will speedily imitate so good an example.

Guy's Hospital Reports contain medical, surgical, ophthalmic, and obstetric cases, treated in the establishment, with autopsies and papers read at the Physical Society of the institution.

It will appear by the following list of papers, that many valuable reports are to be found in the present number:—

“Treatment of Fever.—Diseased Arteries of the Brain.—Cartilaginous Deposits on the Medulla Spinalis.—Epilepsy from Local Disease. By Dr. Bright.

“Case of Ovarian Dropsy cured by the Accidental Rupture of the Cyst. By Dr. Addison.

“Operation on the Internal Iliac Artery for Femoral Aneurism, with an account of the dissection of the limb at the expiration of 18 years, accompanied by plates.—First successful Operation for Carotid Aneurism, with the inspection after Death at the end of 13 Years, illustrated by a Plate. By Sir Astley Cooper, Bart.

“Operation on the Subclavian Artery for Axillary Aneurism, with an Account of the Dissection of the Limb after 12 Years, with

Observations, accompanied by a Plate.—Cases of Femoral and Popliteal Aneurism, with Observations. By Mr. Key.

“Unusual Dislocation of the Femur. By Mr. Morgan.

“Cases of Dislocation and Fracture, with Remarks.—Case of Hydrocele of the Neck. By Mr. Bransby Cooper.

“Case of Tetanus, with Observations. By Dr. Bright.

“Case of Traumatic Tetanus. By Mr. Key.

“Summary of Cases in the Obstetric Ward.—Cases of Hard Tumours of the Uterus, with Observations. By Dr. Ashwell.

“Essays read before the Physical Society: Cases of Small-pox occurring in the Asylum for the Deaf and Dumb; and the Re-vaccination of all the Children of that Establishment. By Dr. Babington.

“Observations on the diagnosis of Pericarditis. By Dr. Hughes.

“Catalogue of additions to the Museum, with Introduction. By Dr. Hodgkin.”

We shall publish selections from these cases in our Hospital Reports, and place all that is important in them before our readers, adding comments when necessary.

—o—

The London Medical

AND

Surgical Journal.

Saturday, January 16th, 1836.

THE NEW UNIVERSITY OF LONDON.

A RUMOUR has prevailed during the last week, that the Chancellor of the Exchequer has appointed Dr. Chambers, Dr. Holland, and Sir Benjamin Brodie, to advise the government on the formation of the medical department of the intended University of London. It is by no means surprising that the Colleges of Physicians and Surgeons should be consulted on the foundation of an institution, which must modify or destroy these bodies, or perhaps form them into one faculty; but it is to be feared, that their advice, if acted on, would deteriorate the principles on which the University ought to be founded.

The notorious corruption of the existing corporators, renders them suspicious witnesses, and unworthy of credit; and if the government be so simple as to act upon such evidence, the new

University will be a failure, and a disgrace to its projectors. The ministry is certain of the support of the House of Commons, and will not venture to slight the evidence given before its Committee on Medical Education and Practice. There can be no doubt but Mr. Warburton, as chairman of that committee, will be consulted, and as he is well acquainted with the delinquencies of the existing medical colleges, and evinced a sincere desire to remove them, he will never consent to their continuance. So far as the government and House of Commons are concerned, there is no doubt of a liberal foundation of the University; but their good intentions may be frustrated in another quarter, in which the present corporations have immense influence. It is not the first time that the motto, “might and not right” has prevailed in legislation, or that the interests of nations have been sacrificed on this principle. The colleges possess might, and must be kept in good humour. They have long enjoyed certain privileges, of which they are about to be deprived. The question is, are they to be annihilated, or to form the examining body of the new institution? Will the Court and House of Lords allow them to be destroyed? We feel convinced that they will not. Will the colleges consent to be united in one faculty? That is the question. The profession declares they ought to be united; and if this were accomplished, there could be no difficulty in arranging the medical department of the new University. The artificial separation of physic and surgery is absurd; and the union of the colleges would not interfere with their respective rights, for there will always be physicians and surgeons. There is no valid objection to such a union. The arrogance and impertinence of one of these bodies towards the other are ridiculous. The public and profession have pronounced this opinion. Let us suppose the new University established, and that the candidates for a medical degree

be examined at Pall Mall East, and those for surgery at Lincoln's Inn Square, what could be the collegiate objection. But some of our contemporaries would abolish both colleges, and elect a body of new examiners. This, under existing circumstances is, in our opinion, utterly impracticable. The present colleges are not to be disposed of by a dash of the pen, nor will they be deprived of their privileges. It is however certain that their policy will be reformed and liberalised.

As to concours, it is totally out of the question while the profession is constituted as it is in this country. It may be introduced in another century. In proof of this position we may state, in addition to our former remarks on the influence of the colleges, that government is to elect the examiners of the new University, who are to be most eminent individuals. * This mode of election is as bad as the collegiate ones; but what power can prevent it? Under all these circumstances, one step is made towards reform, and parliament will accomplish the rest. We confess that we do not expect that the profession will be elevated to the rank it holds in other countries; but we feel convinced that it will be raised from its present anomalous and degraded position. It cannot be made worse than it is, and any change must be for the better.

—o—

MINERAL MAGNETISM.

— — —
 "Audi alterum partem."
 — — —

To the Editor of the London Medical and Surgical Journal.

SIR—I perceive there has been a correspondence carried on in "The Lancet," between Mr. Davidson and Dr. Schmidt, with respect to the trial of mineral magnetism at the Westminster Eye Infirmary. I was present at some of those experiments which were there tried; and, perhaps you will favour me with a corner in your Journal, for the purpose of pointing out to some of the visitors to these experiments, the great impropriety of interfering too much with Dr. Schmidt when he is putting the power of his magnets to the test. With regard to

Messrs. Guthrie and Thomson, no one of an impartial mind can find the least fault. Mr. Thomson in particular, who has taken great trouble in the matter, has no pleasant task to fulfil; but it is greatly to his credit that he has acted with the greatest fairness and impartiality. He has always frankly spoken of the failures of the magnet, while at the same time he has never scrupled to acknowledge when he believed a physiological effect had been produced by its application, and which acknowledgments, as he justly observed at the Westminster Medical Society, on its last sitting, if founded on wrong bases, could only be considered as errors in judgment. I am no friend to mineral magnetism myself, because I believe that the effects said to be produced by its application to the body, are more the result of excited imagination; but, sir, though not a friend to this application, I should wish, as a member of a liberal profession, to give to Dr. Schmidt every opportunity of experiment, and I would not allow him to be interfered with in his method of conducting such experiments. That gentlemen have gone to the Westminster Eye Hospital for the purpose of opposing Dr. Schmidt instead of witnessing his experiments, I am pretty well convinced; but I think it would show more taste in those individuals, were they to treat Dr. Schmidt as a foreigner should be treated, with kindness and courtesy. I do not ask for *partiality* to his system of magnetizing; but I ask for a fair trial for him—"a fair field and no favour." Mr. Thomson has striven to get him this fair field, and in so striving, as I before stated, he has had no enviable task to perform. Those gentlemen who are opposed to the views of Dr. Schmidt, will see the impolicy of interfering with his experiments; for, should they be unsuccessful, how justly may the Doctor complain of such interference! I think, sir, the discussion respecting mineral magnetism, has been carried on by some of the parties in a manner more for the sake of opposition than a thirst after truth. Science is not benefitted by intemperate language or hasty expressions; "Good wine needs no bush." That which is true, will certainly be made appear so. Dr. Schmidt, as far as I have seen of him, appears open and frank, respecting all his proceedings regarding the subject of magnetism, that he may have deceived himself is another thing; but it is certainly due to him to receive a proper hearing, and a gentlemanly consideration from even those who oppose him.

With regard to Dr. Ritchie, that gentleman has behaved in the most liberal manner, and has offered to come before the Society for the purpose of giving them, by experiment, all the information he can on the subject—this is as it should be. Let Drs. Ritchie and Schmidt each experiment before the Society—and let the truth be

shewn, as all true friends to science wish it may be.

Yours very truly,

AN OBSERVER.

—o—

Hospital Reports.

NORTH LONDON HOSPITAL.

Compound Comminuted Fracture of the Leg.— Death in five days.—Autopsy.

JOHN H., aged 35, a labourer at the London and Birmingham Railway, was admitted at two o'clock A.M., on the 9th of December, under the care of Mr. Cooper, with compound and comminuted fracture of the right leg, at about two inches above the ankle-joint. The upper part of the tibia was broken transversely, and projected through the wound, which was also transverse, and about one inch in length. The periosteum was denuded to a slight extent from the bone. The lower portion of the bone appeared to be split into more than one piece, and lay in the interosseous space, and was with great difficulty kept in its proper situation. The fibula was broken a few inches above the external ankle. There was another wound below that, caused by the protrusion of the bone, and from which large coagula of blood were removed (probably from rupture of the saphena vein). There was considerable hæmorrhage from both wounds, venous in the lower one, apparently arterial from the uppermost. There was constant and strongly marked spasmodic action in the muscles of the whole limb, which very much opposed the reduction and the maintenance of the parts, when that was affected. The lint was placed on M'Intyre's splint, the knee being nearly straight, and the foot-piece raised upon a block. A bandage fixed the foot to the splints, and another, beginning just above the fracture, was carried up to the groin. Dry lint was placed upon the wounds, and retained by a third piece of bandage. An anodyne was given to allay the spasm. Cold water was applied over the fracture. The accident occurred about 12 o'clock at night, and the man was dug out, during which operation he experienced great pain in his limb: the fracture was produced by a fall of earth, which drove the limb with great force against some brick-work, which was just being erected.

Nine, A.M. Has passed a quiet night; has dosed at intervals; experienced considerable startings in the limb. The bowels have not been moved, but acted naturally, once yesterday morning. Pulse 72; tongue clean and moist. He is unable to pass his urine, it was therefore drawn off with the catheter. The bandages are stained with blood of a bright red appearance.

R. P. ipecac. comp. gr. x;

Hydr. subm. gr. v;

Fiat pulus hora somni sumendus, habeat olei ricini, ℥ss. cras mane.

R. Julepii salini, 3 viij;

Vin. ant. tartar. 3 ij;

Liq. ammon. acet., ℥ ij.

Misce. capiat, ℥ j ter quaterve in die.

10th. Complaints of pain in the heel, and also in his back; passes his urine spontaneously; bowels open twice by the castor oil; vomited once at breakfast time; pulse 96. Face flushed; had an uncomfortable night, with little sleep. At 12, Mr. Cooper saw him, and having removed the supplementary piece of bandage, examined the condition of the wounds. Hæmorrhage of a venous character still continues from the lower wound, though slight in quantity.

As he complained of so much pain in the heel, the bandage was removed, and the limb raised from the pillow; a soft compress being inserted under the heel. Whilst the limb was raised, very violent spasmodic twitchings of the muscles disturbed the fractured parts, and continued to do so, until they were suppressed by the re-application of the bandages. Before the limb was raised, it was lying in a very good position on the splint. The lint, adhering to the wound caused by the protrusion of the bone, was not removed. That on the lower wound, having become loose by the discharge of the blood, was removed, and showed a deep cavity, filled with a dark coagulum. There was some swelling of the limb; the cellular tissue being infiltrated with serum. Had it not been for the pain in the heel, it was to be regretted that the limb was disturbed, as there was no displacement of the fractured bones.

11th. Complaints of pain in his loins; pulse 120, and of moderate strength; tongue rather white; nausea, and occasional vomiting; bowels very frequently moved yesterday by the oil.

12th. Is very restless; puts the uninjured leg out of bed. The splint has got off the block, and the limb was otherwise disturbed. The urine was high coloured and hot; pulse 135; rested during the earlier part of the night. During the day he experienced cold shiverings; complains of thirst; nausea and vomiting not so urgent. Is stated to have suffered much from ague, whilst working in Lincolnshire. Mr. Cooper had the supplementary bandage undone. Limb looking as well as could be expected; some tumefaction of the leg, but not very great. Pieces of oiled silk put over the lint, in order to prevent the bandage adhering too firmly to them, and disturbing them when it is removed. Cold applications continued. In the evening he thought himself a little better; pulse not so quick as in the morning, 128; tongue more coated.

R. Muriatis morphinæ, gr. iss; hæc nocte in formâ pilulæ.

13th. Yellow hue of the skin; great restlessness at night; delirium; tosses himself about—kicks at the bandages and bed-clothes; the tongue is dry, and brown in the centre; pulse 144.

R. Muriatis morphiae, gr. iss; statim sumendum.

The leg is very hot. Mr. Cooper saw him in the middle of the day, and ordered him the following medicine:—

R. Muriat. morphiae, gr. i; 6tis horis.

Hydr. subm., gr. x. Statim.

The bowels not moved for three days. At four in the afternoon he began to dose, and continued to do so until three next morning, when vomiting came on, and he ejected a quantity of greenish-coloured fluid. In the morning of the 14th he appeared more rational, and expressed himself as being better, but his pulse was 144, and more feeble; tongue moist, but coated. Ordered to continue the muriate of morphiae. At 1 p.m. Mr. Cooper saw him, and requested the bandages to be undone. There was at this time great restlessness of the patient; he attempted to get up and see his leg, and was otherwise disturbed. It was distressing to see the fractured ends of the bones moving about among the soft parts. Some grumous fluid was pressed out from the lower wound. There was less tumefaction of the limb. It was to be regretted that the limb was uncovered, for, as far as position went, the fracture was doing very well; and whilst the bandages were removed, great latitude was permitted to the spasmodic movements of the limb. The excitement produced by this proceeding, together with the crowd of students, appeared to be too much for the patient, as he became much more restless, shouting out, spitting, attempting to vomit, rolling his trunk about, tossing up his arms and head, and talking incoherently. The pupils were contracted. Attempts were made to allay all this disturbance, by administering increased doses of morphiae—2, 2½, and 3 grains, in the course of an hour—but without any effect. It was doubtful whether the pills were swallowed, as he spat forcibly after they were given. At 7 p.m. he died. For the last two hours of his life he was struggling violently, so that at one time it required six men to hold him down. He died in a severe convulsive fit—his teeth gnashing very loudly, and his back bent into a curve—his whole frame being shook. At the period of his death the pupils became very much dilated.

Autopsy.—The brain presented the characteristics of venous congestion—a great number of bloody points were observed in its substance when sliced. The lungs were gorged with venous blood, but there was no appearance of pneumonia—puriform secretion in the bronchiæ. Heart natural: walls of the left ventricle very thick, and its cavity very small—an example of “con-

centric hypertrophy”—its cavities filled with pale straw-coloured coagula. Stomach contained a quantity of dark coloured fluid, similar to what he had vomited. Spleen very large, soft, and quite pulpy in some points, broken down, and containing a grumous mass. Liver large, gorged with blood, but otherwise natural. Gall-bladder distended with deep coloured bile. Venous system, as a whole, much engorged.

The tibia was broken across transversely in front, but the fracture ran upwards and backwards an inch and a half. The lower part was broken into four or five portions, only one of which was anyways loose—the rest were closely fixed, either by the periosteum, or by being driven into the cancellous structure. The ankle joint did not appear to have suffered. The fibula was broken transversely about its centre, or a little above that point.

The internal saphena vein and nerve had been torn across—the former had furnished the dark-coloured hæmorrhage. The arteries did not appear to have suffered, but the end of the lower fragment pressed upon the posterior tibial. There was a quantity of blood effused round the fracture, into the surrounding soft tissues. Masses of dark coloured blood were found in the substance of the gastrocnemius and soleus. The posterior tibial vein appeared to have been torn. A section was made of the large portion of the tibia. The medullary membrane appeared vascular, and was plugged up with a clot of blood for some little way above the fracture: this clot projected from the ends of the bone, and was dark coloured. The periosteum was detached for one-sixth of an inch on each side of the fracture.

Mr. Cooper thinks the patient would have had a better chance had full bleeding been had recourse to as soon as the pulse began to rise, for he was a young, stout, plethoric subject, and would probably have borne the loss of blood well. The next similar case will be subjected to a trial of full venesection.

Erysipelas—Bronchitis—Use of the Nitrate of Silver.

Ann W., aged 27, was admitted Nov. 7th, under the care of Dr. Elliotson. She is a housemaid of plethoric habit, and continually subject to sick headach. Says she is not in the habit of taking spirits, that she lives abstemiously, her usual beverage being table beer. It appears, however, that she has lately lived almost entirely on gin. About six months ago, she had a severe attack of headach, from which she was relieved by bleeding and low diet. She has been free from illness since that time till Wednesday last, the 4th. On the previous evening she had overheated herself by walking fast, and on returning home felt chilly, and on Wednesday afternoon whilst engaged

in washing she was seized with headach and rigors. Next morning the face was much swollen and burning hot, and has so continued to the present time. She has now considerable tumefaction of the whole face and part of the forehead; her eyes are almost closed; vesication has commenced on the lower eyelids and nose; lips parched; tongue dry and furred; thirst urgent; skin hot and dry; pulse 124, full; respiration short and laborious; stethoscope discovers sibilant respiration on the left side especially; no cough; urine scanty and high coloured; bowels confined. She was placed on low diet, the head was shaved, and a solution of the nitrate of silver applied to the parts affected.

8th. The cuticle very black; the swelling a little reduced; pulse, 120.

9th. She is delirious, and has been so since ten last night; the swelling of the face considerably reduced; inflammation entirely gone; breathing less hurried; pulse, 120. In the afternoon there was considerable puffiness and heat of the scalp; the solution of the nitrate applied all over the scalp.

10th. No delirium; pulse, 120; skin hot and dry; much thirst; allowed small beer to drink; erysipelas removed.

12th. She has caught cold. (It appears that during her delirium she got out of bed, and the night nurse neglected to inform any one of it at the time; she remained on the floor for two hours). Pulse hard, 120; skin hot, dry, oppressive thirst; she is very hot except in her head, which feels cold to her, but is hot to others. V. S. $\frac{3}{4}$ viij. She gives rational answers but mutters nonsense.

15th. Erysipelas cured; she has cough and dyspnoea, evident bronchitis; a blister applied to the chest, and calomel, five grains every four hours.

17th. Still sonorous and sub-mucous respiration; pulse, 120. Pil. hydrarg., gr. x, nocte manequ.

21st. Pulse, 144; erysipelas has reappeared; tongue dry; the nitrate of silver again applied.

22nd. The swelling of the face reduced; forehead hot and puffy; pulse very weak; she is delirious; she was purged all night; a little kino was given, which relieved her.

23rd. Heat of forehead reduced, and she is better.

24th. Gums tender; omit medicines; bronchitis again.

27th. Pulse, 130, weak; debility extreme; countenance pale; lips, gums, and tongue pale and dry; thirst oppressive; respiration rapid.

28th. Vermicular pulse, 132; skin dry; tongue very dry; respiration 40 a minute; subcrepitant rattle all over the chest. Died in the night.

Sectis Cadaveris.—Brain—Congested posteriorly, but pale anteriorly, apparently from position after death; the ventricles contained a little fluid. Heart—Left ven-

tricle in a state of concentric hypertrophy; lungs congested—œdematous; both contained an immense quantity of watery mucus in the bronchi; in addition, the right lung was more congested than the left, and there were several patches of grey induration in the upper and lower lobes; the middle lobes free from them. Stomach—Several circumscribed patches of red: it contained much green fluid. Mucous membrane not indurated nor softened. Intestines healthy; subcutaneous cellular tissue under the blackened portion of the skin healthy; left ovary contained two cysts. Uterus contained some purulent fluid; there was a syphilitic ulcer at the upper extremity of the vagina.

—o—

LONDON MEDICAL SOCIETY.

Monday, January 11, 1836.

DR. WHITING, PRESIDENT.

Case of supposed Protracted Pregnancy.—Duration of Pregnancy.—Tubercles in the Placenta.

MR. STATAM said he had to bring before the Society a case which involved a medical question of considerable importance—the protraction of utero gestation: the case which he supposed was an example of this circumstance, had certainly many facts connected with it which led him to form that opinion, whilst he was convinced there were some things against it. The early symptoms of pregnancy were so ambiguous that it was always a matter of great difficulty to determine on the precise time of conception. He believed, however, that it was admitted both by ancient and modern writers that the duration of pregnancy was not always limited to nine months. Several cases were related by modern writers in illustration. Dr. Collins had published a case in the 25th volume of the Edinburgh Medical and Surgical Journal, in which gestation continued for eleven months. Dr. Ryan, in his *Medical Jurisprudence*, mentions that he was engaged to attend a delicate lady who menstruated the last week in February, 1826, and quickened in July, but was not delivered before the 28th of February, 1827, nearly twelve months from her previous indisposition. Dr. Merriman had known cases which lasted till the 44th and one even to the 46th week. There were various other undoubted authorities in support of the possibility of pregnancy being protracted. It was known that domestic animals were very irregular in their periods of gestation—why might it not be so in the human female?

The patient, whose case he had to relate, was 32 years of age, of short stature, and the mother of seven children before the one in question. She always menstruated regularly between each pregnancy; and the catamenia always ceased when conception

had taken place. They ceased last on the 7th of December, 1834; the woman was not delivered until the 5th of December of the following year—twelve months within two days. It was worthy of remark, that at the last cessation of the catamenia she had aching pains in the back: soon after this period, morning sickness and the other symptoms indicative of conception, came on: she quickened in the beginning of April; and afterwards frequently felt the motions of the fœtus, and the abdomen gradually increased in size, and was so large near the termination of the pregnancy, that he considered she would have twins. In July, six months after, Mr. Statam saw her for the first time; she had suffered from a sensation as though a heavy weight had fallen on her left side; she had pyrexia and great pain in the region of the uterus; in fact, she was suffering from an attack of inflammation of that organ; the disease afterwards affected the peritoneum; bleeding, calomel, and opium, and the usual remedies were resorted to; she continued very bad for a fortnight, and had two slight relapses before the expiration of a month. She did not feel the motion of the child during that time. Mr. S. now instituted an examination *per vaginam*, when he found the os uteri so high up that it could scarcely be reached with the finger; the body of the uterus was directed to the right side, and the cervix had become shortened, and was pressed backwards. This was five months before delivery; had it only been the fourth month of gestation, these symptoms would not have been present. At the expiration of the month, the motion of the child was again felt; but the constitution of the mother became exceedingly debilitated; she had cough, dyspnoea, and night sweats; there were, however, no signs of phthisis when the chest was examined. He prescribed a tonic, and the patient recovered after about a month. Mr. Statam left her in September. In October, a thick discharge coming on, she was induced to think she was in the commencement of labour; but it went off in a few hours; but recurred again several times, and with more frequency, till the 5th of December, when she was delivered of a child, which, however, was not larger than usual; this being contrary to the opinion of the generality of writers, who consider it necessary the child should be larger. Now the first point that he (Mr. S.) considered necessary to be inquired into was this—was the protraction owing to the suspension of growth of the child during the disease of the mother? or, was it that there was a deficiency of nutriment from her extreme debility? he could imagine that a fœtus might cease to grow from such causes; he considered the strength of the mother materially affected the growth of the fœtus. Another circumstance which might have some influence, was the extreme state of mental depression

under which the mother laboured from some domestic affliction. Dr. Collins mentions this as one of the causes of protracted pregnancy. Now there were several reasons which led him (Mr. S.) to believe that the above case was one of protracted pregnancy.

1st. The length of time the catamenia had ceased.

2nd. The period of quickening; which was the time the woman usually did so with her other children.

3rd. The advanced state of the uterus five months before delivery.

4th. The discharge at the ninth month.

Against this opinion it might be advanced that the cessation of the menses was the result of amenorrhœa, particularly as the cessation was attended with pain, &c. The usual size of the child might also be mentioned. In answer to questions Mr. Statam said, that after delivery the abdomen was of the usual size; the patient had an uncommon good "getting up." He considered the immense size of the uterus depended on its being very high up, as it pressed upon the diaphragm and obstructed respiration. Mr. Statam grounded his opinion on *all* the points, not on *one* alone—he thought the chief proof was the state of the cervix uteri at the time he examined it. He believed that Dr. Ryan's was the only recorded case in which pregnancy had continued so long as in his case. He (Mr. S.) did not examine the woman at about the nine month. There was not a larger quantity of liquor amnii than usual: indeed there was much less than in general. He did not examine the spine.

Mr. Bryant did not consider there was sufficient evidence to conclude that this was a case of protracted pregnancy. The cessation of menstruation was at best a very doubtful indication, as in the early months of pregnancy a discharge simulating the catamenia might be present. The great enlargement of the abdomen might result from incurvation of the spine.

Mr. Heale thought this was certainly a case of protracted gestation, though he did not consider the cessation of the catamenia any proof; with regard to the time of quickening, he considered it might vary much in the same woman during different pregnancies.

Mr. Lenneker thought that the occurrence of inflammation of the womb after the quickening might be a disturbing cause of the protraction. He believed in those recorded cases of protracted pregnancy; authors had not mentioned whether there had been disturbing causes present. He thought accidental causes affected the period of gestation.

Mr. Crisp thought that if disturbing causes had any influence, there would be many more protracted cases than there are.

Some discussion took place as to the influence the health of the mother exerted over that of the child. It was contended

on one side, that if the mother were in a bad state of health during pregnancy, the child would be thin and puny—and on the other, that children healthy, large, and strong, were frequently the offspring of emaciated parents, and *vice versa*. Several cases were related on each side of the question, in illustration.

Mr. Roberts believed he could mention an *unique* case in which tubercles were found in the placenta. The woman in whom the fact occurred had two children still-born at the eighth month; the third was born alive also at the eighth month. The tubercles in the placenta were none of them large, but in various stages of development: some of them were suppurating; they were scattered over the whole mass. The woman was not consumptive.

—o—

MEDICAL BOTANY.

PLATE XIII.—DAPHNE MEZEREUM.

Mezereon, Spurge Olive.

Off.—The bark of the root.

Mezereon is indigenous. It is also cultivated in our gardens as a flowering shrub. The bark, which is taken from the trunk, larger branches, and root, is in slips of greater or less breadth, sometimes flat, sometimes convoluted, very tough, thin, striated, and fibrous; epidermis smooth, olive coloured, or greyish brown; bark very thin, soft, of a dark green, liber yellowish white, fibrous tough. Smell when recent, nauseous, little when dry; taste at first sweetish, afterwards very hot and corroding the mouth. It is torn off in the spring before the leaves appear. When applied to the skin in its recent state, or infused in vinegar, it raises blisters. It has been most minutely analyzed by Gmelin, who found wax, resin, daphneine, red colouring matter, uncrystallizable and fermentable sugar, azotiferous gum, lignine, brown colouring matter, malic acid, and malates. Daphneine was discovered by Vauquelin in the *Daphne alpina*. It crystallizes in fasciculated prisms, colourless, transparent, brilliant, very soluble in water, alcohol, and ether, assuming a golden colour with a little potass or its carbonate, precipitable by acetate of lead, and converted into oxalic acid by nitric acid. It evaporates, on being heated, in acrid vapours.

The apothecaries use the entire root, and not the bark alone, of which the wood is yellow and hard, and has the same properties as the bark.

Med. use.—The root was long used in the Lisbon diet-drink, for venereal complaints, particularly nodes, and other symptoms resisting the use of mercury. The bark of the root contains most acrimony, though some prefer the woody part. Mezereon has also been used with good effect in tumours and cutaneous eruptions not venereal.

—o—

On the Use of Mineral Magnetism.

M. Becker has for a long time employed mineral magnetism with success, especially in affections of the nervous system. There are three methods of applying magnets—1st, by simple traction, 2nd, by prolonged application, 3rd, by apposition, continued for more or less time: M. Becker prefers the last.

By the first method, the magnetic effects continue for a very short time. The second, the results of which are indisputable, has the following inconveniences:—1st. It is much more painful than the first. 2nd. It requires pieces of magnetised metal properly tempered, that cannot be everywhere obtained. 3rd. These pieces of metal very soon rust, and thus lose their magnetic influence. They should in these cases be repolished; but this precaution is for the most part neglected by patients.

The third method of magnetism, which M. Becker has used almost exclusively for some years, because it is the most simple, and is the most supportable by every patient, is the *method by apposition*. The diseased part is placed for ten, twenty, or thirty minutes to the north pole of a magnet, or else it is put at the side, or else during the night under the pillow or mattress. This practice has often succeeded with Dr. Becker, who relates three cases, two of neuropathy of vision, and one of vertigo, that were cured by apposition. In the last case, the magnet was only put under the pillow, and from the third night the pain ceased, and did not again return.—*Journal d'Hufelande*.

—

Acute Articular Rheumatism quickly Cured by the Use of Tartarized Antimony in large Doses.

A young man, aged 21, was seized with a very severe amygdalitis—erysipelas of the left side of the face supervened almost immediately; some days afterwards, he was attacked with pains in the scapulo-humeral, humero-cubital, and right radio-carpal articulations. Tartarized antimony was administered in six grain doses, and in two days the pains were removed. The patient continued the use of the medicine during three days, in doses of eight, six, and four grains. He then thought himself quite recovered, but the pains returned with increased severity; he again had recourse to the antimony, which he continued to take in decreased doses, and was perfectly cured of the disease.—*Gaz. des Hôp.*

Oraxis.

M. Redvaté has most successfully cultivated the *oxalis crenata*, a single tubercle of which affords a large quantity of wholesome food, the taste of which resembles both the common and sweet potato, or the *convolvulus vatata*.

French Medical Almanack for 1836.

The French Medical Almanack for 1836, just published, by M. Domange, Secrétaire to the *Bureau de la Faculté*, presents the following table of the medical practitioners of Paris:—

Doctors in Medicine and Surgery 1,220
Id. in 1833 1,090

Increase in 1836 . . . 130

An equal number of physicians who figured in the general list for 1833 have ceased to be recorded in that for 1836, either from absence or mortality, 130.

It appears that the number of physicians, who established themselves in Paris in the space of three years, was about 260.

Among the 1,220 doctors inhabiting Paris, there are three commanders of the Royal Legion of Honour, 34 officers, and 255 esquires.

Students registered by inscriptions:—

1832.	1833.	1834.	1835.
5,378	6,746	7,667	8,262

Prize of the Academy of Sciences.

M. Gannal has obtained a reward of 3,000 francs for his method of preserving dead bodies, without precluding him from the prize that may be awarded him when the utility of his discovery, which at present appears undoubted, shall have been confirmed by numerous and long-continued applications.

Sulphate of Copper in Croup.

M. Zimmermann began the use of this medicine in 1827, and published three papers on the subject in 1830. Since that period, he has used sulphate of copper in fifteen other patients, amongst whom he lost two cases. Though M. Zimmerman at the same time employed sanguine emissions, he remarks that it is impossible to mistake the good effects of sulphate of copper in croup. In opposition to the opinion of Gettanau, who denies the good effect of this therapeutic agent, except as an emetic, he recognised in it peculiar properties that do not belong to any other emetic; thus, sulphate of copper causes diarrhoea, salivation, perspiration, and appears evidently to resolve the plastic exudation in the third period, or at least to hinder coagulation, and seems to exercise a specific action on the lymphatic system. In the second and third periods, he commenced with local sanguine emissions, and in different circumstances by general bleeding. He recommends the sulphate of copper to be given from a teacup, and never from a silver spoon, and it should be stirred with the finger or a piece of wood.—*Gaz. Med.*

Intermittent Pleuro-pneumonia.—Neuropathy of the Pneumo-gastric Nerve.

This very rare affection is characterised by the following symptoms: difficult respiration, dry cough, or stringy expectoration, pulse full. The disease commenced with an intense fit of shivering, followed by heat and a severe cough. Every day at noon there was an exacerbation of all the symptoms, commencing with very great shivering, cough, and intolerable pain in the chest, a fit of suffocation, and finally perspiration; at the end of an hour the paroxysm terminated. Ammoniacal mixture was first given; then, two grains of quinine every two hours. The very next day the fit was scarcely perceptible; the day after, there was no fit at all. An observation worthy of remark is, that the symptoms of pleuro-pneumonia, which continued, though in a very slight degree, it is true, in the intervals of the paroxysms, disappeared completely, and in a very short time, simply by the effect of sulphate of quinine.—*Gazette Medicale.*

Intermittent Frontal Neuralgia of one Side.—Suborbital Neuropathy.

The pain first supervened after a fright; it returned every day at two o'clock, commencing at the origin of the suborbital nerve, and extending along its course. The fit lasted from half an hour to an hour. Two grains of sulphate of quinine given every two hours for three days, produced in so short a period a complete cure. The same prompt and favourable effects were observed in another case of frontal neuralgia that appeared without any known cause.—*Gaz. Med.*

Treatment of Venereal Buboës by Blisters.

Doctor Suttens, junr., has published a series of observations that prove the good effect of blisters in the treatment of buboës. He employed blisters from the commencement of the disease, and repeated them until the tumour was dissipated; from four to eight blisters were necessary, and the cure required three each week.—*Gaz. des Hôp.*

SECT. VII. *Mobility of the Pupil—State of the Vision.*

In all the patients operated on, setting aside the rare exceptions which are about to be indicated, the pupils were regular, very movable, and the faculty of seeing was not so much abolished as to hinder them distinguishing easily the light from the darkness, and perceiving very well the passage of an opaque body before their eyes; several even still saw the contour of large objects, and recognized vivid colours.

As to the exceptions, the following is what occurred:—1st. In a man of 64 years of age, the pupils had a dilatation of about half a line: they were very slightly irregular, their mobility very doubtful; nevertheless the patient well distinguished light from darkness, and even the contour of bodies: he had always seen better in a sombre than in a very light place, and had never had pains in the head. A single eye was operated on; no adhesion hindered the exit of the crystalline; the patient saw immediately the day light; but the eye was destroyed by suppuration. It appears rather probable that, in spite of the state of the pupils, this was not a case of amaurosis.

2nd. The following facts present some very different circumstances: it is relative to a man of 45 years of age, of whom men-

tion has already been made; for 30 years, at least, his right eye had distinguished only light from darkness, and not even the evening from the middle of the day; he remembered nothing of the commencement of the disease, and said that he had never had pains of the head; the pupil was regular, very movable, from one to two lines in diameter, the cataract of a uniform milk white: the other eye was perfectly healthy, with the exception of some spots (taies) of recent date. This man was operated on: after the incision of the cornea, and without any other apparent lesion, there flowed out a moderate quantity of the vitreous body, rather fluid: the operation was suspended: no accident occurred. A month later, the extraction was again attempted: immediately after the section of the cornea the aqueous humour flowed out as usually, but a little thready: it was evident that it contained in solution a small quantity of the vitreous body; nevertheless, the crystalloid body was opened with the needle, and immediately the cataract flowed out entirely, under the form of a milky fluid: the pupil remained perfectly black. Seven days later, the cornea and the pupil were very clear, the iris contractile, the patient could tell, though with difficulty, whether the fingers shewn to him were approached or removed; little by little this faculty was lost, without any pain; and when this man quitted the hospital, fifteen days later, he had in the pupil a greyish, triangular spot, which hardly occupied a third of it; the remainder of this aperture was very black, yet the patient perceived no more than the daylight: the iris had resumed its contractility. This case is of a nature to leave doubts upon the state of integrity of the retina, and of the vitreous body previously to the operation.

3rd. The third is relative to a man of 72 years of age, not subject to cephalalgia. His sight had been declining for several years back, but he could not state the precise period. During this time he had always seen better in the shade than in the sun; the pupils were regular, of about a line and a half in diameter—they contracted very little. The patient could not guide himself, but he still distinguished well the contours

of bodies. Extraction was practised on a single side; the patient immediately saw the objects surrounding him. Unhappily, inflammation declared itself, and the cornea became opaque. In spite of the little mobility of the pupils, it cannot, I believe, be admitted that this cataract was complicated.

4th. The fourth case is one of the most remarkable; it relates to a man of 45 years of age, of whom mention has elsewhere been made, and of whom the two eyes were suddenly lost—the second while reading a journal. When he presented himself at la Charité the pupils were very narrow, at most of a line in diameter, the left regular, but very little movable; on this side the patient distinguished the day from the night, but nothing more. The right pupil was a little oval from above downwards, and completely immovable; the right eye did not even perceive the light of day: the cataracts were brilliant, of a pearl grey. Professor Roux operated on the left eye: immediately after the extraction of the crystalline the patient saw his fingers, and demanded so pressingly to be operated on on the other side, that M. Roux finished by consenting thereto. In spite of the narrowness and immobility of the pupil, no adhesion interrupted the extraction, and immediately the patient assured us that he saw likewise his fingers, but less clearly than on the other side. A month afterwards he quitted the hospital, in the following state: on the left the cornea was very clear, although the flap was a little prominent; the pupil very black, immovable, rounded superiorly, irregular below, and prolonged under the form of a notch, as far as the cicatrix of the cornea, to which the iris adhered in a small extent. With this eye the patient recognized a watch very well, and distinguished even the hands of it, though with a little difficulty; but it seemed to him that he saw incessantly a spider's thread stretched before him. On the right, the cornea was clean, the pupil rather narrow, not exactly rounded, perfectly black, immovable; with this eye the patient saw more distinctly than with the other; it seemed to him that he could read large characters: he felicitated himself greatly on the success of this second operation. However, his sight presented this peculiarity, that it was very short: when he walked alone he was obliged to move with much precaution, for he saw scarcely at two or three paces before him.

5th. The following case is interesting in other points of view: it relates to a man of 50 years of age. In splitting wood, during the winter of 1831, a fragment struck his eye, which remained red and painful for four or five days; henceforth the sight declined upon that side, and in three or four months it was destroyed. The right eye commenced to be weakened as soon as the left was lost, and took nearly the same time to arrive at

the same point. The patient had never been subject to pains of the head, nor ever had he seen better in the evening or in the morning than in full day-light; on the contrary, at the period when he saw no more than sufficiently to guide himself, he preferred a vivid light. When he presented himself at la Charité his pupils contracted, but slowly, and to a very small extent; the right was rounded, regular; the left was prolonged a little outwards, into a sort of oval depression. The iris appeared a little dilated forwards; the cataracts were of a greyish-white, scattered over with clouded spangles: the patient distinguished the day from the night, but nothing more. The extraction was practised on both sides, and presented nothing particular, except on the right side a slight lesion of the iris at its external parts.

This man quitted the hospital seven weeks after the operation, in the following state:—the two corneæ were perfectly clean; the pupils very black, the right notched outwards and downwards, the left rounded, nearly of two lines in diameter; both appeared immovable; scarcely did the patient perceive the daylight, far less, said he, than before the operation.

Did there exist an affection of the nervous parts of the eye at the period when this man came to la Charité, or else, was that affection not developed till after he had been operated on?—I cannot say; the preceding history shows that exclusive dependance cannot be placed either upon the little mobility, or upon the irregularity of the pupil, or even upon the almost complete loss of the faculty of seeing the light, for declaring that an amaurosis complicates the cataract. In the patient who forms the subject of this last observation, there was, it is true, a little pain in the eyes after the operation; the right particularly was the seat of some lacerations, the conjunctiva red; there was some pain in the forehead, and in the teeth of the upper jaw: and admitting that these symptoms can account for the loss of the right eye, which, however, presented nothing denoting an internal inflammation, how explain the loss of the left, which scarcely experienced some prickings?*

* I have heard Professor Roux say, in reference to this patient, and to that of the second observation, that he had sometimes seen individuals, on whom extraction had been practised, present, without the development of any consecutive accident, the following state:—

The eye appeared perfectly healthy, perceived the sensation of the light, but by no means distinguished objects.

Or, the following is the manner in which, according to him, this phenomenon may be explained:—We only see distinctly the images of bodies on account of the convexity of the crystalline lens, that unites

6th. An old maid of fifty years had two cataracts. On the left the sight had gradually declined without cephalalgia, and at the end of four years the patient could no longer conduct herself without a guide; the right eye had become weakened shortly afterwards, and had arrived at the same point in 21 months. The left pupil was slightly irregular, *immovable*, of about a line

the rays at the bottom of the eye. Let a concave surface be supposed in the place of the convex surface of the crystalline, for instance, the anterior depression of the vitreous body, the luminous rays will, it is true, be refracted in passing from the aqueous humour into the vitreous body, and will approach to the ordinate (*normale*) raised at the point of incidence: but as all these perpendiculars themselves diverge from before backwards, the luminous rays will also diverge, and will be scattered in place of giving distinct images. Now, if the sight be re-established after the displacement or the extraction of the crystalline, it is so because the vitreous body comes to be convex forwards, and to represent more or less exactly the convex lens no longer existing. But if, for some reason, the vitreous body in certain cases preserves after the operation for the cataract the concave form anteriorly that is peculiar to it, there will necessarily arise what has just been stated: there will be sensation of the light, without formation of distinct images.

This explanation is, as may be seen, very ingenious; but it would demand to be directly proved by the facts. Or, there is found in a rather ancient author the history of a dissection very well made, and which would tend to confirm at least the half of the theory of Professor Roux.

There is the case of a poor woman upon whom Maître Jean depressed two cataracts in the year 1691. The operation succeeded on both sides. Ten days afterwards she saw well enough *to fine hemp*. A month later she died of pneumonia. The dissection of the two eyes was made some hours after death, and the following is what is said by the author in reference to the vitreous body:—"I had the pleasure of seeing through the pupil that the crystalline was no longer in the place it ought to occupy, which is the middle of the anterior part of the vitreous body. That part of the vitreous body was elevated into a *very unequal lump, which imitated the anterior face of a crystalline*, except that it was not depressed; and when with a stylet I gently depressed it, it descended immediately after I had removed the stylet, and returned to its first form."

Nothing can be more precise than this description. It remains, however, to demonstrate that it is always the same with it when the operation is successfully performed, and that, in certain cases of non-success, that change of form does not occur.

in diameter; the left eye distinguished well the day from the night. On the right the pupil was very regular, very movable; the right eye, however, saw a little less than the left, and moreover, better in the evening than in the middle of the day. Extraction was practised upon both sides: no adhesion existed on the left side, notwithstanding the narrowness and the irregularity of the pupil. Unhappily the two eyes were destroyed by suppuration, so that it cannot be said whether the state of the left pupil coincided with a lesion of the functions of the retina. But at least it results from this last case and from the fourth, that the narrowness, the irregularity, and the immobility of the pupil may exist without the least adhesion of the iris to the crystalloid membrane, since the extraction of the crystalline has presented no difficulty.

To terminate what I have to say upon the symptoms, it remains for me to speak of the *aspect of the pupil* itself, or of the cataract before the operation.

SECT. VIII.—All cataracts have not the same appearances: nothing, on the contrary, is more varied, when they are examined very close at hand and carefully. The varieties turn upon the colour of the opacity, its more or less dull or brilliant aspect, the uniformity or non-uniformity of the tint. It is rather difficult to class under a small number of heads all these so different appearances, yet the thing is possible, in making allowance for a little arbitrariness, which cannot be avoided. Let us examine this subject. The aspect of 117 cataracts has been carefully described in 65 patients. The cataract of one of the eyes had an appearance sensibly different from that of the other eye in 3-5ths of the subjects having two of them. Those shades presented by these cataracts may be referred to the four following:—

1stly. *Grey*.—I understand thereby all the hues in which the grey predominated, without there being any tint of blue. This colour has been more frequent than all the others; it existed in 47.

2ndly. *White*.—Namely, white milky, opaline, a little yellowish, mother of pearl-like, &c., &c., but without bluish tint, 41.

3rdly. *Blueish*.—This class contains the greyish or white tints, with a very evident blueish hue, 22.

4thly. *Blackish*.—I do not mean to speak of black cataracts, properly so called; I have met with none of them, but only of cataracts of which the tint approached to a very deep grey or brown, 5.

Finally, two cataracts of an altogether peculiar aspect, and which occurred in a woman of 30 years of age, must be added to these cases. The ground of them appeared brownish, and in the centre of each pupil existed a small white spot, almost exactly square; it was a partial opacity of the anterior part of the crystalloid membrane. It

was necessary to take it away by means of small pincers on both sides after the extraction of the crystalline.

Besides the colour, another point important for consideration is the uniform or more or less spotted aspects of the cataracts: This last appearance is not rare, for in 26 of the 65 subjects of whom there has been question, it existed most frequently in one eye alone, seven times only on both sides. In all these cases there was perceived in the field of the pupil, either simple points more dull, or with a tint a little different from the rest, or else with ill defined, cloudy spots, or else with clouded spangles closely resembling morsels of mother of pearl; all that was defined in a very evident manner upon the very ground of the opacity of the crystalline. In one case, three gray radii, excessively slender, set out from the centre of a cataract of a uniform mother of pearl white, and extended towards the circumference, dividing thus the crystalline into three segments. This case enters, I believe, into the species of cataract described by Professor Jules Cloquet.

Great importance has been attached for a long time to the colour, and to the more or less uniform aspect of the cataract. Maître Jean speaks of them in reference to the prognosis: he gives the list of the good and bad colours; the inequality of the tint is for him a suspicious sign.

In the present day, it is scarcely any longer under this point of view that it is attended to; but some surgeons and oculists of a great name appear to believe that it can be recognized from the aspects, whether a cataract be capsular or lenticular, soft or hard. According to Beer and Travers*, in the membranous cataracts, the colour is always clear, *never uniform*, but of a *spotted*, or *mottled* appearance. According to Beer, the colour of the caseous cataracts is never uniform; they are always more or less spotted; the spots resemble fragments of mother of pearl. It is true that Travers is upon this point of a quite opposite opinion: he thinks that the caseiform cataract is uniformly opaque.

It would, indeed, be very advantageous to know before hand with what species of cataract one may have to do, and particularly to know whether it may or may not be membranous; for it is not without increasing the chances of evacuation of the vitreous body, to attempt to withdraw from the eye an opaque capsule when the extraction has been practised. Unhappily, and in spite of the authority of the able men whom I have quoted above, the diagnosis is most frequently impossible, at least in taking as a basis the characters indicated by them; this is what I reserve myself for proving farther on. But, before examining this question, there is another very important one, which

should find a place here, because it is intimately connected with the first.

Are capsular cataracts frequent?

Several authors, who have written upon diseases of the eyes, have not even entered upon this subject; others have not hesitated to say, that the anterior capsular cataract is by no means rare. (S. Cooper.) According to Tenon, facts and reasoning prove that it is not rare to see cataract depending upon opacity of the capsules. It is true that a little farther on he contents himself with saying that cataracts reside sometimes in the membrane enveloping the crystalline. Professor Dupuytren goes farther.

There may be read, in the *Répertoire Général d'Anat. et Phys.*, tom. 3, *deuxième trimestre*, a very interesting article upon the operations for cataract practised at the Hôtel Dieu; an article in which the author makes M. Dupuytren say that the membranous cataract is to the ordinary cataract (that is to say the crystalline), in the ratio of 1:1½; and this assertion has been reproduced in the *oral lectures* of Professor Dupuytren.

I confess I can hardly believe that some error has not glided into the impression or into the composition. Indeed, in studying the table of 207 persons affected with cataract, who had presented themselves at the Hôtel Dieu from 1815 to 1821, and on whom 264 operations had been practised, (the extraction not having been so more than eight times), these words, *membranous cataract*, are found opposite to each of the cases, in which apparently this species of cataract had been diagnosed. Or, how many times is there question of membranous cataract? 15 times only in 264, which gives the ratio of 1:16 3-5ths.; in place of the ratio of 1:1½.

The difference is great, as is manifest.

Where is the error? does it consist in the omission of a great number of membranous cataracts that have not been indicated in the table of which I have just spoken? May it be, on the contrary, in the ratio of 1 to 1½, which the author of the article attributes to Professor Dupuytren? There is the difficulty; I shall endeavour to resolve it by examining another series of facts.

It is permitted, in many cases, to retain doubts upon the capsular or lenticular nature of a cataract, when it is operated on by depression, or breaking up; it is not the same, at least most frequently, when the extraction is practised. This is the very touchstone of the diagnosis; indeed, after the removal of the crystalline and of its accompaniments, either the pupil remains black, or it remains of a more or less opaque white. In this last case there can be no doubt upon the non-transparency, total, or partial, of the anterior part of the crystalloid; for it is then obliged to be removed either by means of small pincers, or with the cataract needle. Or, in the 121 subjects operated on at la Charité, the extraction has been practised

* S. Cooper, Dictionary of Surgery.

169 times; and in this number, five times only was the crystalline capsule evidently opaque, which will give 1:34 4-5ths, in place of 1:1½, as the ratio of membranous to crystalline cataracts.

I have said *evidently opaque*; indeed, there is a certain number of cases in which the pupil did not rest very clear after the extraction of the crystalline, either on account of the cataract spoon not having been introduced to remove some fragments of the cataract, or because, indeed, there has been in some cases a commencing opacity of the capsule, and that the latter has not been detached. These cases are six in number; and I observe that I only mean to speak here of those in which the operation did not succeed; for it is altogether evident that I ought not to have considered as capable of being cases of capsular cataracts, those in which there remained in the field of the pupil, immediately after the operation, a slight trouble, which was subsequently dissipated completely by the absorption of the fragments of the cataract to which it had been owing. Thus, then, even in admitting as demonstrated, what is far from being so, that the six cases of which I have just spoken, were all cases of membranous cataract, there will be a total of 11 in 169, which will give the ratio of 1:15 4-11ths—still very remote from the ratio of 1 to 1½.

What is to be concluded from that? That it is extremely probable that it is but an error of composition or of impression, which has been made to be stated by the illustrious surgeon of the Hôtel Dieu in the article of the *Répertoire* that I have pointed out, than subsequently in his oral lectures, that the membranous cataract is to the crystalline cataract in the ratio of 1:1½. It is evidently much rarer.

There is scarcely need now of returning to the diagnosis of capsular cataracts; it suffices to call to mind that there were but five, which were evidently of this last kind, while in 33 cases the cataracts presented a spotted or mottled aspect, in order to see how little confidence ought to be placed in this sign, which, according to Beer and Travers, is calculated to make them recognizable.

The following, however, is what was in these five cases, the appearance of the cataract before the operation:—

1st. In an unmarried woman of 26 years of age, the pupil was of a very pure white, *not spotted*; after the extraction, the same tint persisted, the anterior crystalloid membrane was removed by means of the needle, and immediately afterwards, the pupillary aperture became perfectly black.

2nd. In a man of 65 years of age, the cataract of the left side was of a beautiful shining white, with spots that appeared still whiter; after the extraction, there remained in the field of the pupil a demi-opaque pellicle, which was removed by the needle.

3rd. In a man of 60 years of age, the two

cataracts had a uniform bluish tint, with some very fine black striae, irregularly placed on their circumference, and apparently due to a deposit of the pigmentum; after the removal of the crystalline on the right side, the pupil remained very clear, with the exception of a small white point which remained at its superior part, and was not taken away: forty days afterwards, the patient quitted the hospital; the pupil was clear, the same white point persisted as on the first day.

4th. The fourth case is that of the woman who has already been mentioned, and who had at the centre of each pupil a small square, white, very remarkable spot, situated upon a brownish ground. It is manifest, saving in this last case, that the opacity of the capsule has by no means presented a peculiar and characteristic appearance.

Duration.—Before passing to what refers to the operation itself, it remains for me to speak of the formation of the cataract in relation to the time that elapses between the first moment in which the patient perceives the weakening of his sight and that at which he ceases to see sufficiently for guiding himself. This is a rather difficult, or in fact rather a long, subject of research. Indeed, it must be renounced, obtaining indications on this subject from a good number of patients, so little attentive to what happens to them, that they cannot fix, in a manner at all precise, the epoch at which they have for the first time remarked that their sight commenced to decline; sometimes even that at which they have ceased to be able to guide themselves. But it is not the same with all: several remember very well all the epochs; they indicate the month, the circumstance in which they have made these primary remarks; they follow with anxiety the progress of their disease, and mention for each eye in particular the time elapsed between the period of the commencement and that in which the faculty of seeing has been abolished. It is of results furnished by this last class of patients, unhappily too few in number, that we are about to speak.

In 47 subjects it has been possible to determine the time elapsed from the appreciable commencement of the first cataract to the moment in which the patients have ceased to be able to guide themselves. Or, the mean term has been of about five years, one month, and four days.

But by separating what refers to the men (who are 25 in number) from what relates to the women (who are 22 in number), the mean is found to be for the first, four years, two months, twenty-three days, nearly; and for the women, six years, one month, all but a few days.

It is true, that among these last there were two whose disease had marched with so much slowness (14 and 31 years), and who presented two cases so exceptional, that by themselves alone they much augmented

the mean number. Yet, on withdrawing these two women, the mean is maintained for this sex at four years, five months, twenty days, nearly; that is to say, three months more than for the men.

The following is the manner in which these durations of diseases was distributed*.

Men.—Two men, in whom from the commencement to the complete loss of sight, there has elapsed less than a year.

16 . . . from 1 to 5 years

7 . . . from 5 to 10.

Women.

0 below 1 year duration.

13 from 1 to 5 years.

7 from 5 to 10 years.

2 from 10 to 31 years.

Let us see whether the progress of the disease has been equally long for the first and the second eye affected.

Thirty-six patients have been able to indicate how much time the first eye affected with cataract had taken in being lost. The mean number expressive of this time is, two years five months ten days nearly. But by separating what concerns the nine-

* There is a precaution to be taken in seeking the mean terms; namely, to indicate, when that can be done, into how many principal groups are arranged the objects on which we work. Without that, indeed, there is risk of obtaining, not false results, for a numerical result is always true, absolutely speaking, when the data set out from are true, and when no error has been committed in operating upon the numbers; but results, which by no means represent all that we desire to know. An example will render my idea comprehensible. I suppose this very general question: to determine the mean age at which cerebral affections are developed. If it be true that it is at the two extremes of life that these diseases are principally met with, it will necessarily happen, on assembling a certain number of cases, that there will be two groups, the one of infants, the other of old men. If, now, their different ages be added together, and the sum be divided by the number of individuals, there will be a risk of obtaining a mean number (30 years, for instance), very exact, assuredly, but which would teach absolutely nothing; which even, in certain respects, would lead into error, since it would represent an age in which precisely few cerebral affections are met with, in place of representing that, near which the most are developed. It is conceivable that in this case an explanation of two lines will suffice, and the seeking of two means in place of one will suffice for obviating this inconvenience and obtaining precisely what is sought for. Likewise that is a difficulty which cannot constitute an objection against the excellence of numbers; the only question is, of employing them well, as in fact for the best things in this world.

teen men and the seventeen women, the mean becomes 1 year 7½ months for the first; 2 years 7 days for the second. (I lay aside, moreover, from this calculation the two women, of whom there has been question above.)

The following is the manner in which these different durations have been grouped:

Eye lost almost suddenly . . . 1 subject.

— in some days . . . 2

— between from 3 months to

1 year . . . 17

— between from 1 to 5 years 14

— — — — — 8 to 25 years 2

The following are the analogous results furnished by forty-five patients upon the duration of the progress of the disease for the second eye affected. The mean cypher of this duration is, 1 year 8½ months; and by separating what concerns the men and the women, there is for 24 men 1 year 4½ months; and for the 21 women, 2 years 14 days.

By uniting together the two sexes, it is found that the second eye has been lost between

1 to 8 days . . . in 2 subjects.

1 month to 1 year . . — 23

1 year to 5 years . . — 17

5 years to 9 years . . — 3

These cyphers are too small to enable us to seek for the influence that age may have had upon the progress more or less rapid of cataract, but they indicate relatively to the sex a rather remarkable difference, to which I shall soon recur.

It results from these mean terms, that the two eyes are not generally lost with an equal quickness; and that it is particularly the first affected of which the decline marches with the greatest slowness. It is not always thus with it. Indeed, in thirty-two persons affected with cataract, there are two of whom the eyes have taken an equal time for being entirely lost; twenty-one in whom this time has been longer for the first eye affected than for the second; nine in whom the reverse has occurred; and in these thirty last subjects the difference has been such between one eye and the other, that it is a mean term of two years one month twelve days nearly. It must be remarked that the mean term (five years one month four days), which indicates the total duration of the disease until complete maturity of the two cataracts, is superior to the sum of the means representing the time that each cataract has taken to arrive at maturity; this sum, indeed, would only be four years two months nearly. That comes from the fact that in a certain number of individuals there elapses a more or less long interval between the moment in which the first cataract is complete and that at which the second commences.

The following is what has occurred in thirty-two patients (eighteen men, fourteen women), in whom cataracts have not commenced at the same time. In the eighteen

men there have been found thirteen of them, who, having an eye already completely affected with cataract, have preserved the second eye perfectly healthy during a time in general rather long. Thus, two only in these thirteen have preserved it less than one year; the other eleven have preserved it one, two, four, five, and even seven years. In the last five the second eye has been affected before the complete loss of the first.

For what concerns the women, it has been otherwise. In the 14, 5 have preserved their second eye untouched during four to six months after the loss of the first; two only have preserved it 12 and 18 months. In the other 7, the second eye has been affected before the maturity of the first cataract.—
To sum up:—

1st. Abstraction made of the sex, the mean duration of the disease, in reckoning it from the appreciable commencement to the moment in which the patients have ceased to be able to guide themselves, has been five years, one month, four days.

2nd. Thirty times in 32 cases the cataract of one side has taken for arriving at complete maturity, a time different from that taken by the other cataract for arriving at the same point; and 21 times in 30 the first eye affected has been that of which the disease has marched the most slowly.

3rd. The mean duration of the complete formation of the disease has been, for the first eye affected, 2 years, $5\frac{1}{2}$ months; for the second, 1 year, $8\frac{1}{2}$ months.

In regard to the sex:—

4th. The total duration of the malady has been longer in the women than in the men*.

5th. That longer duration is met with again in the women, on examining the progress of each cataract singly.

6th. Thirteen men in 18, and only 7 women in 14 have preserved the second eye perfectly healthy for a time more or less long after the loss of the first; and in the men this time has been generally much longer than in the women. We shall see these last having still the disadvantage in reference to the prognosis.

These different results appear to me sufficiently interesting to induce new researches. I am far from wishing to attach to them more importance than they merit; I know that the numbers on which they are based are too inconsiderable to enable their value to be absolutely depended on; I do not hide from myself that in spite of all the care I have been able to give to the search

after exact indications, it is possible that some errors may have glided into the dates which, of little importance if the cyphers had been elevated, might be of much on account of the opposite circumstance; but I persist in thinking that this subject, forming directly part of the history of cataract, and having been, to my knowledge at least, but little studied, deserves to be so again, and that carefully. It is for future observations to confirm or destroy the first data.

—o—

THE BARKS EMPLOYED IN INTERMITTENT FEVER.

THE barks which are employed for the cure of intermittent fever are the different species of cinchona and their preparations, salix, carapa, swietana febrifuga, melea azedarach. As the history of cinchona is not fully given in any of our dispensaries, I shall take the liberty of attempting it on the present occasion, more especially as it contains some interesting historical facts.

It is now more than three centuries since the Peruvians accidentally discovered the use of cinchona, by observing some animals affected with intermittents instinctively led to it; but others say, by a Peruvian affected with ague having drunk from a pool into which cinchona-trees had fallen, and thereby having obtained a cure of his malady. It is also on record that its efficacy in the cure of gangrene was discovered by an aguish patient labouring under that disease having been cured. Professor Duncan asserts, however, that the natives of Loxa, who are the reputed discoverers of this medicine, would rather die than take cinchona, which they class with opiates, among the poisons causing gangrene. From the febrifuge properties of cinchona, it was called *palo de calenturas*, or *fever tree*, by the Spaniards. The exact period at which it was discovered is unknown, but is said to be about the year 1500. It was not known to Europeans until 1640, after it performed a signal cure on the lady of the Spanish viceroy, the Countess del Cinchona, at Lima, and, on her return to Europe, it soon came into use. This occurrence gave rise to the synonyms for cinchona: *cortex vel pulvis comitessæ*, &c., *cortex china*, *chinchina*, *chinchona*, *kina kina*, *kin-kina*, *quina quina*, and *quinquina*. But according to the authority of Don Joseph Villerbel, a Spanish physician quoted by Badus, the Peruvian bark was first brought into Spain in 1632, and thence it passed in other parts of Europe. At first it was improperly used, and consequently failed in many cases, an occurrence that excited the hostility of the faculty to such a degree, that the medicine would have fallen into disuse, had not the Jesuits imported it in large quantities from their brethren in South America.

* This result is found moreover confirmed, if in the 8 subjects in whom the two cataracts have commenced at the same time, we compare men with women. Indeed, the mean duration of their formation has been 3 years, 4 months and a half for the five men; 4 years, 1 month and a half for the three women.

In 1649 a Jesuit brought a quantity of it into Italy, which was sold at a high price, and was so lauded, that it soon found its way into all parts of Europe. Cardinal de Lugo, of Rome, purchased some of it for the poor; and on account of this, and the general patronage of his brethren, it was now denominated *cortex vel pulvis jesuiticus*, *pulvis patrum*, *pulvis cardanalis* de Lugo—Jesuits' bark.

Through the same influence it was deemed innocuous and salutary, while it was strongly recommended, in 1661, by Pope Innocent X., who ordered his physician to draw up the *Schedula Romana*, which indicated the dose and proper time for taking it. In this schedule it was advised at the commencement of the cold fit of ague—the worst time that could be selected, and hence its failures were so common, that it became generally considered useless. This led some to exhibit it in excessive doses, and, as death sometimes happened, the bark was denounced as a dangerous, if not a poisonous remedy.

A remarkable case occurred while this unfavourable impression was prevalent, which contributed very materially to increase the doubts of its value; and that was in the instance of Archduke Leopold of Austria, to whom it was administered with temporary benefit only, and fell into discredit with the faculty throughout the continent of Europe.

In the year 1655 cinchona was introduced into this country, and was at first considered a doubtful and a dangerous remedy. In 1658 it was given to Mr. Underwood, an alderman of the city of London, who died while using it, and his death was ascribed to it. This impression was so general among the physicians of the period, that Cromwell, who laboured under intermittent at the time, was suffered to languish and die of his disease, without a trial of the bark, his medical attendants being afraid to employ it. Morton, who makes this statement, observes, "*nondum vires corticis in hoc veneno subijendo, saltem hic loci comprobatæ erant.*" (*Pyretologia*, 1692.) Dr. Prejeau, who was President of the Royal College, and contemporary of the illustrious Harvey, advocated its employment, according to Sir George Baker, (*Med. Trans.* vol. iii), as also did Dr. Brady, Professor of Medicine in the University of Cambridge, and Dr. Willis. Dr. Morton was not experienced in its use, and Dr. Sydenham was at first its opponent; but with that candour and judgment which distinguished him, he determined to watch its effects, and to form his opinion after the results of repeated experience. He was soon convinced that in many cases it was efficacious, in others highly serviceable; and that in those in which it had failed it was either injudiciously administered or it was adulterated. It was usually given during the paroxysm, until subsequent experience proved it should only

be used in the apyrexial period, or in other words, after the fits had terminated. It appears by the account of the classic Mason Good, that it was very difficult to procure it in any quantity, and, therefore, that it was probable that it was considerably adulterated. He states on the authority of Sturmius, who warmly patronized its use, that pure bark was so scarce on the continent, that twenty doses of the powder were sold at Brussels in 1658 for sixty florins, for the purpose of being sent to Paris; and that this order so completely exhausted the apothecary's stock, that he himself was incapable of obtaining any even at that price; and that for the use of an aguish patient, who was attacked in the month of February, he was obliged to wait to the following June before he could obtain a supply. (*Febrifugi Peruviani Vindictiarum pars Prior*, Antwerp, 1659.) Bartholine of Copenhagen having received a present of three doses or six drachms of the powder from some friends, who had brought it from Italy, was induced to try it upon a lady who had a quartan fever. The first dose was rejected from the stomach; and, in order to prevent a repetition of this accident, and consequently the loss of his entire stock, he macerated his two remaining doses in wine for forty hours, and gave the infusion during two successive paroxysms. The only effect was, that the fever was changed from a double to a single quartan; and here he was obliged to stop, having no more of the medicine. (Thomæ Bartholini *Hist. Anat. et Med. Cent. v. Hist. l. Haffniæ*, 1661.) But, even in 1678, Morton complains that the bark offered for sale was become so inert, corrupt, and adulterated, that it was necessary to increase the dose from two drachms to one, two, or three ounces; and under such circumstances we cannot wonder that the medicine disordered the digestive organs.

In order to guard against all objections raised against the bark, Sydenham proposed to himself the following regulations for its use:—

1. To be cautious in the quality of it he employed; and to allow no intermixture, from fraud, or a view of increasing its virtues.

2. To administer the bark in the intervals, instead of in the paroxysms of the fever.

3. To give it at the rate of two scruples every four hours, instead of two drachms twice a-day, after the *Schedula Romana*.

Under these regulations the bark acquired all the success which has at any time been ascribed to it; and the most important point in these regulations was that which effected a change in the period of exhibiting the remedy. Sydenham made this valuable change after repeated consideration and observation. He says, "*Dirè multumque apud se agelat.*" yet Morton, who published his *Pyretologia* in 1692, only three years after the death of Sydenham, alleges

that he had given the bark to persons of all ages, at every season of the year, cured every species of intermittent quickly and radically, and had found it more useful in the intervals than in the fits. But Lister, who was a contemporary of Sydenham and Morton, and who treats neither of them with respect, accuses the former, a few years after his death, of having copied his mode of giving the bark from the miserable mountebank Talbor, who was its inventor;—"auctore suo, misero ille agyratâ Talbor."—(M. Lister Octo Exercitationes Medicinales de Cort. Peruv. exhibendi tempore.) Talbor was not an empiric: he had served his apprenticeship to an apothecary at Cambridge, and acquired more fame for his mode of exhibiting the bark than any one of his contemporaries. He was appointed one of the physicians to Charles II., against the influence of the College; was specially sent for to Paris to attend the Dauphin; succeeded in curing him, and afterwards revealed his arcanum for a stipulated sum to Louis XIV., which was found to be an infusion of the powder of bark in port wine, as a cordial.

It is right to mention, that from 1638 to 1776 no other cinchona was supplied in commerce, except that of Loxa and its vicinity. The late erudite Professor Duncan informs us, that "La Condamine mentions the cinchona of Riobamba and Cuenca, in the province of Quito, as well as that of Ayavaca and Jean de Bracamorros. In 1753, Don Miguel de Santisteban, in travelling from Loxa to Santa Fé de Bogota, observed that everywhere in the same elevation with Loxa there were cinchona trees. From him, in 1761, Mutis received the first specimen of the *c. cordifolia*. Mutis, in 1772, found cinchona near Santa Fé, and sent it to Europe from Carthagena. Till then all the cinchona was gathered in the woods of Loxa, Ayavaca, and Jean de Bracamorros, and shipped, under the name of *Cascarilla fina de Uritasinga*, at Payta, to double Cape Horn. In 1776, Don F. Renquifo discovered *c. nitida* of Ruiz at Huanuco. Ruiz and Pavon, authors of the *Flora Peruviana*, examined in the vallies of the tributaries of the Amazon river, and almost at the same time cinchona was found in the northern and southern extremities of South America, in the mountains of Santa Martha, and in the kingdom of Buenos Ayres at La Praz and Cochabamba. Since 1780, Europe has received cinchona, of different value, from Payta, Guayaquil, Lima, Buenos Ayres, Carthagena, and Santa Martha."

Dr. Paris observes, in his Pharmacologia, that "notwithstanding the labours of the Spanish botanists, the history of the genus (cinchona), is still involved in considerable perplexity; and owing to the mixture of the barks of the several species, and their importation into Europe under the common name, it is extremely difficult to reconcile

the contradictory opinions which exist upon the subject." There are no less than twenty-five distinct species of cinchona, according to this able and learned writer, independent of any additions which we owe to the zeal of Humboldt and Bonpland; while Professor Thomson, of the London University, states, that in a large collection of dried specimens of the genus cinchona, in his possession, collected, in 1805, both near Loxa and Santa Fé, he finds many species which are not mentioned by any Spanish botanist. Professor Duncan states, that, according to the authority of M. Von Bergen, a drug broker at Hamburg, there are eight commercial species of cinchona bark, and these are described at length in the Edinburgh Dispensatory, twelfth edit., 1830.

Three kinds of cinchona bark are mostly used in this country:—

1. *Cinchonæ lancifoliæ cortex*. l. e. cortex Peruvianus, d. lance-leaved cinchona-bark, common quilled bark, *pale* bark.

2. *Cinchonæ cordifoliæ cortex*. l. e. cortex Peruvianus, d. Heart-leaved cinchona bark, commonly called *yellow* bark.

3. *Cinchonæ oblongifoliæ*, l. e. cortex Peruvianus. d. Oblong-leaved cinchona bark, *red* bark.

In consequence of the great demand there is for cinchona, it is so generally adulterated that it is almost impossible to obtain a genuine specimen, more especially of powdered bark. Hence its frequent failures, and cause of its depreciation in the minds of the faculty. Various other barks are constantly mixed with it, and in some cases the virtues are extracted from good bark by decoction, and the useless residue is mixed with a portion of the genuine article, and supplied in this state in commerce. There is a minute description of the distinctive characters of cinchona in all our Dispensatories, which need not be detailed at present, being well known to members of the medical profession, and of little interest to those fellows who do not belong to that faculty. The distinctive characters of good cinchona are its density, weight, and dryness, and that a decoction made of it has a reddish colour when warm, becomes paler on cooling, and deposits a reddish sediment. "Those pieces," says Dr. Duncan, "whose taste is simply intensely bitter, or very astringent, or nauseous, or merely mucilaginous, whose surface is smooth or polished, or a dark colour, pale, yellow, or red, which are tough or spongy, whose fracture is fibrous, woody, or powdery, and their internal colour white, or grey, are to be rejected. It is still more difficult to know genuine cinchona bark in the form of powder."

The cinchona bark has been repeatedly subjected to chemical analysis by some of the first chemists, but until the year 1821, its constituents were not accurately determined. Yellow bark contains, according to Vauquelin,

a peculiar acid, which he calls kinic acid, and which Dr. Duncan has denominated cinchonic acid, and contains the largest quantity of quinine. Red bark contains both cinchonine, first discovered by Dr. Duncan, and quinine in large proportions. The yellow bark ought therefore to be preferred, and next to it the red and grey sorts. There are various other principles in the cinchona bark, according to Pelletier and Caventon, which are detailed in all our modern works on *materia medica*.

Medical Use.—Dose and Mode of Administration.—Cinchona acts upon the living fibre as a powerful tonic, stimulant, and antispasmodic; on dead animal matter, as an antiseptic. *It was long considered as a specific for intermittent fevers; but it sometimes fails to produce its beneficial effects. It is very much employed in the last stage of continued and eruptive fevers when typhoid symptoms appear, and great prostration of the vital powers are present. Accordingly, it is much praised in typhus, confluent small pox, yellow fever, scarlatina maligna, cynauche maligna, gangrene, and mortification; in acute rheumatism, certain forms of dysentery, scrofula, ill-conditioned ulcers, rickets, in dyspepsia, hypochondriasis, and during convalescence after various inflammations. It is exhibited in powder, infusion, decoction, tincture, wine, and extract, and recently combined with sulphuric acid in the form of quinine. It is likewise applied in the form of powder to ill-conditioned, carious, or gangrenous ulcers, and is used in gargles and enemata, and when the stomach is irritable, the sulphate of quinine has been applied to a blistered surface with success.

It is said by some writers that the best form of administering cinchona is in the state of fine powder; the dose varying from ten grains to two drachms, diffused in wine, water, or milk, or made into an electuary with honey or currant jelly. But it sometimes causes vomiting when exhibited in whey, and in such cases either the dose must be diminished, or some other form must be preferred. In such cases the infusion, decoction, or tincture, will be substituted for the powder with advantage. But the infusion does not contain so large a proportion of the active principles of the medicine as the powder, and is very liable to become decomposed and spoiled after a very short time. The decoction is also an objectionable preparation, while the great power of the menstruum in the tincture prevents us exhibiting the bark in sufficiently large doses to ensure its efficacy. A vinous infusion is sometimes employed, and very often the bark is only mixed with the wine, but this is an unpleasant form to exhibit it. The extract was long considered one of the best preparations, but it is now generally admitted that the active properties of cinchona are destroyed in making this formula.

Since the discovery of the active principle of cinchona, and its preparation as an alkali neutralized by sulphuric acid, and forming the sulphate of quinine, we can now exhibit this valuable remedy in a much less objectionable form than any which had been previously in use. One grain of the sulphate of quinine is said to be equal to a drachm of powdered bark. The dose is from two to twenty grains; though half a drachm has been given in twenty-four hours. Dr. Perrine, of Adam's county, in America, exhibited eight grains every six hours; and Professor Speranza, of Italy, gave it in doses of 12, 24, and 30 grains, and in one case, 108 grains as a dose, before the fever was arrested. This immense quantity, equal to 13½ ounces of cinchona, could not, I apprehend, be given with safety, had the medicine been genuine, as very violent effects are frequently observed when this remedy is pushed too far. In this country, in which intermittents are much more tractable than in Italy, the majority of the profession find that doses of one, two, or three grains of quinine, administered every six hours, effect a speedy cure. Professor Cooper informs us, in his valuable edition of Good's Study of Medicine, that every case of ague he treated in the King's Bench and Fleet prisons, yielded to doses of two grains. Professor Graves is also a strong advocate for small doses of this and other tonics, as appears by the Dublin Journal of Medical and Chemical Science for May last. Professor Elliotson has found quinine succeed when free doses of bark had failed. He states that he tried it in 150 cases of ague, many of which were combined with so much inflammation of the head, chest, and abdomen, as to require venesection, others with dropsy and chronic disease of the lungs or liver; but *every one was cured*. He never knew quinine increase inflammation or interfere with antiphlogistic measures; he has invariably given it under all circumstances, and adopted it with any other measures required by the symptoms. He has found five grains every four hours generally successful. He is of opinion, that it is the best practice to exhibit ten grains after the paroxysm is over, which, except in quartans, prevent the next paroxysm; and, if repeated daily at the same hour, often cure the disease. But in some cases it is necessary to administer small doses of the medicine every six or eight hours, so as to push the remedy to 20 or 30 grains in twenty-four hours (*Med. Chir. Trans.* vol. xiii). Many other physicians disapprove of such large doses, more especially should inflammation be present in the head, chest, or abdomen; and repeated experience has convinced me of the value of this statement. I fully agree with Dr. Graves, of Dublin, that excessive doses of quinine or carbonate of iron are in general unnecessary.

There are other vegetable alkalies, as

salicine, piperine and ilicine, of great value in the cure of intermittents. MM. Robiquet and Petroz have discovered an alkali analogous to quinine in the bark of carapa, which had cured agues in America that defied the power of cinchona. (Quarterly Journal of Foreign Medicine, vol. iv.) Another French writer, M. de Martin, has mixed quinine, formerly pulverized with cerate, then applied to a blistered surface, from which it was speedily absorbed, and cured ague, (Rev. Med. Sept. 1827)—a fact worthy of recollection in all cases in which the stomach is irritable.

The other barks used for the cure of intermittents are suritenia febrifugia, the melia, azedarach or bead-tea, and the tellicherry bark. These are far inferior to cinchona, though much praised in India. Various other remedies are employed for the cure of intermittents; but those I cannot consider on the present occasion.

—o—

THE CONNEXION OF PHYSIOLOGY AND PATHOLOGY.

A Paper read before the Medical Society of the London University.

(Concluded from page 783).

THE next subject I have selected for consideration, is the pathology of congenital malformations, because that subject is so peculiarly interesting in itself, and serves so admirably to demonstrate the dependence of pathology on physiology.

Congenital Malformations.—Deviations from the natural arrangement and distribution of the elementary particles of the tissues, produce the various species of congenital malformations usually called monstrosities. Alterations in their number, which are the causes of several malformations, may arise from hypertrophy or atrophy.

Setting aside the superstitious ideas and absurd prejudices which accompany the history of monstrous formations, which was almost wholly composed of an incoherent assemblage of marvellous tales and inaccurate descriptions, it is to modern anatomists that we are indebted for the greatest advances in this department of medical science, especially to Littré, Geoffroy St. Hilaire, Soemmering, and a few besides. Littré conceived, and the others have adopted, the idea of regarding a certain number of monstrosities as the result of an arrest or suspension of the progress of the development of the organs of the foetus.

Vicious conformations usually make their appearance at birth—they generally occur in the mother's womb, before the individual is perfectly formed. And here we can trace some analogy between this pathological condition in the human foetus and the normal physiological condition of those animals which occupy a much lower rank

in the scale of organization; for, in the lower classes of animals, such as zoophytes, the conformation of their organs is not so absolutely determined by fixed laws, but that it may be modified and changed under the influence of certain causes which influence their nutrition. But in those animals this condition obtains at all periods of their existence, whereas, in man, it is almost exclusively confined to the period of his foetal life.

The conformation of a foetus found deformed at its birth, may have proceeded regularly during the earlier periods of its evolution, and have been subsequently modified by some derangement or defect in its development. And the development of the foetus may be modified in various ways: sometimes the formative process, or *nus formativus*, as it has been termed, possesses less energy than natural, and the development of the organs is in consequence suppressed, in which case they are found either imperfectly formed or altogether deficient: sometimes, on the other hand, this force seems to acquire an excess of energy, and then there is a corresponding excess of development, and the organs exceed their natural limits either in size or number. In other cases, again, the development cannot be properly said to be either excessive or defective, but the formative process appears to have been simply perverted, thus producing various modifications in the general transposition of the viscera, and in certain varieties in the origin of the principal arteries.

To these three classes every species of monstrous formation may be referred. Meckel supposes that these species form series, rising by regular gradations from the natural form to the most unnatural deformity. M. St. Hilaire is rather disposed to consider each individual monster as constituting in itself a distinct species.

Whatever be the nature and number of these malformations, the *implicit obedience to certain laws* which nature constantly observes in the midst of these apparent anomalies, is very remarkable. Thus the situation of the organs has never been so perverted that the lungs were placed in the skull, or the brain in the pelvis; nor have the organs been observed so confounded together as that the alimentary canal, for instance, made a continuous tube with the aorta, &c. All which would no doubt occur if certain laws did not still preside over this state of apparent disorder and confusion. Another illustration of the existence of these laws is, that man and the higher orders of animals may present such an arrest in their development, that several of their organs shall represent exactly the natural state of these parts in the inferior animals; whereas the latter can never attain such a degree of development as that their organs shall resemble the corresponding parts of the higher orders. Thus, for example, the human brain, arrested in

its evolution, may present an appearance more or less exactly analogous to the brain of fishes or reptiles, but the simple brain of these animals can never attain the degree of complicated structure which the human brain presents.

When several malformations exist in the same individual, they are not, in general, referable to the same class. Several of them result from the law so ingeniously conceived by M. St. Hilaire, which establishes that the exuberance of nutrition in one organ involves, to a greater or less extent, the total or partial atrophy of some other organ, and vice versa. Innumerable applications may be made of this law of compensation, as it is termed, to the study of monstrosities. Thus, in several individuals who have on one hand or foot supernumerary fingers or toes, the hand or foot of the opposite side has fewer than ordinary. Thus, in a fœtus with umbilical hernia, the left foot had only one toe, but the right foot had eight, and the eighth was divided (Neumann). In another fœtus, which had but one foot, the left hand had two thumbs (Sue). M. Légalas presented to the Academy of Medicine a fœtus which had no thumb on the left hand, but two thumbs on the right. This same fœtus had likewise only eleven ribs on one side, but had thirteen on the other.

It may be laid down as a general law, that those organs are most subject to imperfect development which are latest in attaining their complete evolution. Thus the intestinal canal is one of the first organs of which any trace is perceptible; at first it is only a continuation of the vesicula umbilicalis, which gradually elongates itself, into two tubes, one, inferior, constituting the large intestine, the other superior, forming the small intestine and stomach. Now, in all the monsters hitherto examined, the primitive portion of the intestinal tube has been found perfect, whilst, on the other hand, those parts which are subsequently developed have repeatedly been found deficient. The same law applies to all the other organs of the body.

There are several malformations, differing widely from each other, and apparently presenting the greatest discrepancies in their specific characters, which may nevertheless be traced to one common source—imperfect development. Amongst these malformations may be enumerated the different accidental openings and separations of parts, which, in the natural state, are united and closed. These solutions of continuity are all situated in the median line, and proceed from an arrest of development. There is, in fact, a period in the evolution of the fœtus, when almost every organ is composed of two parts, separated by an interval, which subsequently diminishes and fills up as the fœtus approaches the full term of gestation. The gradual obliteration of this intervening space pro-

ceeds from the fulfilment of a law demonstrated by M. Serres. viz. that all the parts of the body are formed from the circumference towards the centre. Hence it follows, that if the evolution of an organ be arrested at any time near the period of its first formation, the organ will be composed in general of two parts. To this cause must be referred those cases which present a greater or less extent of deficiency in the parietes of the cranium, as at the sutures, the various degrees of separation of the spinal canal, from the simple division of a spinous process, to a perfect cleft in the very body of the vertebræ—the absence of the liver, alba, hare-lip, and so on.

In all these unnatural formations, the same laws are observed as preside over the natural development of parts; and every imperfection of development an organ presents corresponds exactly with the state of that organ in some of its stages of development. If we next turn our attention to the accidental apertures and communications which many of the internal organs occasionally present, we shall find that they also are referable to an arrest in the development of these organs: thus, the unnatural communications between the cavities of the heart, which have been observed after birth, are the natural state of the parts at certain periods of the evolution of the fœtus. In the female the genital, urinary, and digestive organs have often been found communicating and uniting into a sort of common reservoir, previously to their opening externally; and if we follow these organs through the different stages of their development, we arrive at a period when this triple communication was the natural conformation of parts.

Many displacements are likewise evidently the result of an arrest of development: thus, the presence of the testicles in the abdomen; the situation of the kidneys in front of the vertebræ; the immediate attachment of the hands to the scapula, or of the feet to the ossa coxarum, are, in the adult, so many displacements, but were the natural situations of those parts at a certain period of foetal life. Again, during the first months of foetal life several organs, which subsequently incline to the right or left side, occupy a perpendicular position in the median line. Thus the heart, instead of the oblique direction which it afterwards assumes, is parallel to the axis of the body; so likewise the stomach, and indeed the whole intestinal tube, which at first consists of a simple canal, extending in a straight line from the stomach to the anus; these peculiarities of structure may continue after birth, and are then evidently the result of imperfect development.

Lastly, to this cause also may be traced even the congenital anomalies of colour which different individuals present. Thus the black pigment of the choroid does not make its appearance in the fœtus until the

fifth month after pregnancy; and if at that period its formation does not proceed, the choroid will appear red after birth, as in the case of Albinos.

If the interpretation given to the facts adduced be correct, we must adopt the general conclusion that the greater number of monstrous formations may be referred to vices of development, and consequently do not require for their explanation any hypothesis of previous disease having affected the fœtus. If monstrosities be the result of a fault of development, we must look to the *causes* of that fault of development, in order to ascertain by what physiological laws it is determined, and thereby trace the dependence of this part of pathology on physiology.

Now, it would seem that external mechanical causes, which exert an influence on the quantity and quality of the nutriment the fœtus receives, do possess the power of preventing the regular development of the fœtal organs, a fact which has been proved by direct experiment; for M. St. Hilaire produced certain malformations by artificially modifying the condition of the embryo at different periods of its existence. He caused several eggs to be hatched, some of which had been previously varnished in different parts, and others enveloped wholly or partially in gold-beaters' skin, while others again had had their shells perforated by various means. At the expiration of the usual period of incubation, it was found that in some the chicken was not at all developed; in others it had not attained its natural size; whilst in some instances its growth was quite preternatural.

Again, the conjecture that the quantity and quality of the nutriment it receives considerably influence the development of the organs of the fœtus, derives considerable support from the very interesting experiments made on bees by M. Hubert, of Geneva, in which he succeeded in producing at pleasure males, females, or neuters, by placing the young insects in a cell containing a greater or less supply of honey. So that we may consider anything that exerts an influence on the nutrition of the fœtus, as strong moral emotions (which are so often cited as the causes of monstrosities), may, to a certain extent, arrest or pervert its development. That this result is merely the operation of a physiological law, is evident. The diminution of the left lobe of the liver after birth, from the change which takes place in the supply of blood to that organ, is an instance of the physiological operation of that law; for the volume different organs attain, and that of their respective arteries, are directly proportional one to the other.

Quite a sufficiency of the lesions of structure have here been adduced to convince, I should think, any unprejudiced person that their course and progress, may even their very existence, depends upon those laws which, manifesting themselves in the healthy

body, are termed physiological laws. So strong and inseparable is the link which connects pathology with physiology. Of functional diseases it is needless to enter into detail, because they evidently may be referred to two great classes, viz.—increased and diminished activity of the organ or organs affected. Both these opposite conditions may co-exist in different organs at the same time, and then, if produced by the same cause, their co-existence is for the most part referable to that physiological law which so frequently manifests itself both in health and in disease, viz.—that law of compensation, by which increased activity in the functions of one organ is accompanied with a corresponding diminution in the function of another associated organ. If, then, diseases of function are referable to the increase or diminution of that function, upon the application of a stimulus or sedative, and the subjection of the organs to the influence of such agents be a physiological law, we must allow that that law was intended to serve some important end. Only two examples will be ample to show its importance.

1st. The secretion of bile by the liver is, in a healthy individual, generally directly proportional to the quantity and quality of the food upon which it has to act. Now, if the quantity of bile were invariably the same, there would obviously at times be too much for the quantity of food taken; at other times too little, according to the sum of the virtals which the individual has consumed.

2nd. The most natural and most frequent stimulus to the skin is warmth. The important property the skin possesses, of being excited to increased function by heat, either externally conveyed to the body, or produced by violent exercise, is obvious.

The laws which preside over disease are, then, the laws which preside also over health; and it is just because those laws are general, because they are impressed on the nature and not on the individual, that man is subject to disease.

Reviews.

Pharmacopœia in usum Nosocomii Regii Glasguensis. Auctore R. McGregor, Chir. ejusdem Nosocomii Pharmacopœo, &c. Editio Secunda. 18mo. pp. 36. 1835.

THE author of this work is apothecary to the Royal Infirmary of Glasgow, and was requested by some friends and pupils to publish the pharmacopœia of that institution. He has confined himself to the description of the preparations employed in the hospital to which he belongs; and as

these are excellent and few in number, we shall place them before our junior readers. It is always an advantage to students who attend the medical and surgical practice of a public hospital or dispensary, to know the formulæ employed in such an institution; and we hope ere long to see numerous formularies of this description. The author has executed his task very creditably. In our opinion, however, the prescriptions are too few in number, and might be advantageously increased in a future edition:—

“*Acidum Hydrocyanicum (Prussicum) Medicinale.*

Rx. Cyanidis Potassii grana triginta et duo,

Acidi Tartarici Crystallorum grana septuaginta et duo,

Aquæ destillatæ unciam.

Cyanidi et Acido phialæ vitreæ inditis addatur aqua, tunc phiala illico obturata et subinde agitata per horam dimidiam seponetur, ut Bitartras Potassæ formatus subsederit: dein effundatur Acidum Hydrocyanicum et Acidi Sulphurici diluti minima decem addantur. Grana centum hujus liquoris continent grana duo cum semisse Hydrocyanici Acidi Absoluti. Dosis. Mimina decem.

T. CLARKE.

Aqua Cardiaca (Toddy).

Aqua Citri Medicæ (Lemonade).

Aqua Lauri Cinnamomi.

Rx. Spiritus Lauri Cinnamomi drachmam, Aquæ fontanæ uncias duodecim. M.

Aqua Menthæ Piperitæ.

Rx. Spiritus Menthæ Piperitæ drachmam, Aquæ fontanæ uncias duodecim. M.

Aqua Menthæ Sativæ.

Rx. Spiritus Menthæ Sativæ drachmam, Aquæ fontanæ uncias duodecim. M.

Aqua Supercarbonatis Sodæ (Soda Water).

Aqua Tamarindi Indicæ (Tamarind Water).

Bicyanis Hydrargyri (Percyanis).

Rx. Cyanidis Ferri (Prussian blue) partes octo,

Oxidi Hydrargyri rubri per Acidum Nitricum partes undecim.

Aquæ destillatæ partes quadraginta.

Coquatur mistura donec expers coloris fit; dein coletur per chartam et vaporet ut chrystalli formentur. Dosis, octava pars grani.

Bolus Camphoræ,

Rx. Camphoræ, ope pauxilli Alcoholis fortioris in pulverem tritæ, grana sex,

Conservæ Rosæ Gallicæ quantum sufficiat.

Camphoræ conservam adde et fiat bolus.

Bolus Diaphoreticus Usitatus.

Rx. Pulveris Ipecacuanhæ et opii grana decem.

Electuarii Opiati quantum sufficiat ut fiat bolus.

Sumat æger talem unum omni hora donec sudaverit; sudore erupto bibat abunde de liquore aliquo diluente tepido. Detrahantur lecto stragula lintea et augentur stragula lanea præsertim super pedes.

Bolus Kino Compositus.

Rx. Pulveris opii granum,

———— kino grana decem,

Syrupi simplicis quantum sufficiat.

Misce. fiat bolus.

Bolus Communis vel Usitatus.

Rx. Pulveris radices Convolvuli Jalapæ scrupulum, Calomelanos (Proto-Chloridis Hydrargyri) grana sex, Pulveris radices Amomi Zinziberis grana tria.

Terantur simul et ope Mucilaginis Acaciæ Arabicæ fiat bolus.

Cataplasma Acetatis Plumbi.

Rx. Micæ panis quantum velis, Solutionis Acetatis Plumbi quantum satis sit ad madescendum panem.

Cataplasma Carbonis Ligni.

Rx. Cataplasmatibus communis partes sex, Pulveris Carbonis ligni partes duas. Misce.

Cataplasma Conii Maculati.

Rx. Foliorum Conii Maculati uncias duas, Aquæ libras duas.

Coque ad octarium, dein adde, Farinæ seminum Lini Usitatissimi quantum satis sit ad idoneam spissitudinem faciendam.

Cataplasma Convallariæ Multifloræ.

Rx. Radicis Convallariæ Multifloræ quantum velis,

Contunde in pulpam.

Cataplasma Dauci Carotæ.

Rx. Radicis Dauci Carotæ quantum velis, Coque ad aptam molliem et contunde in pulpam.

Cataplasma Emolliens vel Commune.

Rx. Farinæ Hordei Distichi, Furfuris Tritici Hiberni triti, utriusque, partes æquales.

Coque ex aqua ad idoneam spissitudinem, et illinatur superficies Oleo Napi sylvestris.

Cataplasma Iodurettum.

Rx. Cataplasmatibus Lini quantum velis, solutionis Iodinii Rubefacientis q.s. Misce. Lugol.

Cataplasma Lini Usitatissimi.

Rx. Aquæ bullientis partes quinque, Farina seminum Lini partem unam. Lento igne agita simul per sexagesimam horæ partem.

Cataplasma Panis cum Lacte.

Rx. Micæ panis bene tritæ partes duas, Lactis recentis partes sex. Coque simul leni igne per vigesimam horæ partem, et assidue agita donec

spissitudo idonea Cataplasmatibus fit.
Illinatur superficies pauxillo olei.

* Cataplasma Papaveris Somniferi.

R. Farinæ seminum Lini quantum velis,
Decocti Papaveris somniferi quantum
satis sit ad faciendum cataplasma.
Misce.

Cataplasma Hyosciami Nigri.

Fit eodem modo ut prius.

Cataplasma Vini Rubri.

R. Aquæ bullientis partes quinque,
Farinæ seminum Lini partem unam
et dimidiam,

Lento igne agita per horæ sexagesi-
mam partem: dein ab igne remove
et adde vini Rubri partes duas.

Ceratum Terebinthinæ Venetæ.

R. Terebinthinæ Venetæ partes quinque,
Ceræ flavæ partem unam.

Liquescant simul.

Cerevisia Fortior (Porter).

Cerevisia Tenuis (Small Beer).

Cerevisia Zinziberis (Ginger Beer).

Collyrium Perchloridis (Muriatis) Hydrar-
gyri.

R. Perchloridis (Muriatis) Hydrargyri
granum,

Aquæ destillatæ uncias sex. Solve.

Collyrium Perchloridis Hydrargyri cum
Vino Opii.

R. Collyrii Perchloridis Hydrargyri
uncias sex,

Vini Opii drachmam. Misce.

Collyrium Nitratis Argenti.

Fit ex duobus, tribus quatuor vel pluri-
bus granis ad unciam Aquæ destillatæ.

Collyrium Sulphatis Cupri.

R. Sulphatis Cupri granum,

Aquæ destillatæ unciam. Solve.

Collyrium Sulphatis Zinci.

R. Sulphatis Zinci grana duo,

Aquæ destillatæ unciam. Solve.

Convallariæ Multifloræ radix (Solomon's
Seal).

Cyanis Potassii.

R. Cyanidis Potassii et Ferri (Potassæ
Prussiatæ) bene triti et caute sic-
cati in olla ferrea quantum velis.

Inde pulverem crucibulo ferreo ope-
rito, dein ignem subministra quem
auge et auctum serva quamdiu Gas
prodierit; massæ residuæ nigræ
continenti Carburum Ferri et
Cyanidem Potassii affundatur aqua
frigida, ut solvatur Cyanis; dein
per chartam coletur et vaporet bal-
nei aquosi Calore ut Crystalli for-
mentur, quæ siccantur et servantur
in vase bene obturato: Crystalli
virides primum formatæ rejiciantur.

T. CLARKE.

Decoctum Avenæ Sativæ (Water Gruel).

Decoctum Hordei Distichi (Barley Water).

Decoctum Oryzæ (Rice Water).

Electuarium Carbonatis Ferri.

R. Sulphatis Ferri,

Carbonatis Sodæ, utriusque, partes
æquales.

Solve sales seorsim in aqua et per-

misce; lavetur Carbonas, qui petit
fundum, bis terve, dein exprimatur
valide et postea misceatur cum
saccharo et pulvere Aromatico ut
fiat Electuarium.

Servetur in vase bene obturato.

Dosis drachma dimidia ad drachmam.

T. CLARKE.

Electuarium Laxans.

R. Bitartratis Potassæ uncias duas,

Sulphuris sublimati unciam,

Syrupi Empyreumatici, q. s. Misce.

Dosis, drachma ad drachmas quatuor.

Embrocatio Usitata (Oleum Ammoniatum).

Enema Anodynum vel Opiatum.

R. Tincturæ Opii drachmam,

Aquæ calidæ vel Butyri recentis li-
quefacti unciam. Misce.

Enema Commune.

R. Sulphatis Magnesiæ,

Vel Muriatis Sodæ (Chloridis Sodii),
utriusvis unciam,

Aquæ tepidæ libram. Solve.

Enema Fœtidum.

R. Pulveris Assafœtidæ ferulæ Gummi
resinæ drachmas duas, vel Tinc.

Assafet. unciam dimidiam,

Aquæ tepidæ libram. Tere simul.

Enema Cucumeris Colocynthis.

diam,
Aquæ calidæ octarios duos.
Macerare per horas viginti quatuor in
vase vitreo optime operculato, et
in loco frigido et obscuro: dein
cola in usum.
Sumat hujusce infusi dimidium, par-
titis vicibus quotidie.

(To be continued.)

SKETCHES OF THE MEDICAL PROFESSION IN PARIS.

NO. I.—M. CIVIALE*.

M. CIVIALE has attached his name to an admirable surgical operation—*Lithotrity*. Discoveries of this kind are not always the offspring of genius; but they do not the less render their author celebrated. "*Lithotrity* is glorious for French surgery, honourable for its author, and consoling for humanity." Such is the decision of Messrs. Chaussier and Percy, in their Report to the Academy of Sciences. It is the decision of competent and able men, after having seen with their own eyes the ingenious operator seize and break in the bladder stones of large size, and thus in a few moments accomplish a miracle. Indeed, the result obtained by M. Civiale had previously exhausted the patience of a great number of surgeons, eager in the search for it, but forced to abandon the pursuit. Such, then, was the opinion pronounced by those two learned men, in concise and appropriate language. The greater part of the medical public adopted it; and M. Civiale, strong in this decision, pronounced before the whole Academy, and countersigned by M. Cuvier, believed he was warranted in considering himself the inventor of an operation valuable for suffering patients, and honourable to himself and his country. Nevertheless, this has been disputed; and but little was necessary to make some of his contemporaries prove, that what he and the learned men above mentioned considered as new, was not so at all; that others before him had, no doubt, thought of it; that an account had been published of it twenty years before; and that they had themselves kept back the invention, only to render it perfect. Nor was this all; for after having proved that he was not the inventor of these instruments, they wished to prove that the instruments were not worth inventing—in fact, that they were detestable; and that, moreover, he did not employ them aright. In vain did he publish, in justification of his apparatus and his ability in using it, more than forty cases, of which thirty at least were decisive in his favour. These cases, according to his critics, proved nothing. Several of those who were operated upon are dead. Of course, this could only be from the operation. All have either had fever, or experienced some pain; and a good lithotritic operation ought not to produce either the one or the other. Some have laboured under incurable irritation of the bladder, which must be the fault of the instruments, and not of the presence of the calculus for five or six years previously. Some, it is true, have had no subsequent ailments; but

if they have not hitherto, they will by and bye, which amounts to the same thing. In short, M. Civiale, more talented in breaking calculi than in defending his reputation, did not know what to make of these charges.

Happily for him, the Academy of Sciences thought differently from his critics. It appeared to them that their objections were not sufficiently well founded to deprive M. Civiale of his honour, and his operation of its utility. In fact, the real proprietor of a surgical operation is he who knows how to apply it with success. All the fine theoretical reasonings, and the *legerdemain* of dates, prove nothing. In June, 1826, the Academy of Sciences awarded to M. Civiale six thousand francs; and, in June, 1827, another sum of ten thousand francs (being the Montyon prize), for having been the first to practise lithotrity with success. Other rewards, though less in amount, were given to Messrs. Heurtloupe and Leroy, for having invented or improved lithotritic instruments.

It is with a very ill grace that the adversaries of M. Civiale have contested his right. As to priority of invention, it belongs neither to them nor to M. Civiale. It is very certain that from very early antiquity different methods of this kind have been proposed; and there have been left on record even some examples of success. But it is equally true that all attempts had been completely abandoned for a very long time; and that the crushing of the stone in the bladder was considered an insoluble surgical problem. No one spoke of it—at any rate in public. It was not till after the experiments of M. Civiale that lithotriters were seen to spring up on all sides. As to the excellence of his operative apparatus, the critics shew a very bad spirit in endeavouring to raise a prejudice against it, when it has been proved by numerous and authentic cures; and they show a still worse spirit in boldly proposing others as better, with nothing more favourable to back them than two or three unsuccessful operations.

The medical public has been disgusted with these miserable intrigues; and if I have said a few words respecting them, in speaking of M. Civiale, it is because it appeared desirable that one who has not personally mixed in the debate, should give utterance to the public opinion respecting it. It is only fair that M. Civiale should enjoy the reward of his long protracted labours; and that he should be recompensed for his trouble by the friendship of philanthropists and the esteem of his countrymen.

In order to justify this eulogium, it may be well to give a sketch of his ingenious operation; a subject especially interesting to those afflicted with calculus, the number of whom is greatly more considerable than is generally supposed. M. Civiale did not arrive at his fortunate invention by a single

* This series of sketches is translated from the *Medecins Français Contemporains*.

effort; for knowledge is not won at so slight an expense. His first idea was to dissolve the stone in the bladder by means of an appropriate re-agent. The attempt was not new; it had been made many times before, without success. Two obstacles always presented themselves: first, the necessity of protecting the bladder against the action of the chemical agents destined to dissolve the calculus; and, secondly, the uncertainty in which the operator was involved, as to the employment of one re-agent rather than another, from his being ignorant of the nature of the stone attacked. To overcome the first of these obstacles, M. Civiale invented a kind of pouch, which was introduced into the bladder by means of a straight tube, in which it was kept closed, and was then expanded, like a purse, and was made by a particular mechanism to inclose the stone. Agents introduced through the tube were thus brought into contact with the calculus isolated from the bladder. This contrivance would have been practicable, had it not been for a circumstance which the author had not previously taken into consideration; but which, when once known, convinced him that he had lost his time and his trouble, like his predecessors. To make a pouch was not all that was required—it was necessary to find a material which, at first very thin and flexible, would afterwards resist the action of the chemical agents directed against the stone. Not one could be found in all the three kingdoms; and M. Thenard, whose decision was but too infallible, assured him it was necessary to abandon this project and seek another, if he had still any patience remaining.

M. Civiale is obstinate. He was not discouraged; and he ultimately obtained his object, as we shall presently see. According to his original design, and even supposing the practicability of the pouch, it would be necessary to obtain previously some fragments of the calculus to dissolve. In order to procure this indispensable sample, it was requisite to introduce into the bladder instruments large enough to divide the stone, and so contrived as not to wound that viscus. Several facts mentioned by authors, as well as his own study of the structure of the urethra, convinced him that it was possible to introduce through that canal sounds completely straight, and a third of an inch in diameter, or even more. He was convinced in this opinion as to these two very important facts, by experiments on the dead subject and on himself. He proceeded, therefore, to the invention of two pieces of apparatus, destined at first only to separate some small fragments of the stone, and thus to serve as a preparatory step to the main operation, consisting in the dissolution of the stone by chemical agents. The following is M. Civiale's description of the first of these pieces of apparatus.

"A metallic cylinder or tube, with thick walls, about a quarter of an inch in diameter, and four inches long, was indented longitudinally with four grooves, which were converted into tubes by another metallic cylinder, with thin walls, and grooves to correspond; and into which cylinder the first slid. To one extremity of the inner tube were fixed four branches by means of hinges; each branch being likewise formed of two pieces, also united by a hinge. Metallic wires of a middle size were introduced through the four grooves, and after passing in a gutter along the internal surface of the first piece of each branch, were fixed with the extremity of the second. They served to move the branches, separating and drawing them together at pleasure by a mechanism analogous to that by which the motions of flexion and extension of the fingers are effected. At the other extremity of the cylinders was an apparatus for giving to the branches the movements necessary to seize the stone, and fix it securely, so that it might not escape but at the pleasure of the operator, who might make all the wires act together, or either of them separately. The central passage, an eighth of an inch in diameter, was designed to receive the perforator, or the stylet as it was otherwise called. The latter was furnished at its outer extremity with a handle, by the assistance of which it was made to act upon the stone, while at the same time it limited its introduction into the canula to a certain point, so that its inner extremity might reach the coats of the bladder."

Such was the first of the instruments contrived by M. Civiale. The second was much more simple, although constructed on the same principles. It consisted likewise of two metallic tubes, sliding one within the other. "At the extremity of the inner tube were soldered six branches of elastic steel, slightly curved inwards. At the opposite extremity was fixed a strong screw by means of which the tubes could be moved one upon the other. The stylet, or *lithotriteur*, consisted of a steel rod, with a three-sided pyramidal extremity internally, while the other was fixed into a handle, which facilitated its action on the foreign body, and limited its introduction into the canula to the proper point. When the *outer* tube was pulled back, the branches fixed to the inner tube, being set free, separated by their natural elasticity; while, on the contrary, when the outer tube was made to slide forward on them, they were brought together, and formed by their union a round extremity, by which the instrument was introduced into the bladder."

These two instruments were invented only to procure some fragments of the stone, in order to ascertain its chemical composition. It would seem a reflection likely to occur to M. Civiale, that if it was possible to act at all upon the stone, there was nothing to

prevent its being entirely destroyed. Nevertheless this did not occur to him till very late, when he found himself obliged to renounce his pouch of protection against the acids and alkalies.

The last of these instruments presented much greater advantage than the first, both with respect to strength and facility of executing the manipulations required. It is that which M. Civiale still employs; but he has made it undergo several very advantageous modifications. The six elastic branches are reduced to three; and the *lithotriteur* has a little head armed with teeth; while to its other extremity has been adapted a bow and drill, similar to those which watchmakers use. With this ingenious instrument, skilfully employed, M. Civiale has succeeded, in ten or fifteen minutes, in grinding to powder a stone of ordinary size. The operation is truly admirable, both for its innocence and its success. Whoever has seen M. Civiale, as I have, introduce his instrument through the urethra with the greatest facility, reach the bladder at once, seize the stone very quickly with his fingers of steel, and make the *lithotriteur* act upon it, cannot but applaud this *chef d'œuvre* of patience, and of difficulty overcome. When once the bow is set in motion, we are not long in hearing a sound which is more or less dull, and which announces the action of the perforator on the calculus. At the end of two or three minutes this noise becomes all at once more obscure; and the practised hand of the operator perceives that a portion of the stone is detached. The elastic branches are immediately drawn back into their case; becoming charged as they approach each other with a greater or less quantity of detritus. The rest is expelled with the urine. After a few minutes, if the patient be not too much fatigued, the operation is recommenced. Very often a single sitting is sufficient for the entire destruction of the calculus; but in that case it is necessary that the operator should have to do with a small and very friable stone. In the great majority of cases it is necessary to return to it several times.

The advantages of this operation appear to me very great. The pain which attends it is almost nothing*. The canal of the urethra, previously distended by sounds progressively increased in size, accommodates itself very easily to the introduction of the instrument. After the operation the patient is able to take exercise as freely as before; and in general he feels much relieved by the diminution which the calculus has sustained; and especially by the conviction that his cure approaches. But its greatest advantage is, that in the majority

of cases it obviates the necessity of having recourse to lithotomy; an operation which is terrible to the apprehension of patients, is always accompanied by severe pain, and is too often followed by death or by incurable infirmities. It is true that lithotritry is not always applicable. For instance, encysted stones, or those of a very great size, cannot be seized and ground away; but in these cases even cystotomy would offer but slight probabilities of success. Besides, as M. Civiale very justly observes, the greater part of these obstacles would never occur at all, were it not that those afflicted with stone, frightened at the idea of lithotomy, recoil perpetually from the operation; endure for years the most agonizing pains, rather than submit to it; and thus allow stones of enormous size to form in the bladder, with complications of every kind. These distressing occurrences will no longer exist, when lithotritry shall become familiar to a great number of practitioners. Encouraged by the mildness of that operation, patients will have recourse to it as soon as the pain and the sound shall have proved the commencement of a calculous deposition in the bladder; and the stones being still very small, very friable, and not having deteriorated the constitution by a long-continued presence, the patients will be altogether quit of them with the greatest ease.

Various objections, to which, however, facts have furnished a complete refutation, have been made to lithotritry. It has been affirmed, or rather *supposed*, that the introduction of straight sounds was impossible; but the contrary has been proved by the testimony of many practitioners ancient and modern; and among others the celebrated Lieutaud, who gives a positive declaration to that effect. Straight instruments of that description have even been found in Herculeaneum. Nevertheless, their employment had been so proscribed or neglected, that M. Amussat has the reputation of having made a discovery, by demonstrating very recently, that the true structure of the urethra was not at all opposed to the introduction of straight instruments. This objection, therefore, falls to the ground at once.

The great size of the instruments, the pain of the operation, the length of the treatment, its dangers and its consequences, have not furnished arguments of a more valid description. The urethra is very dilatable; and, unless in the case of a peculiar conformation, it may in a few days be dilated sufficiently to admit with facility tubes of three, four, or even five lines diameter. The pain is very slight; and if we cannot entirely ensure the patient against it, that is an inconvenience which does not at all militate against the employment of lithotritry. Most frequently, too, the pains are owing to the serious nature of the alterations induced by the continued presence of the calculus, and the extreme nervous sus-

* At the discussion which recently took place at the Academy of Medicine, some of the speakers alleged that the pain attending lithotritry was *greater* than that of lithotomy.

ceptibility which is the consequence of its long residence; all which are things which would not have taken place, if the operation had been performed at the commencement of the malady. The treatment is in general of short continuance; but it may be considerably protracted by various causes. This is without doubt a misfortune; but it appears to me, after all, that a calculous patient ought to consider himself very happy in obtaining relief from his sufferings, and perhaps even saving his life, by an exercise of patience; and that at the worst, it is better for him to remain three months under the hands of the slowest lithotriteur, than two minutes under the knife of the most expert lithotomist. Besides the length of the treatment being commonly in direct proportion to the duration of the malady, the practice of lithotripsy must ultimately abridge it greatly.

The immediate dangers of the operation are illusory. It is alleged that the bladder may be pinched, wounded, &c. All this may happen with imperfect instruments, or in unskilful hands; but the same inconvenience attends every possible operation in surgery. The skill of the operator is always taken for granted. The most simple operation (that of bleeding for instance), may be followed by the most serious accidents, and even by death, from the awkwardness of an ignorant pretender. There is no valid ground of objection here.

Dangers of a more remote description, such as chronic inflammation of the urethra or bladder, the leaving behind of some fragments of stone not triturated, &c., are only presumptions which experience has not confirmed. None of the patients treated by M. Civiale have met with any troublesome symptoms, either local or general, as consequences of the operation; and in the case of several who have died since, examination has proved that the cause of their death was altogether unconnected with the operation, and that the bladder contained no calculous fragments.

From these considerations, which M. Civiale has very properly insisted on in his favour, we cannot avoid expressing a wish, that lithotripsy should engage more of the attention of practitioners; and we cannot but applaud the Academy of Sciences for having, as much as in them lay, encouraged and recompensed M. Civiale for his labours.

Various modifications having been made in the operative instruments, by Messrs. Leroy (d'Éliolles), Heurtloupe Amussat, and Meirieux, it would appear that lithotripsy, notwithstanding its apparent simplicity, presents to the operator difficulties which are sufficiently great; and that in order to succeed, he must make multiplied efforts on the dead body, and have great skill in manipulation, with respect to all parts of the apparatus. M. Dupuytren himself, whose surgical dexterity is so justly renowned,

failed in an attempt which he made lately at the Hôtel Dieu.

The results obtained by M. Civiale from his first operation in 1823, to 1827, have been most satisfactory. Out of forty-three patients operated upon by him, forty-two have been cured of the stone: not of all their maladies, present and to come, as seems to be desired by the author of a *Letter to the Academy of Sciences, containing a Critical Examination of M. Civiale's Work, &c.* This letter has done a great deal of good to M. Civiale, though that was evidently very far from the intention of the writer, whose comments are not distinguished for their impartiality. Several patients have died since undergoing the operation; but the autopsy has proved the innocence of that proceeding. Time will dissipate all the doubts which prejudice and unsuccessful attempts have given birth to on the subject of lithotripsy. It may be considered as only of yesterday's date; but like all useful things, it must ripen and come into general use. Every thing induces us to hope that M. Civiale will experience every day an increase of the esteem and gratitude which his fellow-citizens have shewn him, and to which he is entitled from all the friends of science and humanity.

WESTMINSTER MEDICAL SOCIETY.

RICHARD QUAIN, ESQ., IN THE CHAIR.

Saturday, January 9, 1836.

Disease of the Chest simulating Phthisis— Mineral Magnetism.

DR. ADDISON related a case which he had lately had under his care, and in which he had committed a mistake in his diagnosis, and therefore was more anxious to lay it before the Society, as a caution against giving hasty opinions. The patient, a boy about ten or twelve years of age, was sent to Dr. A. by a surgeon, in order that he might be treated for an amaurotic affection, supposed to be dependant on a hydrocephalic tendency. Dr. A. was proceeding to prescribe for the patient, when a pupil present found that disease of the chest was present. The chest was then examined, and found to be the "pigeon-chest." The heart was beating violently. On examining the chest with the stethoscope, the left lung was found to be affected with pneumonia, which was attended with a peculiar mucous râle, very much like that sound which is attendant on the softening of tubercles. Dr. A. therefore considered that the patient had tubercular affection of the lung, and that he was now suffering from pneumonia accidentally acquired. One thing, however, staggered him with respect to this diagnosis, which consisted in the fact of the peculiar sound he had alluded to not being at the apex of the

lung as it usually is in the early stage of phthisis, but as low down as the sixth or seventh rib. He prescribed for the above symptoms. Feeling great interest in the case from the perplexity attending its diagnosis, Dr. A. visited the child at Hackney, when he again examined the chest, which examination led him still to believe his first opinion had been the correct one. The child, however, materially improved, but the mucous râle still continued. The disease gradually disappeared, and the patient got health and strength. Now, what was the source of the fallacy in this case—for it was evidently not phthisis, from the fact of the rapid improvement in the patient's health? On reflecting on the case, and again examining the child after the pneumonia had ceased, he found that the patient had been labouring under emphysema, and that the peculiar mucous râle was the result of pneumonia supervening on that disease.

He had brought forward this case in order to show the necessity of giving very careful diagnoses in affections of this nature. Had he not seen this child after the first and second time, the impression on his mind would have been that it was labouring under phthisis, and had the case been placed under the care of an empiric, and done well, it would then have been called a perfect cure of consumption; and the proof of its being that disease, would rest on the authority of Dr. A. In answer to a question, Dr. A. replied, that he had treated the disease in the way usually pursued—it continued under his care three or four weeks, the peculiar mucous sound remaining all the time. When the child's general health improved, the sight also became better.

Dr. Leonard Stewart thought that the short space of time in which relief was afforded in cases similar to the present, was quite sufficient proof of there not being phthisis. As far as his experience went, he had never seen any benefit result in the last-named disease in so short a space of time, as was evident in Dr. A.'s case.

Dr. Addison, in answer to a question from Mr. Smith, remarked that the symptoms in the above case were such as he generally found were indicative of the presence of pneumonia. There was not, however, that distressing cough and constant expectoration which were said by some authors to be symptomatic of pneumonia; indeed, he believed that in pneumonia in general there was little cough and no expectoration, except occasionally when blood was thrown up. When, however, pneumonia was complicated with bronchitis, expectoration was generally profuse. He had two cases under him at that time, both in one bed, in which this fact was fully confirmed. He believed that pneumonia was not a very uncommon disease, though he thought it was frequently overlooked, for want of strict attention on the

part of the practitioner. He had adopted no difference in the treatment of the two cases he had then under his care, pneumonia with bronchitis, and pneumonia alone, except that in the first his treatment had been rather more sedative than in the last.

A long discussion now ensued between Drs. Choune and Addison as to the correctness with which Dr. Cullen had defined some of the diseases of the chest. It was contended by the first speaker, that Dr. Cullen had pointed out the difference between peripneumonia and catarrh, and that the same author stated that when the parenchymatous substance of the lungs was inflamed, there was no expectoration: but when the bronchi were affected, that symptom was present. Dr. Addison, on the contrary, contended that, until the discoveries of Laennec, our knowledge respecting diseases of the chest was obscure and imperfect, and that Cullen was most incorrect in his descriptions. At the present time, however, he (Dr. A.) was convinced that when pneumonia was present, it may be invariably detected; for we had now, thanks to Laennec, diagnostic marks, which would always distinguish one disease of the chest from another. With regard to complications in diseases of the chest, there would always be complications in every disease.

Mr. Fernandez believed that pneumonia was a frequent disease; he did not consider, however, that the diagnosis was so easy. He had lately examined a body: the patient during life was attended by an eminent physician, well acquainted with the use of the stethoscope, and who was at a loss to give a diagnosis. On examination after death, the passages of the bronchi were completely stopped up by the thickening of the membrane, so that there was no passage for the air.

The question of Medical Magnetism was then brought forward; and, after a long discussion, it was decided that Dr. Ritchie should be invited to attend at the Society at its next meeting, and to prove by experiment the influence of the magnet in connexion with the body in health and disease.

Dr. Ritchie, who was present, very kindly agreed to give the Society all the information he could respecting the subject of Mineral Magnetism, and that he would attend the next meeting for that purpose.

The Society then adjourned.

Saturday, January 16, 1835.

RICHARD QUAIN, ESQ., IN THE CHAIR.

The Society was occupied this evening with the experiments of Dr. Ritchie, in explanation of the present theory of magnetism; not, as he said, for the purpose of opposing the peculiar views of Dr. Schmidt, but in order that the Society might more clearly understand the subject, and then

judge for itself. Dr. R. gave a most interesting lecture, which embraced his own views regarding this branch of natural philosophy. He contended that magnetism was entirely produced by electricity, and that it can be produced by nothing else—even the earth owing its magnetic influence to that power. With regard to Dr. Schmidt's view that the north pole produced a north pole and nothing else, Dr. R. contended that it produced both poles, and that the south pole did the same. In support of this assertion the following experiment was tried:—a circular piece of soft iron was placed on the south pole, and drawn several times over it round the entire circle, every particle thus becoming an elementary magnet; so that if the ring were broken, one end of the piece of iron would be a north, the other a south pole, and if still more divided, every portion would be a perfect magnet. The ring was broken and the magnetic power of the portions proved. Now the same result would happen if he had drawn the ring of iron over the north pole instead of the south; he might then ask this question—What produced the south pole in such case, if the assertion was correct that each pole only produced its like? With regard to the magnetism of the earth, Des Cartes was wrong in supposing there was an electric current passing from north to south—there was no such thing—all depended on arrangement; any piece of iron kept long in one position became a permanent magnet. In illustration of this, Dr. Ritchie walked to the fire-place, took up the poker and shovel, and found from experiment both were permanent magnets. The following interesting facts were mentioned. If the magnets were lost on ship-board, a permanent magnet might be formed very easily in the following way:—make several pieces of iron wire red hot, then cool them, and hold them in a vertical direction for some time, and then blend them together; one end would be a north pole and the other a south, and thus the magnet would be furnished. He contended, that while the magnet was at rest no electric or physiological effect could be produced, but only when assisted by motion. It was generally supposed that when an electric shock was received from a Leyden jar, it was the result of something passing from the jar into the body; but according to his idea on the subject, that opinion was incorrect. The effect was produced from the electricity residing in the body in a state of equilibrium, being rapidly decomposed by the application; the system was thrown suddenly into a new state, which produced the sensation generally termed "a shock." It was curious to read the history of electricity, as applied to medical purposes—at one time being praised up as a valuable remedial agent, and a few years afterwards, considered of scarcely any utility; with

regard to himself, he thought that good effects were often produced by its application, and bad ones sometimes. He had, perhaps, received as severe a shock as any one; it was from sixteen large jars: he could scarcely describe the effects, but he could compare the sensation to nothing else than what he considered would arise from a cannon ball, nearly spent, striking the point of the elbow without taking the arm entirely off; he felt the effects for several weeks, the nerves of the part being in a state of great agitation. Little was known of the effects or uses of electricity, but he thought that it was a subject worthy of being seriously thought about and tried. Our knowledge of the use of the magnet was less: we only knew that it pointed to the north.

Dr. Schmidt was not prepared to explain his views by experiment, as he supposed Dr. Ritchie would have occupied the evening; but the Society had seen his (Dr. S.'s) experiments on a former evening. With regard to Dr. R.'s assertion, that all magnetism was the result of electricity, he might ask whether a third power might not be operating, and which power was not recognizable. He thought Dr. Ritchie was too positive in stating that the magnet produced no physiological effects, as the arguments he had adduced in support of that opinion were founded entirely on theory. Now, he (Dr. S.) need scarcely say that one fact was worth all the theories in the world. He would not rest his assertions on experiments; he had seen what he was convinced in his own mind were physiological and curative effects from the application of the magnet. He asked Dr. Ritchie to examine the new views he had brought forward, and then, if they were controverted, and he was convinced that he had been in error, he would acknowledge it, and that publicly. With regard to the method of forming magnets which he had advocated, he had succeeded in that way in producing more powerful magnets than he had ever before seen. He still believed the same poles, when placed opposite to each other, produced greater power, and that the opposite poles destroyed each other. Some further remarks were made on each side of the question.

Dr. Ritchie said he should be happy to meet Dr. Schmidt at any time, and examine into the views advocated by the latter gentleman; if he found them to convince him of their correctness, he should certainly lose no time in making it known. He believed, however, there was not so much difference of opinion between himself and Dr. Schmidt as might be supposed; the disadvantages Dr. S. laboured under, as a foreigner, in making himself clearly understood, might account in part for this.

Mr. Golding Bird having taken some interest in the question, had tried the following very ingenious experiment. He pro-

cured a piece of soft iron, in the shape of a horse-shoe magnet, and attached to it two copper wires, which communicated with a small galvanic battery, so that he could at a single moment make the soft iron a magnet capable of sustaining a weight of sixty pounds, and as quickly could reduce the iron to its natural state. He applied this instrument, magnetized, to the closed eyes of an intelligent young woman: the effects produced were a sense of warmth, lacrymation, &c. He demagnetized the instrument without her knowledge, and without taking it from her eyes, and she still declared the same effects were induced.

On the motion of Mr. Chinnock the thanks of the Society were given to Dr. Ritchie for his attendance.

Dr. Johnson wished Dr. Schmidt to have the same honour paid him, but the President said it was against the laws of the Society to thank one of the members, Dr. S. having that evening entered himself a member. He might, however, state to Dr. S. that this was the only reason for his not receiving the thanks of the Society. The Society then adjourned.

—o—

GREAT MEETING OF MEDICAL STUDENTS AT THE CROWN AND ANCHOR.

—

ON Monday evening, before six o'clock, the great room at the Crown and Anchor was filled with medical students, having been called there by public advertisement, to discuss matters which were of "vital importance to them." Before the chair was taken, on a fair computation, somewhere about 1,500 persons were present. Amongst others on the platform, we noticed Mr. Wakley, M.P., Mr. Liston, and Mr. Carpue. Mr. Mead having been unanimously called to the chair, proceeded at once to state the object of the meeting. He stated they had been called together for the purpose of exerting a moral force against their oppressors—of adopting means to remedy injustice which was practised on them at Apothecaries' Hall. It was only on Thursday week last that a student of his (the Chairman's) went for the purpose of being examined at that institution. His examiner happened to be one who is not in the habit of deporting himself towards the candidates for diplomas either with courtesy or fairness, but, on the contrary, is rough in his manners, and puts questions of such a character that they cannot answer any useful purpose, but rather tend to confuse and irritate the candidate. In the commencement of this transaction, the Secretary to the Society of Apothecaries had borne a part which was worthy of his general conduct, which was neither kind nor polished. No questions were asked the can-

didate as to where he had been educated—that was known before; and he felt convinced, from the manner adopted towards him, that he was to be "rejected." Mr. Mead here stated some of the questions which had been put to his pupil, and answered by him. We shall not repeat them here—but if called upon to give an opinion respecting them, we cannot consider the answers as anything but satisfactory ones, and such as should have been given. With regard to the little pettifogging cross-examinations, we have only to say they were unworthy of a scientific institution. The Chairman had, in the course of three years, passed a vast number of pupils—one only before had been rejected, and that too by the same examiner! Why was this? Was it not to be supposed there was some private cause for such a circumstance? He thought—nay, he was convinced of it; for the gentleman who was last "rejected" was of superior attainments, indeed was "eminent" in the sphere in which he moved. It was then a private feeling which had instigated his rejection; and he (the Chairman) contended, that until the examinations were conducted in public—that is, open to the whole profession—there would be no safety to the medical student. The rejected candidate had demanded a *public* examination (complaining also of the injustice he had received), but this the Court of Examiners had refused him.

The Chairman then called on the meeting to be quiet and orderly, and to prove that the medical students of London could exert a great moral power in defence of their rights, and the removal of their oppressors.

Letters were read from Messrs. Hume and Warburton, in which those gentlemen fully concurred in the objects of the meeting, and expressed regret that other engagements prevented their attendance.

A series of resolutions were passed, which had for their object the *radical reformation* of the Company of Apothecaries—the establishment of *concours*—and the formation of a Society for the protection of medical students.

The meeting was, though an animated and enthusiastic one, conducted with strict order, decorum, and unanimity, however much the enemies to the cause have wilfully and shamefully misrepresented it.

Mr. Carpue spoke of the necessity of reform in all our medical corporations. Mr. Wakley being loudly called for, came forward, and was received with the most deafening cheers. In a speech of great eloquence, wit, and satire, he exposed the abuses of "Rhubarb Hall." He contended that the rejected candidate had not been *legally* examined: the law of the Society of Apothecaries stated that the student was to be examined as to competency by a majority of the Court; a Court could not be formed unless seven examiners were present. How was it that a person

could be "rejected," according to that law, when there were four examining tables, and candidates at each? He contended that the Court of King's Bench would compel the Society to examine the "rejected" again; but he (Mr. W.) would not advise an appeal to that Court, but would wish the gentleman to abide by his demand of being tested in public. It had been said by the pretended friends of medical students, that they were too nervous to stand up before the public; but the speaker contended that not to be the fact—no other evidence of its falsehood being wanting than the spirit that had been shewn that night, and the unanimity with which the resolutions calling on the legislature for *concours*, had been carried. He would boldly state, because it was true, that the Apothecaries' Company had done much good; but, when he balanced the evils against the good which belonged to it, he found the latter "kicked the beam." Mr. Wakley then spoke of the hardship which the rejected candidate was exposed to. In numerous instances which had come under his notice, men of unquestioned talent and attainments had been rejected. When he reflected on the anxieties, the cares, the toils of the medical student—when he thought on these—and the hopes of his friends who had contributed to support him in London, in many cases at great sacrifices—he could hardly fancy a man so cruel, so totally lost to every human feeling, as to wish to "reject" any man—to turn his expected horn of triumph into one of despair and degradation. He had seen rejected candidates, their last shilling spent, throw up the profession in despair; though, had they been treated as their merits entitled them to, they would have been ornaments of the science of medicine.

The establishment of *concours* would do away with these evils, would establish a system of examination in which giggling, annoying, unfair questions, asked more with the intention of shewing the quibbling dexterity of the examiner, than of testing the knowledge of the candidate, would never be put. Any resolutions that might be carried at that meeting, he could confidently state, would meet with every attention in Parliament; there was not a member of that high assembly but received with the greatest attention any thing relating to the reformation of the profession. He might suggest one thing to the meeting: the Chancellor of the Exchequer was just about framing the charter of a new Metropolitan University; now, if a deputation from that meeting would wait on the right honourable gentleman, and state to him the resolutions that had been passed that evening, he was convinced it would be of benefit; nothing could be lightly received when coming from such a meeting. Those resolutions would come "just in time." The honourable gentleman sat down amid tremendous applause.

Mr. Liston, being seen on the platform, was loudly called on; and expressed himself as favourable to the objects of the meeting; and sat down amid great cheers.

A petition to Parliament, embodying the resolutions, and signed by the chairman in the name of the meeting, was decided on; and we understood that a deputation was also formed to wait on the Chancellor of the Exchequer, as suggested by Mr. Wakley.

Want of space precludes our giving a more lengthened report of the meeting. We trust we have said enough to shew that it was one of the greatest importance; and important in nothing more than in shewing the unanimous feeling of the rising profession against our corrupt and close corporations. We congratulate the medical students of London on the step they have taken. It will do much for the establishment of that reform which is so much required; and, though we should not wish to go to the full extent of some of the speakers, we do wish heartily to see that for which we have so long fought for in their defence and for their interest—a just reward of talent, and a fair, equitable, and *public* examination!

—o—

The London Medical

AND

Surgical Journal.

Saturday, January 23rd, 1836.

MEETING OF MEDICAL STUDENTS.

OUR readers will find a report of a meeting of the medical students of London, which was held on Monday last, at the Crown and Anchor Tavern, to take into consideration subjects of great importance to their interests. The cause of this was, that a candidate for examination for the license of the Apothecaries' Company, complained of having been unfairly examined, rudely treated, and unjustly rejected. It was stated that he was pronounced eminently qualified by a private teacher. He felt highly indignant at what he considered gross injustice; he mentioned his case to his contemporaries, who with bold and manly independence accompanied him to the Apothecaries' Hall, where he respectfully demanded a public examination, which was instantly refused. The appearance of, as we have been informed by one of the committee of students, 600 of the above candidates at

Blackfriars, terrified the worshipful Company, who magnanimously applied to the civil authorities for protection. There was no necessity whatever for this proceeding; but as tyrants are always cowards, it was adopted. The students retired on their friend receiving a refusal, and conducted themselves, as the profession might expect from gentlemen of education and science, in the most proper and decorous manner. They repaired to an adjoining hotel, and after having duly considered the injustice done to one of their body, determined to call a public meeting. These proceedings took place on Thursday se'nnight, and on the following Monday, though the notice was very short, between 1500 and 2000 students, besides a large number of practitioners, assembled at the Crown and Anchor. Their proceedings were cool, determined, and orderly, and they unanimously adopted the substance of the resolutions which will be found in another of our pages. We have received an account of the proceedings from many sources, and from our own special reporters, on every one of whom we place the most perfect reliance; and all agree, that the meeting was conducted in the most orderly and proper manner, and that it was grossly and wilfully misrepresented by the reporter of the *Times*.

But we leave this disgusting topic, and proceed to notice the real question. An examiner of the Apothecaries' Company, unmindful of his oath to act impartially in ascertaining the knowledge and competency of a fellow citizen to obtain admission into a certain department of the medical profession, is charged with having, from caprice or private motives, perpetrated the grossest act of injustice. The charge may be true or false. It must be either. But the law does not give power to any one examiner of the Apothecaries' Company, or of any other examining bodies, without just cause, to disgrace an individual, and have the finger of contempt

or scorn pointed at him. More than one of the former examiners of this court have done this atrocious deed, as we proved it before the Parliamentary Committee on Medical Education and Practice. They iniquitously placed the mark of disgrace on the foreheads of medical students, who, to our personal knowledge, were much better informed than themselves; but what else could be expected from unlettered men, whose pelf has placed them in situations for which education, talent, or genius, never intended them. We have often shewn, in this journal, the impropriety of having such persons placed at the head of the profession; and this is now the general opinion. As shareholders in a wholesale commercial establishment, they should be confined to their proper business, and leave science to those who have cultivated it. In fact, this is their own opinion, expressed to Parliament, when told they must be either wholesale druggists, according to their charter, or a scientific society of pharmacy: they declared they preferred the former. A court of examiners for ascertaining the fitness of candidates for admission into the medical profession, selected from such a body, must necessarily be incompetent and partial, nor can it be influenced by that high sense of honour and justice which characterize the better informed examiners of the universities and colleges. These invariably reject a candidate with most painful feelings, because they appreciate the injury they do his reputation and prospects in society. It is, however, true that some learned individuals have been rejected by the medical boards, but not in the same proportion, as by the Apothecaries' Company.

It is highly creditable to the medical students to boldly express their grievances, as it demonstrates that their acquirements are such, that they even solicit a public examination—that is, public as regards the profession. Such examinations are held in Dublin, Paris,

and other metropolitan cities, and deter examiners from acting unfairly.

We look upon the meeting which gave rise to the foregoing remarks, as one of great importance to the cause of medical reform, and to the modification or abolition of the Apothecaries' Company, as an examining body. We are ready to admit, that this Company has done much good in improving the education of medical practitioners; but it has done much more injury to the medical profession and public.

It affords us much pleasure to observe the false report in a morning paper, contradicted by the chairman of the meeting; and we feel convinced, from the high mental cultivation of the present race of medical students, that the expression of feeling ascribed to them was wholly untrue. It was a malicious fabrication, to disgust the public against them, for the purpose of *burking* their petition. It however has signally failed to produce such effect—the days of the Hall are numbered, and its fate determined.

—o—

Hospital Reports.

NORTH LONDON HOSPITAL.

Remarkable Dilatation and Hypertrophy of the right side of the Heart.

ROBERT WHEELER, aged 23, was admitted, Dec. 15, under the care of Dr. Elliotson. He is a tailor, of very moderate habits, having never been addicted to drinking. His appearance is strumous, fair skin, rather light hair, swelled lip, and rather dilated pupils. He has always been weakly, and has had several attacks of rheumatism, but none for the last five years. He has been subject to a cough and palpitation for the last two years, but continued to work till three weeks ago, since which time he has become gradually worse. He began, however, about four months ago, to suffer from cough and pain in the left side, for which he was leeches and blistered without relief.

Present Symptoms.—No particular symptoms in the head, except a little giddiness; he is occasionally, however, very drowsy, sleeping between each question that is asked him; he coughs a good deal, and expectorates a very frothy mucus; respiration is rather quick and shallow; chest small and

narrow; there is no pain in breathing or coughing; he can only lie on the left side; if he attempts to lie on his right his breathing is worse, and he has pain in the region of the liver; respiration is more difficult at night and in foggy weather, and he sometimes cannot lie down at all; he complains of palpitation of the heart in making any exertion: a fluttering is observed in the cardiac region by mere inspection; a pulsation is observed in the internal jugular veins, which are enlarged—it is greatest on the left side, where the external jugular vein is also enlarged and pulsates—the pulsation is synchronous with the pulse, and to the finger feels to have considerable force.

Auscultation.—Respiratory sound feeble generally; there is a sub-mucous or subcrepitant rattle over the greater part of both lungs, especially the inferior, and still more posteriorly and inferiorly; the impulse of the heart is very great, and is perceived very distinctly under the left clavicle, and over the whole anterior and inferior left side of the chest; it is felt also very distinctly (so as to raise the head) on the right anterior, and lateral part of the chest, fully as high as the nipple, and as far laterally as to a line dropped from the posterior boundary of the axilla. There is a loud bellows sound (giving all the impression that it is deeply seated) with the systole, along the whole length of the sternum, but loudest about opposite to the fourth rib; also to the left of the sternum, in the cardiac region inferiorly, is a second cardiac sound, rather loud, but otherwise healthy; a loud bellows-sound in the spaces above the clavicles on each side. Percussion is very clear in the upper and anterior parts of the chest, but inferiorly it is dull on both sides: it is dull for a very great extent in the cardiac region. Pulse very weak, rather quick, numbering 104. Pain in the region of the liver, which can be felt much enlarged and protruding beyond the cartilages of the ribs: the enlargement of the liver is not felt by pressure with the whole flat of the hand, but is very distinct by placing the ends of one or two fingers on the abdomen, and depressing them quickly, but not forcibly—the edge of the viscus is thus very distinctly felt. There is ascites—fluctuation being very distinct. The legs are much swelled by effusion; urine scanty and albuminous; extremities cold.

17th. In the morning he appeared as usual, was sitting up in bed and talking, and suddenly fell dead.

Post Mortem Examination six Hours after Death.—The face, lips, and ears, had become very livid, though they were not so at the time of death. In cutting the skin over the sternum, a considerable quantity of venous blood flowed out: there was effusion into the pleura, and adhesion on the left side. The lungs were of a dark colour externally. It seemed as if the pulmonary

structure was dark, and surrounded by a lighter cellular tissue, forming polygonal boundaries to it. The lungs were also emphysematous, at the edges especially, and in one or two places there were large blebs of air under the pleura. There was great congestion in the lungs, and great effusion into the bronchi, if not also œdema. The bronchial membrane was not examined. In the lower lobes the lungs appeared solidified—they did not collapse at all when the chest was opened. The pericardium contained some ounces of fluid. The heart was seen of an enormous size, lying transversely almost in the chest: the parts seen consisted of the right auricle and right ventricle—the left ventricle being concealed by the right. The point of junction of the right auricle and right ventricle had a contracted appearance, from the enormous dilatation of these two cavities, so that it looked almost as if there were two hearts joined at this point. The right auricle was of an enormous size (looking larger than the ventricle when in health), and of a dark blue colour: the coronary vessels appeared much distended. On opening the left ventricle, it was found moderately dilated. Dr. Carswell, who has since seen it, thinks its walls about the healthy thickness: the aortic opening, and also the arch, is very narrow, embracing the index finger with considerable tightness. The sigmoid valve was thickened and opaque. The mitral valve was very much ossified (so as to cause a hard projection, which could be felt on the external surface of the heart); opaque and thickened. The ossific matter was on the auricular side of the valve: where it was best seen it appeared to be deposited under the lining membrane, at the base of the valve, so as quite to cause a tumour over one part of this; the lining membrane was destroyed, so as to expose the bare surface of the bone: other parts were still covered by the membrane. On passing the finger through the valve from the auricle, the orifice was found much contracted (the bases of the valves being glued together); so that the point of the fore-finger touched the valves all round. The left auricle was much dilated and hypertrophied; its lining membrane was opaque and thickened; the sigmoid valves of the pulmonary artery were healthy; the pulmonary artery itself was dilated, admitting two fingers with ease; the right auricle was enormously dilated, and its walls very thick; the tricuspid valves opaque and thickened; the opening from the right auricle into the right ventricle much too large—it was a circle of full two inches in diameter. On laying open the right cavities of the heart, the tricuspid valves appeared to be much too small to close the auriculo-ventricular opening. The cavity of the right ventricle was much dilated, but its walls hardly thicker, if at all, than natural. There was very marked dila-

tation, forming a sort of pouch in the left superior corner of the ventricle.

Abdomen.—There was considerable effusion into the peritonæum: the liver was moderately enlarged, of a dark colour, and uncommonly hard; on cutting into it, as much venous blood rushed out, and as suddenly as though the vena cava had been cut, and it continued to pour out an enormous quantity of blood: it still, however, remained hard after all the blood that could be squeezed out. The gall-bladder was flaccid and pale. The spleen was not enlarged, but excessively hard. The kidneys small, pale, and of a stony hardness; so that when cut in two the thumb could not be forced into their structure. Some urine was taken from the bladder, and found to be aluminous. The stomach and intestines were not examined.

In making some remarks on this case, Dr. Elliotson said that it was very common, when the left ventricle was much hypertrophied, for the heart to lie across the chest. This, however, was a case of hypertrophy of the right ventricle—a very rare affection, and the first of the kind he had ever seen. With regard to the stethoscopic signs—the great impulse, and the extent over which it was perceived, were both explicable by the great hypertrophy and dilatation. The bellows sound might have arisen from either of the auriculo-ventricular valves: perhaps it is probable that the right was one source of it, and that the bellows sound heard in the neck extended from that point. It is rather remarkable there was no morbid second sound. Was it from the transverse position of the ventricle not allowing the blood to enter from the auricle with any degree of force, aided perhaps by the degree of contraction of the mitral valve? The subcrepitant rattle may be accounted for by the œdema and emphysema.

—o—

Case of Simple Fever, protracted by Irritation of the Bowels, and attended by Relapse. By Dr. Bright.

HENRY GRANT, aged 14, was admitted, under my care, August 12, 1835, on the 14th day of fever. He stated, that he was attacked with headach, shivering, and pain in his back, while at work; and the symptoms he described were, in all respects, those of a simple continued fever. At the time of admission, he was greatly oppressed with symptoms of acute fever: skin very hot, and covered with miliary eruption: pulse 130, feeble, but sharp. He said he had no headach, but had a tendency to wander. His bowels were relaxed, and there was some tension of the abdomen: tongue dry, brownish in the centre, white at the edges; no cough.

Radatur caput, et applicetur Embrocatio communis.—Habeat Sodæ Carbonatis, gr. x. ex Julepo Menthæ, sextâ quâque horâ.

13. Aspect improved; tongue moister, and less furred; skin pungently hot: pulse 120. He has not the least cough, nor any pulmonary symptom. Three watery yellow stools, sinking to the bottom of the vessel.

Adde Vini Opii m. iij. singulis dosibus Misturæ.—Applicetur Cataplasma Lini ampl. abdomini.—Injic. Enema Amyli c Syrupi Papav. alb. $\frac{3}{4}$ ss. horâ somni, urgente diarrhœa.

14. Pulse 108: abdomen less tender; motions very loose and gritty, but only two in number.

Rep. Medicamenta.

15. Pulse 92: skin hot: one loose stool of the same character.

Rep. Medicamenta.

17. Pulse 96: skin hot: bowels open as before.

Rep. Medicamenta.

Aug. 19. It appears that the injection has been omitted the last two or three nights.

Injic. Enema Amyli c Syrupi Papav. alb. $\frac{3}{4}$ iij. omni nocte.

20. Dejections still very loose; but a portion of the fæces has changed its character, and floats on the surface. Pulse 92: skin less hot: tongue gradually cleaning.

21. A slight feculent motion, with some tenesmus. Pulse 80, rather weak: skin temperate. He has been sick, after taking nourishment.

Habeat Sodæ Carbonat. gr. x. Spir. Lavend. comp. $\frac{3}{4}$ ss. ex Julepo Menthæ, sextâ quâque horâ.—Omitt. Enema.

22. Motions to-day nearly natural. He is better in all respects.

Rep. Medicamenta.

24. Motions not quite so healthy.

28. Omitt. Cataplasma Lini. Repetantur alia Medicamenta.

Sept. 4. Habeat Infus. Carsearillæ c Sodæ Carbonat. gr. xv. ter die.

He now appeared to be quite convalescent; and, as he expressed a great desire for animal food, a small quantity was allowed.

18. He has suffered a relapse: bowels relaxed: the dejections not natural: skin hot: pulse 120: tongue furred: some cough.

Hydrarg. c Cretâ, gr. iij. statim.—Sodæ Carbonat. gr. x. c Vini Opii, m. iij. ex Julepo Menthæ, sextâ quâque horâ.—Low diet.

19. Applicetur Cataplasma Lini abdomini.—Hydrarg. c Cretâ, gr. ij. horâ somni.—Rep. Mistura.

22. The irregular and unnatural state of the bowels remains.

Hydrarg. c Cretâ, gr. ij. Pulv. Ipecac. comp. gr. iij. horâ somni.—Rep. Mistura.

28. He has improved decidedly; and his febrile symptoms are gradually diminishing; but he complains of a pain and tenderness in the left iliac region.

Applicetur Emplast. Cantharidis parti abdomini dolenti. Habeat Liquoris Calcis

$\frac{3}{4}$ iv. quotidie c. Lacte.—Omitt. alia omnia.

He was kept entirely in bed, and strictly upon a mild milk diet, taking Liquor Calcis with his milk, till the 19th of October; during which period he took two doses of three grains of the hydrargyrum c. cretâ, each followed by two drachms of castor-oil. —His motions having now gradually acquired a healthy appearance, he was allowed two eggs, and some beef tea, daily; and on the 30th he left off all remedies, but continued in the hospital a week longer, to protect him from the danger of relapse; and left it at that time, full of flesh, and healthy in his appearance.—*Guy's Hospital Reports.*

—o—

HISTORY OF MEDICINE IN CHINA.

(Continued from page 768.)

"JUST as Choo-foo-tsze, an eminent Chinese philosopher, (considered second only to Confucius), taught six hundred years ago, that there belonged to plants the distinction of sex; and any poor Chinese gardener will tell you, that this is a male plant, because it bears no seed; and that is a female, because it does bear children, (as their root for seed is); yet neither the philosophers, nor the gardeners of China seem to have followed up these hints, with an experimental scrutiny, to ascertain in what that sexual distinction consisted.

"8. So neither their genius, nor their doing, have prompted them to dissect carefully the bodies of the dead for the benefit of the living; and they remain satisfied with the fact of the blood's circulation without endeavouring to explain it.

"9. Although they teach that the blood goes round as in a circle which has no beginning nor any end, yet they choose to denominate what they call Tsun-k'ow, the inch mouth; i. e. that part of the wrist where they place the fore-finger in feeling the pulse, the head-quarters of the blood, or in their style, that part where the court is held, and a report made by the pulse of all that is going on in the little world, *man*; the most distant region of which microcosm they place in the foot.

"10. The Shoo-king, compiled by Confucius, mentions Woo-hên, as skilled in the cure of diseases about 3000 years ago. The next names of eminence in this department, are Tsang-kung, and his pupil, Pên-tsoo, otherwise called (Loo-e) Doctor of Loo, who lived about 2100 years ago. During the civil wars of China, the state of society however afflictive to humanity, was probably favourable to discovery in the art of medicine, and one in which practitioners are of unusual importance, a circumstance that has gained a medical man in China the appellation of Kwo-show, "the nation's arm," meaning, that by his art he saves persons from death.

" 11. The middle of the 3rd century was in China a period of civil war, and great slaughter of human beings. It was then the, now deified, physician Hwa-to lived, and to him is attributed great skill in the use of the knife. He is said to have laid bare and scraped the bone of the arm of the deified hero Kwan-foo-tsze, and saved him from the effects of a poisoned arrow which entered his arm.

" 12. He removed the eye-ball of a king's child, cut away the diseased part, and replaced the eye-ball. It was Hwa-to who first discovered the present mode of gelding swine and fowls in China. Tsaon-tsaou, who is by some Europeans called the Bonaparte of that age in China, ordered the doctor to be decapitated (the books say), because he refused to attend on the general's wife; but, popular tradition says, because he proposed to trepan the general's skull, and cure him of some affection of the brain.

" 13. In consequence of Hwa-to's murder his wife burnt all his manuscripts; and one that he offered to the jailor, called 'the green bag recipe, able to bring the dead to life,'—containing many important secrets, being, from fear, refused, he burnt it before his death.

" 14. Shun-yu-e, a doctor of some note, lived about this time.

" 15. In the fourth century, Wang-shuh-ho was chiefly famous for his work on the pulse, an epitome of which is given in Du Halde's China.

" 16. In the sixth century Chin-kwei lived, who is said to have cut into the abdomen, removed diseased viscera, stitched up the part again, and healed the patient in a month's time. He gave an opiate to the patient which rendered him insensible before he began the operation; the opiate is called Ma-fuh-san, which seems to express that it was in the form of a powder.

" 17. There was one man of eminence, called Heu-yin-sung, who rather undervalued the doctrine of the pulse, and said, he could do without it. It was he who being advised to write a book, said, 'words cannot communicate my art.'

" 18. The above mentioned are a few of the desultory names of eminence connected with medicine in China. There are four persons still more eminent as writers, and who are well known by the epithet Sze-takea, 'the four great masters,' or leaders of separate schools, and authors of distinct systems. From the first of them to the last embraced a period of twelve centuries.

" 19. The first is King-chung-chang. He lived during the How-han, A.D. 220, and was a native of Nan-yang.

" 20. The next is Lew-chow-chin. He lived under the Sung Dynasty, A.D. 1200.

" 21. The third is Le-tung-hwan, who lived under the first Tartar Dynasty, A.D. 1300; and the last is,

" 22. Choo-tan-ke, a native of Che-keang

province, who lived during the late China Dynasty Ming, A.D. 1500.

" The first named is considered, 'The father of physic;' he left numerous writings which are still much read.

" The Chinese commence their theory by maintaining that man is a Seaou-teen-te, a little heaven and earth—a world in himself—an universe in miniature—a microcosm. With respect to the greater universe, viz. the system of nature, as it appears in celestial and terrestrial phenomena, the Chinese teach, that there is an eternal and necessarily existing power, or principle of order, which they call Tae-keih, and which may be translated by an indefinite and vague expression, such as—'the eternal,' or 'infinite principle.'

" This eternal principle, in their view, is merely the first link of the great material chain;—it is not a being distinct from the universe, nor is it endued with any moral perfections.

" They represent this first cause, this first link of the chain, by a circle, or zero.

" But, as they find it difficult to account (from what they see in nature), for all the appearances which present themselves, on the supposition of a simple homogeneous body, acting on itself, they suppose that, when the present system of nature assumed the form it now possesses, the one eternal principle was divided, and became a Dual Power, or two powers, called, in their language, Yin and Yang, and which is represented by a figure of a circle divided in two, by a waving line across the centre.

" This figure is very commonly seen as a sort of sacred ornament on various occasions among the Chinese.

" From all that I can recollect of the original import of the words, Yin and Yang, I am inclined to translate the word Yin, by calling it a Vis Inertia, and the Yang, a Vis Mobile; and in my further disquisitions on this most ancient theory, I shall, instead of the original terms, which recall no associations to the mind of an English reader, employ the terms by which I have translated them.

" The Vis Inertia, the Chinese consider to be of the feminine gender, and attribute to it darkness, weakness; passive, and inferior qualities.

" The Vis Mobile, they consider to be of the masculine gender, and attribute to it light, strength; active, and superior qualities.

" To one or other of the Dual Powers, viz. the Vis Inertia, or the Vis Mobile, all existences in the universe (and, by the way, all numbers), belong.

" However, the Dual numbers of Pythagoras, and the infinitely changing series of Chinese Diagrams, called Pakwa, are not now our subject, and I therefore pass them over, and return to the Dual Powers.

" On the regular action of these two powers reciprocally, the order and harmony of the universe, both naturally and morally

depends. Excess or defect in either power, introduces disorder and confusion into the system of nature, and the affairs of mankind.

"Thus far of the Dual Powers on the grand scale of universal existence; but every individual human body is a world in itself—a microcosm; and although, in nature generally, woman takes her place amongst the dark and weak—the *Vis Inertia*.—and man is classed with light and strength—the *Vis Mobile*;—yet in each animal body, whether male or female, the Dual Powers exist; and every part of the body is ascertained to belong either to the *Vis Inertia*, or the *Vis Mobile*.

"A due reciprocal action of these on each other, preserves the harmony of the system, which is health; excessive or defective action in either power, causes disorder or disease; and high degrees of excess or defect cause death.

"The object, therefore, of Chinese physic is, to preserve in due strength and exercise the *Vis Inertia* and the *Vis Mobile*: that the first may offer a competent resistance, and the latter may not destroy by acting with undue force. Or (according to the phraseology of the celebrated, but unfortunate and unhappy Brown), 'that the fire of human life may not go out for want of fuel; nor the combustion be too vehement and too soon terminated by having an excessive supply.'

"Such, gentlemen, is an outline, I believe, tolerably accurate, of the fundamental principles of Chinese philosophy and medicine, which system, they say, was taught in the antediluvian age, and has maintained its ground, in this most singular country, ever since.

"The doctrine of a *Vis Inertia*, and a *Vis Mobile*, may appear to some, at first glance, the same as the matter and motion of *Asclepiades*; but, I am inclined to think, the theory is different.

"*Of the Affinities of Dead and Living Matter*.—As in the system of the universe, Europeans believe that the planets are endowed by their Maker with certain attractions; and as in minute particles of dead matter, there are affinities of adhesion, cohesion, and repulsion; so the Chinese maintain that in animated matter there exists certain affinities and repulsions in reference to all nutriment or medicine taken into the stomach; for example, mercury will affect the liver; and they say, injure the generative powers. Opium affects the heart and its functions.'

"I would ask, by the way, does this doctrine resemble the attractions, repulsions, and affinities of *Hippocrates*?

"However that may be, with the Chinese, the existence of the above named Dual Powers, of these affinities and correspondence, is received as an axiom in all their theories of physic.

"Natural bodies, or the elements of mat-

ter, are divided by them into five classes, viz.: metal, water, wood, fire, earth; and these five elements produce and destroy each other in a perpetually revolving circle; thus metal produces water; water, wood; wood, fire; fire, earth; and earth, metal. And having thus gone round the circle, the same operation recommences, and goes round ad infinitum.

"But, in nature, destruction is going on as well as production: thus metal destroys wood: wood (or vegetation) destroys (or impoverishes) earth; earth destroys water—water, fire, and fire, metal.

"And thus it is that the system of nature is perpetually going the round of production and destruction. No substance is annihilated; it is its form only which is destroyed; it rises again in some other; it is corrupted, only to be again generated. The disposition to generate, or corrupt, to produce or destroy, reciprocally, is chiefly referred to in medicine.

"The viscera of an animal body, are divided into five classes, or as *Du Halde* calls them, 'noble parts'—the liver, heart, lungs, kidneys, and spleen—the latter, I think, sometimes includes the pancreas and stomach.

"The *Materia Medica* are all classed under one or other of the five elements; those that belong to

"*Moh joh kan*, wood, have an influence on the liver,

"*Ho joh sin*, caloric, on the heart,

"*Too joh phe*, earth, on the spleen,

"*Kin joh fie*, metal, on the lungs, and

"*Shwuy joh shin*, water, on the kidneys.

"Again, tastes are divided into five, viz. sour, sweet, bitter, acid, salt.

"The five tastes have certain affinities to the five elements, and to the five viscera; the affinities are these:—

"Sour, to wood and the liver,

"Sweet, to earth and the spleen,

"Bitter, to heat and the heart,

"Acrid, to metal and the lungs,

"Salt, to water and the kidneys.

"Farther, as *Dr. Herschel* has proved that the rays of light differ in their degrees of heat, and that the red ray possesses the greatest heating power; and as it is light which gives colour—so the Chinese divide their colours into five; and refer red to heat and to the heart.

"The five colours are these:—*tsing*, *hwang*, *chih*, *pih*, *hib*. Green, yellow, red, white, and black, and the affinities are these:—

"*Tsing shoh muh*, *juh kan*,

"*Ch'eh shoh ho*, *juh sin*,

"*Hwang shoh 'too*, *juh phe*,

"*Pih shoh kin*, *juh fie*,

"*Hih shoh shwuy*, *juh shin*.

"Green is related to wood, and affects the liver.

"Red to heat, and affects the heart,

"Yellow to earth, and affects the spleen,

"White to metal, and affects the lungs,

"Black to water, and affects the kidneys.

"Thus the Chinese divide natural bodies; the viscera, tastes, and colours; and such as I have stated, is their belief of the affinities, attractions, and repulsions, or in one word, the correspondences in nature.

"The system is possessed of a beautiful symmetry; but I fear it wants, (what is indispensable to all science), the basis of truth. How do they prove what they say?

"Perhaps some of the ideas are not without support from analogy; how they correspond or disagree with theories, formed or promulgated in the western world, in ancient and modern times, I shall leave to our worthy president to point out, as his professional pursuits, for many years, in different parts of the world, and his extensive reading, eminently fit him for the task.

"I have promised to state the different views of the four great masters of the healing art in China, whom I mentioned to you at our last meeting; but that I must defer till a subsequent opportunity.

"*Rule of Medical Practice.*—I promised, on a former occasion, to lay before you, gentlemen, a view of the different systems of the four great masters of Chinese medicine; that promise I am unable to keep; for I cannot command time enough to read Chinese medical writers and inform myself fully on the subject.

"Their differences are thus briefly stated in the first volume of a work, entitled *E tsung peih tuh*, 'The best authorities in medicine, very necessary to be read.'

"First. The first writer, Chang-chung-king, in whose great and original work on fever, the Imperial College of Physicians say, not a single sentence is found taken from any more ancient authority, antecedent to his own time, (which was sixteen centuries ago)—was remarkably decided in his practice; and all who take him as their model 'err in giving immoderately large doses of medicine.' he was the first publisher of prescriptions in China; but his prescriptions direct taels weight (or ten ounces) of different ingredients to be taken, where the men of our day can only bear tseen, or single ounces.

"From this circumstance, one writer infers, that the human constitution is much weakened in China, since the time of Chang-chung-king, who is, I think, from the little I have read, considered their first and greatest physician.

"About a thousand years elapsed before their second great master appeared; viz. Lew-show-chin, and all who followed his system 'erred in an immoderate use of bitter and refrigerating remedies.'

"In the thirteenth century, Le-tung-hwan the third great leader of the Chinese school of medicine, directed the fashion to an extreme degree of stimulating, or as the Chinese expresses it, 'elevating and strengthening remedies.'

"His system, two centuries afterwards, Choo-tan-ke opposed, and went to an extreme in cleansing, or 'attenuating, and lowering the powers of nature.'

"I have seen a brief memoir of the third named writer, Le-tung-hwan, which states, that he was thoroughly versed in all the learning of his age and country, and was remarkable for a retentive memory. He attached himself to an eminent practitioner, and procured from him all that his long experience had amassed.

"Like many eminent men, he seems to have grown proud and morose; for, unless in difficult and dangerous cases, he showed great displeasure when called on for his assistance.

"I once before noticed to you, incidentally, that the Chinese rule given to physicians to ascertain a patient's complaint, is expressed in four words:—

"Wang, look.

"Wan, listen.

"Wan, ask.

"Tsee, feel,

"What method can be more rational? And with such a comprehensive and concise precept before our eyes, what can be more unfair than the representations of those Europeans who say, the Chinese pretend to know every thing concerning a complaint by feeling the pulse, and asking questions by stealth?

"In the work entitled *Sze-tsee-san-shoo*, from which I have taken the above precept, it is laid down as the only regular practice to proceed thus: to inquire of the patient the probable cause of his complaint—whether from affections of the mind; from excess in eating or drinking; from irregular conduct, &c., before proceeding to feel his pulse. The order, however, is, that of the precept given above—first look at the patient's countenance, next mark the tone of his voice; then ask him all about his *Ping-yuen*, the probable source or origin of his malady—and finally feel his pulse.

"The same writer, however, mentions, that there are foolish people in China, who want to try the doctor's skill, and will not tell him the truth. He reprobates the absurd practice, and to discountenance it quoted the saying of an eminent statesman, *Soo-tung-po*, who declared, that when he called a doctor, his object was to have his bodily complaints cured; and he gave the physician every possible aid, by telling all that he knew of the cause and progress of his disorder. In the same work, next follow various rules to judge of diseases by the patient's look and voice, as well as by his pulse; and I dare say, many of the remarks will agree with the experience of all ages and countries.

"I cannot now, however, enter upon an account of them."

(To be continued.)

Neuralgia of the Splenic Plexus.

N—, aged 48, married, and the mother of several children, habitually constipated, and suffering from disordered menstruation, one morning felt a pain in the left hypochondrium, as if in consequence of an exertion. The pain extended under the false ribs, from the vertebral column, and was felt to the extent of four fingers. It returned at intervals, was very severe, piercing, and burning; the left hypochondrium and all the superior portion of the abdomen were tumefied with gas. The pain seemed afterwards to fix itself more particularly in the renal region, accompanied with vomiting and a flow of high-coloured urine, voided with pain. But it very soon returned to its former place; then, moving again, it became located in the splenic region; it then took a more decidedly intermittent type. The fits came on every night, from one o'clock to six or seven in the morning. The patient had spasms in the hypochondrium, which was accompanied with a sensation of anxiety, but was not augmented by pressure. The painful part, which was slightly swelled, was of a higher temperature than the rest of the body; the face was sallow and clay-coloured; sometimes there was vomiting of a watery mucous matter, without any relief during the fits; there was no fever, nor was there any sign of gastric derangement; but complete exemption from apyrexia, except slight sensibility in the affected region. In this case also, sulphate of quinine produced the best results, administered in doses of two grains every two hours, as soon as the intermittent symptoms were clearly declared; it arrested the fit from the first day. The second night, the pain being again felt, the quinine was given the next day, from one o'clock to eight in the evening, in two grain doses every second hour, and the paroxysm did not again appear. The health and strength of the patient, which had been remarkably injured, were soon quite re-established.—*Gazette Medicale.*

Poisoning by Colchicum.

A woman, twenty-five years of age, on the second of June, 1835, after a very slight repast, drank, for the purpose of destroying herself, a glass of vinous tincture of colchicum, which had been prepared about two months previously, and which was composed of two bulbs of colchicum dried, and powdered to half a pint of white wine and an equal quantity of brandy. She drank about five ounces of the liquid, and suffered excruciating pain in the epigastric region. Half an hour afterwards two pints of milk were given her; and a physician who was called administered two grains of tartar emetic,

which caused copious and long continued vomiting.

An hour after midnight, M. Caffa was sent for; he found the patient generally cold; very great paleness; no rigidity of the limbs; decubitus on the back; no convulsive movements; epigastrium painful, especially on pressure; constriction of the chest; difficulty of respiration. The abdominal parietes seemed of a higher temperature than the rest of the body; the pupils were not dilated; the tongue was cold; the pulse thready and very slow; there had not been any alvine defection. She had intense thirst; and her intellects remained quite perfect. There were severe cramps exclusively confined to the two plantar regions. She alternately uttered plaintive cries, and sunk into a state of profound prostration. She had frequent vomitings of an inodorous and colourless liquid in very small quantities. Sinapisms were applied to the soles of the feet.

On the morning of the third of June the pulse had recovered in strength and frequency; the cramps were less painful. Ten leeches were applied to the epigastrium; but the patient continued to sink, and died at five o'clock in the evening.

An autopsy was made ninety-two hours after death, but nothing interesting could be learned, as the digestive tube had been previously removed to the Palais de Justice.

Carlsbad Waters.

The existence of small quantities of iodine has been detected in these waters by M. Neutwich of Carlsbad.

Coroners' Inquests—Fees to Medical Practitioners.

We have received a letter from Mr. James Baker, which he is about to forward to the profession, requesting their co-operation to obtain the support of their Parliamentary friends in favour of remunerating Medical Practitioners for their service at inquests. We are happy to state that Mr. Warburton, Mr. Hume, Mr. D. Whittle Harvey, and other Members of Parliament, have promised to support the measure.

BOOK.

Case of Loss of the Uterus and its Appendages soon after Delivery, together with Remarks on the Propriety of Removing that Organ in Cases of Inversion or Scirrhus. By John C. Cooke, M.R.C.S.E. pp. 21. London and Coventry.

All communications and books for review are to be addressed (post paid) to Dr. Ryan, 4, Great Queen Street, St. James's Park, Westminster, or to G. Henderson, 2, Old Bailey, Ludgate Hill.
